The distinctive feature of a magnetohydrodynamic plasma is that, in addition to compressive disturbances, the magnetoacoustic waves with their affinity to sound waves, there arises the possibility of a wave which propagates without compressing the plasma, driven purely by magnetic tension forces. This is the Alfvén wave, named in honour of the 1970 Nobel Laureate Hannes Alfvén (1908–1995) who first described the wave in 1942 and made fundamental contributions to the foundations of magnetohydrodynamics. Alfvén waves are closely analogous to the familiar transverse waves of an elastic string, the magnetic field providing the tension force that determines (together with the string or plasma density) the speed of propagation of the wave. The magnetic field in a plasma is also able to provide another force, akin to the plasma pressure; this is the magnetic pressure, ${B_0}^2/2\mu$ N m^{-2}. Overall the field provides magnetic pressure forces that resist any tendency to compress the plasma (acting in addition to the plasma pressure) and magnetic tension forces which act to straighten any distortions in the magnetic field. The tension force gives rise to the Alfvén wave; the magnetic pressure force gives rise to slow and fast magnetoacoustic waves. Broadly, the fast magnetoacoustic wave results when the magnetic pressure force acts in unison with the plasma pressure force; the slow magnetoacoustic wave results when these two pressure forces act in opposition.

To describe magnetohydrodynamic waves in detail it is necessary to examine the equations of ideal MAGNETOHYDRODYNAMICS. We consider an inhomogeneous medium because it allows a description of waves in the important case of a magnetic flux tube but also includes, as a special case, the classical problem of waves in a uniform medium. Consider, then, a basic state in which there is an applied unidirectional magnetic field $\boldsymbol{B}_0 = B_0\hat{\boldsymbol{z}}$ aligned with the z-axis in an appropriate coordinate system. In equilibrium the plasma density is ρ_0, the temperature T_0, the pressure p_0 and the field strength B_0. These quantities may all vary in a direction perpendicular to the applied magnetic field; equilibrium is achieved by requiring that

$$\text{grad}\left(p_0 + \frac{B_0^2}{2\mu}\right) = 0 \tag{4}$$

showing that any spatial variations in magnetic pressure are balanced by corresponding variations in plasma pressure. The case of a uniform medium corresponds to taking B_0, p_0, T_0 and ρ_0 all constant.

We consider isentropic (or adiabatic) disturbances governed by the equations of ideal magnetohydrodynamics. Denote by p and ρ the pressure and density perturbations of an ideal plasma with ratio of specific heats γ (usually taken to be 5/3). The perturbed magnetic (induction) field is $\boldsymbol{B}$ and the fluid motion is $\boldsymbol{v}$. To examine small-amplitude linear disturbances about this equilibrium, it is convenient to introduce the perturbation in total pressure, p_T:

$$p_T \equiv p + \frac{1}{\mu}\boldsymbol{B}_0\cdot\boldsymbol{B}. \tag{5}$$

Then, splitting the velocity field $\boldsymbol{v}$ into components perpendicular and parallel to the applied magnetic field, so that $\boldsymbol{v} = \boldsymbol{v}_\perp + v_z\hat{\boldsymbol{z}}$, the linearized equations of ideal magnetohydrodynamics yield

$$\rho_0\left(\frac{\partial^2}{\partial t^2} - v_{\rm A}^2\frac{\partial^2}{\partial z^2}\right)\boldsymbol{v}_\perp + \nabla_\perp\left(\frac{\partial p_{\rm T}}{\partial t}\right) = 0 \tag{6}$$

$$\rho_0\left(\frac{\partial^2}{\partial t^2} - c_{\rm t}^2\frac{\partial^2}{\partial z^2}\right)v_z + \frac{c_{\rm s}^2}{c_{\rm f}^2}\frac{\partial}{\partial z}\left(\frac{\partial p_{\rm T}}{\partial t}\right) = 0 \tag{7}$$

$$\frac{\partial p_{\rm T}}{\partial t} = \rho_0 v_{\rm A}^2\frac{\partial v_z}{\partial z} - \rho_0 c_{\rm f}^2\,\mathrm{div}\,\boldsymbol{v}. \tag{8}$$

This system of coupled partial differential equations determines the relationship between the flow $\boldsymbol{v}$ and the total pressure variation $p_{\rm T}$. The operator $\nabla_\perp$ denotes the component of the gradient operator that acts perpendicular to the applied magnetic field (i.e. perpendicular to the z-axis). Notice the occurrence of the four speeds $c_{\rm t}$, $c_{\rm s}$, $v_{\rm A}$ and $c_{\rm f}$, each a function of the coordinates perpendicular to the applied magnetic field.

It may be noted that equations (7) and (8) combine to give

$$\frac{\partial^2 v_z}{\partial t^2} = c_{\rm s}^2\frac{\partial}{\partial z}(\mathrm{div}\,\boldsymbol{v}). \tag{9}$$

The absence of magnetic effects in this equation is simply a reflection of the fact that magnetic forces act perpendicular to the magnetic field and so have no effect on motions along the field.

Uniform medium

In the case of a uniform medium, B_0, p_0, T_0 and ρ_0 are all constants and so are the basic speeds $c_{\rm t}$, $c_{\rm s}$, $v_{\rm A}$ and $c_{\rm f}$. This allows a relatively straightforward reduction of equations (6)–(8). It proves convenient to work in terms of the compressibility $\Delta \equiv \mathrm{div}\,\boldsymbol{v}$. Then Δ satisfies the fourth-order wave equation

$$\frac{\partial^4\Delta}{\partial t^4} - (c_{\rm s}^2 + v_{\rm A}^2)\frac{\partial^2}{\partial t^2}\nabla^2\Delta + c_{\rm s}^2 v_{\rm A}^2\frac{\partial^2}{\partial z^2}\nabla^2\Delta = 0 \tag{10}$$

involving the three-dimensional Laplacian ∇^2.

Since the medium is uniform and unbounded we may Fourier analyse equation (10) in a Cartesian coordinate system (with position vector $\boldsymbol{r} = (x, y, z)$), writing

$$\Delta(x, y, z, t) = \Delta_0 \exp\,\mathrm{i}(\omega t - \boldsymbol{k}\cdot\boldsymbol{r}) \tag{11}$$

where Δ_0 is the amplitude (a constant), ω the frequency and $\boldsymbol{k} = (k_x, k_y, k_z)$ the wavevector of the disturbance; other variables (e.g. flow $\boldsymbol{v}$ and field $\boldsymbol{B}$) are represented similarly. The Laplacian operator becomes

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} = -k^2$$

where $k = (k_x^2 + k_y^2 + k_z^2)^{1/2}$ is the magnitude of the wavevector. Then, for $\Delta_0 \neq 0$, equation (10) yields

$$\omega^4 - (c_{\rm s}^2 + v_{\rm A}^2)k^2\omega^2 + c_{\rm s}^2 v_{\rm A}^2 k_z^2 k^2 = 0. \tag{12}$$

This is the dispersion relation for magnetoacoustic waves; it relates the wave frequency ω to the wavevector $\boldsymbol{k}$, thus describing the propagation.

The dispersion relation (12) may be solved to give the phase speed c ($\equiv \omega/k$). In terms of the angle ϕ that the wavevector $\boldsymbol{k}$ makes with the applied magnetic field $\boldsymbol{B}_0$, with $k_z = k\cos\phi$, we obtain

$$c^2 = \frac{1}{2}c_{\rm f}^2\left[1 \pm \left(1 - 4\frac{c_{\rm t}^2}{c_{\rm f}^2}\cos^2\phi\right)^{1/2}\right]. \tag{13}$$

The smaller root (corresponding to the $-$ sign) is the slow magnetoacoustic wave, and the larger root (corresponding to the + sign) is the fast magnetoacoustic wave. The waves are compressive (since $\Delta \neq 0$) and so involve density, pressure and temperature variations—as do sound waves. Unlike sound waves, magnetoacoustic waves exhibit anisotropic propagation, their phase speeds depending on the angle of propagation to the applied magnetic field; this is simply a reflection of the directionality that an applied magnetic field imposes on a plasma. When propagation is along the applied magnetic field $\boldsymbol{B}_0$, so that $\phi = 0$, then $c^2 = c_{\rm s}^2$ or $v_{\rm A}^2$. When propagation is perpendicular to the applied magnetic field, so that $\phi = \pi/2$, then $c^2 = 0$ or $c_{\rm f}^2$; in other words, the slow wave is unable to propagate across the magnetic field, whereas the fast wave propagates with the speed $c_{\rm f}$. This is the greatest speed that the fast wave can achieve; at any other angle its speed lies below $c_{\rm f}$ and above (or equal to) the greater of $c_{\rm s}$ and $v_{\rm A}$. The phase speed of the slow wave is always less than or equal to the smaller of $c_{\rm s}$ and $v_{\rm A}$.

Magnetoacoustic waves are compressive but disturbances that are incompressible ($\Delta = 0$)—producing no changes in plasma density of an element moving with the fluid—are also permitted and in fact provide a distinct form of wave motion. This is the Alfvén wave with dispersion relation

$$\omega^2 = k_z^2 v_{\rm A}^2 \tag{14}$$

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

giving a phase speed c according to

$$c^2 = v_A^2 \cos^2 \phi. \tag{15}$$

Evidently, then, the phase speed of an Alfvén wave cannot exceed the Alfvén speed, v_A. Moreover, like the slow wave, the Alfvén wave is unable to propagate across the magnetic field, since $\omega^2 = 0$ when $\phi = \pi/2$. The Alfvén wave involves no motions along the magnetic field ($v_z = 0$) and no variations in plasma density ($\rho = 0$), pressure ($p = 0$), temperature or total pressure ($p_T = 0$). Thus the Alfvén wave is a transverse wave that propagates incompressibly, involving no changes in plasma density or pressure.

Altogether, then, we see that in the presence of an applied magnetic field there are three waves available to the medium, the Alfvén wave and the fast and slow magnetoacoustic waves. All three waves exhibit a degree of anisotropic propagation but this is most marked in the Alfvén wave and the slow wave, neither of which can propagate orthogonally to the applied magnetic field; the fast wave is only weakly anisotropic and achieves its greatest phase speed ($c = c_f$) when propagating perpendicularly to the applied magnetic field. The anisotropy exhibited by magnetohydrodynamic waves is in sharp contrast to the isotropic behavior of sound waves in an uniform medium, this simply being a reflection of the directionality imposed by a magnetic field.

The behavior of the magnetohydrodynamic wave speeds is conveniently represented in a diagram by plotting the phase speed c as a function of propagation angle ϕ, using a polar coordinate (c, ϕ) representation; see figure 1.

Related to the information provided in the phase speed plot is the behavior of the group velocity $\boldsymbol{c}_g$ of a wave, defined by

$$\boldsymbol{c}_g = \frac{\partial \omega}{\partial \boldsymbol{k}}. \tag{16}$$

The group velocity of a wave is the velocity with which energy (and information) is propagated by the wave. For the Alfvén wave equation (16) gives simply $\boldsymbol{c}_g = v_A \hat{\boldsymbol{z}}$, showing that an Alfvén wave propagates energy and information *along* the applied magnetic field, whatever the direction of the wave itself. The group velocity for magnetoacoustic waves is more complicated to obtain and is usually displayed in diagrammatic form, showing a plot of the *group speed* $c_g = |\boldsymbol{c}_g|$ as a function of propagation angle; see figure 2. Again, note the highly anistropic behavior of the slow wave which is confined to propagating energy close to the applied magnetic field, whereas the fast wave propagates energy approximately isotropically in all directions.

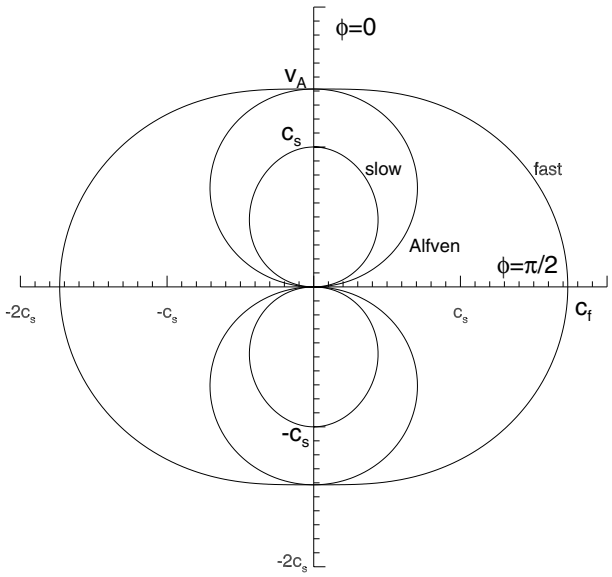

Figure 1. Phase speed diagram for magnetohydrodynamic waves, showing the phase speed $c(\phi)$ (in units of the sound speed c_s) as a function of the angle ϕ of propagation to the applied magnetic field, for the case $v_A > c_s$.

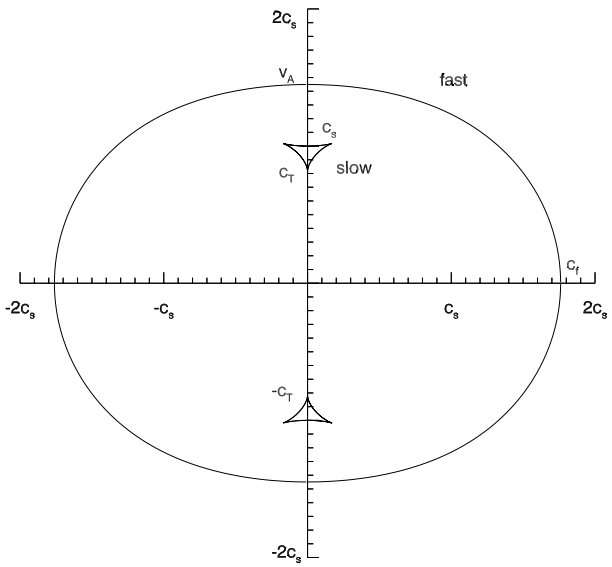

Figure 2. Group speed diagram for magnetoacoustic waves, showing the group speed $c_g(\phi)$ (in units of the sound speed c_s) as a function of the angle ϕ of propagation to the applied magnetic field, for the case $v_A > c_s$.

Magnetically structured media

The nonuniform media generally encountered in space plasmas may frequently be modeled in terms of a magnetically structured plasma. Structuring may be in the magnetic field, plasma density or temperature, or through the presence of plasma flows. Both Cartesian and cylindrical coordinate representations are possible. The cylindrical form is particularly interesting in view of the wide-spread occurrence of flux tube structures. Returning to equations (6)–(8), we express them in cylindrical coordinates (r, θ, z), writing $\boldsymbol{v} = (v_r, v_\theta, v_z)$. Equation (6)

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

then yields

$$\rho_0(r)\left(\frac{\partial^2}{\partial t^2} - v_{\rm A}^2(r)\frac{\partial^2}{\partial z^2}\right)v_r + \frac{\partial^2 p_{\rm T}}{\partial r\,\partial t} = 0 \qquad (17)$$

$$\rho_0(r)\left(\frac{\partial^2}{\partial t^2} - v_{\rm A}^2(r)\frac{\partial^2}{\partial z^2}\right)v_\theta + \frac{1}{r}\frac{\partial^2 p_{\rm T}}{\partial\theta\,\partial t} = 0. \qquad (18)$$

These equations may be reduced to ordinary differential equations by writing

$$v_r(r,\theta,z,t) = v_r(r)\exp\,{\rm i}(\omega t + n\theta - k_z z) \qquad (19)$$

for mode number $n = 0, 1, 2, \ldots$. The resulting equations may be manipulated to yield the equation

$$\frac{\rm d}{{\rm d}r}\left\{\frac{\rho_0(r)[k_z^2 v_{\rm A}^2(r) - \omega^2]}{[m^2(r) + n^2/r^2]}\frac{1}{r}\frac{\rm d}{{\rm d}r}(rv_r)\right\} = \rho_0(r)(k_z^2 v_{\rm A}^2(r) - \omega^2)v_r \qquad (20)$$

for v_r, with m^2 given by

$$m^2(r) = \frac{(k_z^2 c_{\rm s}^2 - \omega^2)(k_z^2 v_{\rm A}^2 - \omega^2)}{(c_{\rm s}^2 + v_{\rm A}^2)(k_z^2 c_{\rm t}^2 - \omega^2)}.$$

Equation (20) is sometimes called the Hain-Lüst equation.

The differential equation satisfied by $p_{\rm T}$ is also of interest:

$$\rho_0(r)[k_z^2 v_{\rm A}^2(r) - \omega^2]\frac{1}{r}\frac{\rm d}{{\rm d}r}\left(\frac{1}{\rho_0(r)(k_z^2 v_{\rm A}^2(r) - \omega^2)}r\frac{{\rm d}p_{\rm T}}{{\rm d}r}\right) = \left(m^2(r) + \frac{n^2}{r^2}\right)p_{\rm T}. \qquad (21)$$

Equations (20) and (21) possess singularities at $\omega^2 = k_z^2 v_{\rm A}^2$ and $\omega^2 = k_z^2 c_{\rm t}^2$, where the leading coefficients of the differential equations vanish; these singularities generate the Alfvén continuum and the slow continuum, respectively. The presence of these singularities is an indication of a number of interesting effects connected with the phenomenon of resonant absorption, of particular interest in the question of solar CORONAL HEATING MECHANISMS and in the absorption of p-modes in sunspots.

There is a simple solution of equations (8), (17) and (18) that we may note immediately. If $\partial/\partial\theta = 0$, corresponding to symmetric disturbances of the tube, then equation (18) reduces to

$$\frac{\partial^2 v_\theta}{\partial t^2} = v_A^2(r)\frac{\partial^2 v_\theta}{\partial z^2}. \qquad (22)$$

This is a torsional Alfvén wave which propagates torsional oscillations v_θ with the local value of the Alfvén speed $v_{\rm A}(r)$. Equation (22) illustrates the phenomenon of phase mixing of Alfvén waves, whereby a wave rapidly becomes highly corrugated with large radial gradients building up in v_θ. The buildup of such large gradients is important for the damping of magnetohydrodynamic waves because ordinarily the Alfvén wave in particular is difficult to damp. In a uniform medium the Alfvén wave may propagate vast distances before it is significantly damped by ohmic or viscous processes. However, with phase mixing or resonant absorption operating damping is considerably more efficient.

We may illustrate phase mixing by noting that the solution

$$v_\theta = v_0 \sin\, k_z[z - v_{\rm A}(r)t] \qquad (23)$$

of the Alfvén wave equation (22) gives a wave of amplitude v_0, and $|v_\theta| \le v_0$ at all times. However, the radial gradient $\partial v_\theta/\partial r$ of the motion grows in amplitude linearly in time t, for

$$\frac{\partial v_\theta}{\partial r} = -v'_{\rm A} t v_0 k_z \cos\, k_z[z - v_{\rm A}(r)t] \qquad (24)$$

where v'_A denotes the slope of the Alfvén speed profile. Thus $|\partial v_\theta/\partial r|$ grows secularly on a timescale of $1/v'_{\rm A}$. This phase mixing timescale can be very short. For example, in a coronal loop where the Alfvén speed changes from say 2000 km s^{-1} in the loop to 1000 km s^{-1} in the loop's immediate environment, across a distance of 500 km, the phase mixing timescale is 0.5 s. The result of such phase mixing—and resonant absorption achieves similar results—is that wave damping may occur in significantly shorter times or distances than is the case for magnetohydrodynamic waves in a uniform medium. In fact, an estimate of wave damping for an Alfvén wave undergoing phase mixing in a medium with Alfvén speed gradient $v'_{\rm A}$ gives a damping length (the distance a wave travels before its amplitude is reduced by a factor e, or 37%, of its initial value) of order $(6v_{\rm A}^5/\omega^2 v'^2_{\rm A}\nu)^{1/3}$. The cube root dependence means that damping lengths in a structured medium are considerably shorter than those in a uniform medium. For the coronal conditions illustrated above (and taking ν to be 2×10^{11} m^2 s^{-1}), the damping length for a wave of period 100 s is about 10^4 km. Such considerations are important in the question of coronal heating.

Flux tube waves

Magnetic flux tubes, regions of magnetic field that are distinguished from one another through plasma density or temperature, magnetic field strength or plasma flow, are of particular interest. Two types of flux tube have received detailed study: the isolated flux tube of magnetic field embedded in a field-free medium and the magnetically embedded tube of dense plasma in a magnetic medium. The isolated tube finds specific application in the solar photospheric tube (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES) and the embedded tube has application to the solar wind and the solar coronal loop.

Consider again equations (20) and (21), examining the specific case of a flux tube of radius a, field strength B_0 and plasma density ρ_0 embedded in a magnetic environment with field strength $B_{\rm e}$ and plasma density $\rho_{\rm e}$:

$$B_0(r) = \begin{cases} B_0, & r < a \\ B_{\rm e}, & r > a \end{cases} \qquad \rho_0(r) = \begin{cases} \rho_0, & r < a \\ \rho_{\rm e}, & r > a. \end{cases} \qquad (25)$$

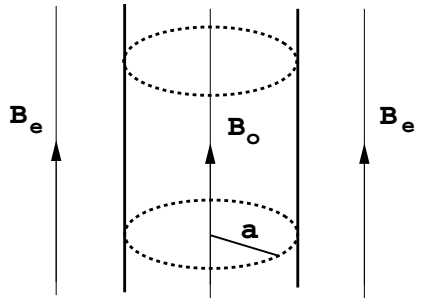

Figure 3. The equilibrium state of a magnetic flux tube of radius a, field strength B_0 and plasma density ρ_0 embedded in a magnetized plasma of field strength B_e and plasma density ρ_e.

The tube is in magnetostatic pressure balance with its surroundings (see equation (4)). The Alfvén, sound and slow speeds within the tube are v_A, c_s and c_t, and their values in the external medium are v_{Ae}, c_e and c_{te} (see figure 3). The case of an isolated tube embedded in a field-free environment corresponds to setting $B_e = 0$ (so that $v_{Ae} = 0$), but for magnetically embedded tubes in a strongly magnetized plasma (i.e. a plasma in which the Alfvén speeds exceed the sound speeds) the field strengths B_0 and B_e are generally comparable and, moreover, $v_{Ae}, v_A >> c_e, c_s$.

For the equilibrium (25) the differential equation (21) may be solved for p_T in terms of Bessel functions $J_n(n_0 r)$ in $r < a$ and $K_n(m_e r)$ in $r > a$, with the result

$$\rho_e(k_z^2 v_{Ae}^2 - \omega^2) n_0 \frac{J_n'(n_0 a)}{J_n(n_0 a)} = \rho_0(k_z^2 v_A^2 - \omega^2) m_e \frac{K_n'(m_e a)}{K_n(m_e a)} \quad (26)$$

where

$$n_0^2 = \frac{(\omega^2 - k_z^2 v_A^2)(\omega^2 - k_z^2 c_s^2)}{(c_s^2 + v_A^2)(\omega^2 - k_z^2 c_t^2)}$$

and

$$m_e^2 = \frac{(k_z^2 c_e^2 - \omega^2)(k_z^2 v_{Ae}^2 - \omega^2)}{(c_e^2 + v_{Ae}^2)(k_z^2 c_{te}^2 - \omega^2)}.$$

Equation (26) is the dispersion relation for flux tube waves, describing magnetoacoustic waves in a uniform magnetic flux tube; it applies for waves that are confined to the tube, requiring that $m_e > 0$. The integer n that arises (through the Fourier analysis in equation (19)) in the description of tube waves defines the geometry of the vibrating tube. The case $n = 0$ corresponds to a symmetric pulsation of the tube, with its axis remaining undisturbed, and is commonly referred to as the sausage wave (or mode). The case $n = 1$ describes the kink mode, which involves lateral displacements of the tube (maintaining a circular cross-section) with the axis of the tube resembling a wriggling snake; the plasma in the neighborhood of the tube is also disturbed. There are also fluting modes ($n \geq 2$), which leave the axis of the tube undisturbed but distort the tube boundary. See figure 4.

The restriction $m_e > 0$ imposed on the flux tube dispersion relation means that the amplitude of a wave

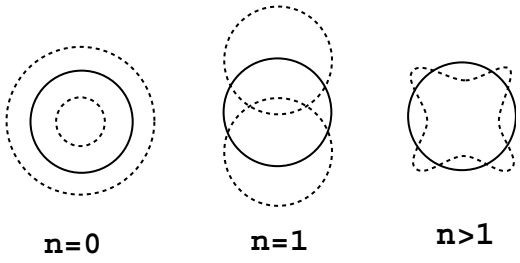

Figure 4. The modes of oscillation of a flux tube, showing the sausage ($n = 0$), kink ($n = 1$) and fluting ($n \geq 2$) waves.

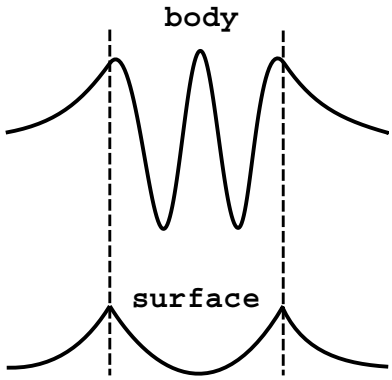

Figure 5. Surface and body waves in a flux tube. Surface waves are largely confined to the region near the boundary of the tube whereas body waves occupy the whole of the tube.

declines with radius r ($>a$), so that far from the tube there is no appreciable disturbance. Inside the tube (for $r < a$) the disturbance is oscillatory if $n_0^2 > 0$ or nonoscillatory (evanescent) if $n_0^2 < 0$. Modes that inside the tube are oscillatory in r are called body waves, because they disturb the whole of the interior of a tube. Waves that have an evanescent form inside and outside the tube are called surface waves, since they are mainly confined to the region near the boundary of the tube. See figure 5. Magnetoacoustic surface waves may also exist on a simple planar interface between two magnetized plasmas. Finally, we note that just as there are both slow and fast magnetoacoustic waves in a uniform medium, there are slow and fast tube waves, and these may be body or surface modes of the sausage, kink or fluting form. Moreover, the presence of the tube radius a in the dispersion relation means that, unlike magnetoacoustic waves in a uniform unbounded medium (equation (12)), the phase speed c ($=\omega/k_z$) of a tube wave depends on its wavelength ($2\pi/k_z$): tube waves are dispersive.

Two speeds prove to be of special significance in magnetic flux tubes: the slow speed c_t of the tube and a mean Alfvén speed c_k, defined by

$$c_k^2 = \frac{\rho_0 v_A^2 + \rho_e v_{Ae}^2}{\rho_0 + \rho_e}. \quad (27)$$

The speeds c_t and c_k are important in both isolated

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

and magnetically embedded (photospheric and coronal) tubes. The speed c_k is called the kink speed, and it is the speed with which the kink mode of oscillation propagates for waves that are much longer than a tube radius ($k_z a \ll 1$). The speed c_t is associated with both slow body and slow surface waves. The slow surface wave is of particular interest in isolated flux tubes. We may illustrate these speeds for a strongly magnetized plasma and for a photospheric flux tube. In a strongly magnetized plasma such as the solar corona (for which Alfvén speeds are much larger than sound speeds), the slow speed is close to the sound speed inside the tube. For a high-density ($\rho_0 \gg \rho_e$) strongly magnetized plasma (with $B_0 \approx B_e$) the kink speed is $\sqrt{2}v_A$, and so is some 40% higher than the tube's Alfvén speed. By contrast, in a photospheric tube with $\rho_0 \approx \rho_e/2$ and $v_A \approx c_s$, the tube speed c_t is about $v_A/\sqrt{2}$ and the kink speed c_k is about $v_A/\sqrt{3}$, so both speeds are well below the Alfvén speed.

Ducted waves

For a strongly magnetized plasma the dispersion relation (26) possesses two sets of modes, namely fast and slow body waves. There are no surface ($n_0^2 < 0$) waves. Both sets of modes are dispersive, with the fast waves being strongly dispersive. An interesting aspect of these waves is that the fast body waves occur only if $v_{Ae} > v_A$. Thus fast body waves occur in regions of low Alfvén speed which typically correspond to regions of high plasma density; this is the usual circumstance in coronal loops. Regions of low Alfvén speed in strongly magnetized plasmas provide wave guides for fast magnetoacoustic waves. It is interesting to report that fast kink mode oscillations in coronal loops have been identified by the TRACE spacecraft.

There are close analogies here between the behavior of fast magnetoacoustic body modes in a strongly magnetized plasma and Love waves in the Earth's crust and Pekeris sound waves in an internal ocean layer; consequently, fast sausage waves are sometimes referred to as magnetic Pekeris waves and fast kink waves as magnetic Love waves. The distinctive dispersive wave signature they produce when impulsively excited has received interest because of its possible importance in the interpretation of oscillations detected in the corona at radio wavelengths. In particular, an impulsively generated fast body wave produces a signature which consists of three parts: a low-amplitude periodic phase, followed by a larger amplitude quasi-periodic phase, and finally a decay phase. The shortest timescales in the motions are those in the quasi-periodic phase. An estimate of the timescale τ in the periodic phase is provided by

$$\tau = \frac{2\pi a}{j_0 v_A}$$

where j_0 (=2.40) denotes the first zero of the Bessel function J_0. For a tube of radius $a = 10^3$ km and Alfvén speed $v_A = 10^3$ km s^{-1} this produces a timescale of about 1 s.

Nonlinear waves

Magnetohydrodynamic waves may become nonlinear, having amplitudes that are too large to permit a linear treatment. Many of the MHD waves detected in the solar wind and waves generated by a solar flare—and seen to rapidly propagate out across the solar disk—are nonlinear. Alfvén waves provide an exact solution of the nonlinear MHD equations. Nonlinearity frequently leads to wave amplitude growth and steepening, just as an ocean wave undergoes such changes on approaching the shore line. Shock waves are nonlinear waves with profiles that are particularly sharp—discontinuities in the ideal case—and across which dissipative processes act to balance nonlinearity. Conservation relations (total energy, mass, momentum, etc) determine the character of the shock wave. In keeping with the existence of both slow and fast magnetoacoustic waves, both slow shocks and fast shocks may occur. Slow shocks may arise in photospheric flux tubes and in the solar wind, and are also invoked in MAGNETIC RECONNECTION theories; fast shocks would seem to be implicated in observed blast waves generated by a solar flare. When dispersive effects are important, as in magnetic flux tubes, solitons may occur; solitons are waves that propagate nonlinearly preserving their basic shape, even after interactions with other nonlinear waves, and achieving a balance between nonlinearity and dispersion. There are theoretical grounds for believing that solitons may occur in the Sun (see, for example, SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: THEORY).

Magnetohydrodynamics

Magnetohydrodynamics (or MHD for short) is the study of the interaction between a magnetic field and a plasma treated as a continuous medium (e.g. Cowling 1957, Roberts 1967, Priest 1982, 1994). Most of the universe is not a normal gas but is instead a plasma. We are all familiar on Earth with the three states of matter (solid, liquid and gas). You change from one state to another (such as ice to water) by heating, and if you raise the temperature of gas sufficiently it changes to the fourth state of matter, namely plasma. In the plasma state the atoms have split into positive ions and negative electrons, which can flow around freely, so the gas becomes electrically conducting and a current can flow. (MHD can also be used to describe the behavior of an electrically conducting liquid.)

Many dynamical processes in the universe are caused by the subtle nonlinear relationship between a magnetic field and a plasma. In a normal gas such as the air we breathe, there is virtually no interaction with a magnetic field. But in a plasma the extremely close coupling with the magnetic field means that whatever the plasma is doing intimately affects the magnetic field and vice versa. Indeed, on Earth we are in an extremely unusual part of the cosmos, a tiny island of solid, liquid and gas. But, as soon as we go up to the ionosphere, the plasma universe begins, including the region between Earth and Sun, the whole of the Sun itself, as well as the interstellar and intergalactic media and the stars and galaxies contained in them.

In MHD we are not concerned with individual particles but treat the plasma as a continuous medium. It builds partly on electromagnetism and partly on fluid mechanics. The assumption of a continuous medium is valid for length-scales much larger than the mean-free path for particle collisions

$$\lambda_{\rm mfp} \approx 300\left(\frac{T}{10^6\ {\rm K}}\right)^2\left(\frac{n}{10^{17}\ {\rm m}^{-3}}\right)^{-1}\ {\rm m},$$

which is typically 3 cm in the solar chromosphere and 30 km in the solar corona.

The magnetic field has several physical effects:

(a) It exerts a force, which may accelerate plasma or create structure.
(b) It stores energy, which may later be released as, for example, a solar eruption or a solar flare.
(c) It acts as a thermal blanket, which, when wrapped around a cool solar prominence, say, may protect it from the surrounding corona.
(d) It channels fast particles and plasma.
(e) It drives instabilities and supports waves.

MHD is important in a wide variety of cosmic phenomena. The different aspects of MHD are described in the articles that follow and the applications are discussed in many of the articles throughout the encyclopedia, notably in those about the Sun, where MHD phenomena are widespread. In this introductory article, we first describe a *magnetic flux tube* and then introduce the fundamental equations. Particular attention is given to the *induction equation* and the *Lorentz force* with which a magnetic field acts on a plasma. Then we describe the force balance of a plasma at rest, known as magnetohydrostatics, and mention briefly the possible wave modes and instabilities.

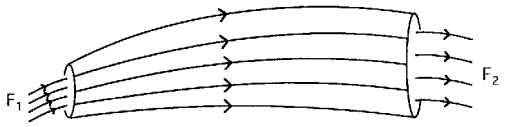

Figure 1. Segment of a magnetic flux tube.

Magnetic flux tubes

A magnetic field line is a curve such that the tangent at any point is in the direction of the magnetic field. Its equation, for a two-dimensional magnetic field having components (B_x, B_y), is

$$\frac{{\rm d}y}{{\rm d}x} = \frac{B_y}{B_x}$$

or ${\rm d}x/B_x = {\rm d}y/B_y = {\rm d}z/B_z$ in three dimensions.

A magnetic flux tube is the surface generated by the set of magnetic field lines which intersect a simple closed curve. Flux tubes are the building blocks of a magnetic configuration, but they must not be thought of as independent isolated structures.

The strength (F) of a flux tube is the amount of magnetic flux crossing a section (S), i.e.

$$F = \int_s \boldsymbol{B}\cdot{\rm d}\boldsymbol{S}.$$

Consider a finite segment of a flux tube bounded by plane sections S_1 and S_2 (figure 1). There is no flux across the walls of the tube, and so physically, if no flux is created inside the tube, the flux (F_1) entering through section S_1 equals the flux (F_2) leaving through section S_2. In other words, the strength (F) is constant along the tube. Mathematically, integrating over the whole surface (S_V) of the segment of the tube between S_1 and S_2 gives, since $\boldsymbol{B}\cdot{\rm d}\boldsymbol{S}$ vanishes on the curved part

$$\int_{S_V}\boldsymbol{B}\cdot{\rm d}\boldsymbol{S} = \int_{S_1}\boldsymbol{B}\cdot{\rm d}\boldsymbol{S} + \int_{S_2}\boldsymbol{B}\cdot{\rm d}\boldsymbol{S} = -F_1 + F_2$$

where F_1 is the flux from left to right and, on S_V, ${\rm d}\boldsymbol{S}$ is in the direction of the outwards normal. However, the Gauss divergence theorem gives

$$\int_{S_V}\boldsymbol{B}\cdot{\rm d}\boldsymbol{S} = \int_V \nabla\cdot\boldsymbol{B}\,{\rm d}V = 0$$

since $\nabla\cdot\boldsymbol{B} = 0$. Thus $F_1 = F_2$ as required, and therefore $\nabla\cdot\boldsymbol{B} = 0$ implies that no flux is indeed created and the strength is constant along the flux tube.

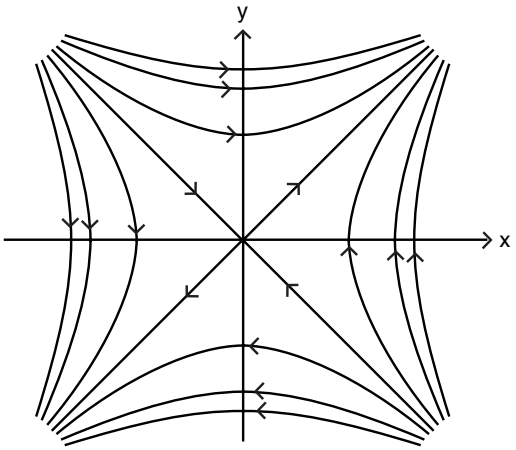

Figure 2. Field lines for the magnetic field $(B_x, B_y) = (y, x)$.

If the cross-sectional area (A) of a flux tube is small, then $F \approx BA$. Thus, as the magnetic field lines become closer together, so A becomes smaller and, since F is constant, B increases in value, and vice versa.

When sketching field lines from expressions for the field components there are three stages:

(a) Evaluate the expressions for the field lines and sketch a typical one.
(b) Decide the directions of the arrows.
(c) Decide the spacings of other field lines.

Thus, for example, if $B_x = y$ and $B_y = x$, the field lines are given by $\mathrm{d}y/\mathrm{d}x = x/y$ or $y^2 - x^2 =$ constant. When the constant is zero we obtain the two field lines $(y = \pm x)$ through the origin (called separatrices); when the constant is positive (negative) we have branches of a rectangular hyperbola intersecting the y-axis (x-axis). From the orientations of the axes in figure 2 we have decided that the positive directions are to the right and upward; thus, for instance, on the positive x-axis the field is simply $B_y = x$, which is positive and so the arrow is directed upwards. Also, as one moves out along the x-axis the magnitude of the field increases and so the field lines become more closely spaced. The origin is a special point, an X-type neutral point, where the field vanishes and the topology of nearby magnetic field lines is hyperbolic; it represents a weak spot in a configuration where magnetic energy tends to be released after the formation of a current sheet.

Fundamental equations

The MHD equations are a unification of the equations of slow electromagnetism and fluid mechanics. Maxwell's equations are

$$\nabla \times \boldsymbol{H} = \boldsymbol{j} + \frac{\partial \boldsymbol{D}}{\partial t} \qquad \nabla \cdot \boldsymbol{B} = 0 \tag{1}$$

$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t} \qquad \nabla \cdot \boldsymbol{D} = \rho_c \tag{2}$$

where $\boldsymbol{B} = \mu \boldsymbol{H}, \boldsymbol{D} = \epsilon \boldsymbol{E}$ and $\boldsymbol{j}$ and ρ_c are the electric current and charge densities present in the plasma. (Sometimes a subscript 0 is placed on μ and ϵ.)

Here $\boldsymbol{H}$ is the *magnetic field*, $\boldsymbol{B}$ is the *magnetic induction* (although we shall loosely refer to it as the magnetic field), μ the *magnetic permeability* of free space, $\boldsymbol{E}$ the *electric field*, $\boldsymbol{D}$ the *electric displacement*, ϵ the *permittivity* of free space, ρ_c the *charge density*, $\boldsymbol{j}$ the *electric current density*. These are supplemented by Ohm's law

$$\boldsymbol{E} = \boldsymbol{j}/\sigma \tag{3}$$

where σ is the electrical conductivity.

The equations of fluid mechanics for a perfect gas, on the other hand, are

$$\rho \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = -\nabla p \tag{4a}$$

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} + \rho \nabla \cdot \boldsymbol{v} = 0 \tag{4b}$$

$$p = \mathcal{R}\rho T \tag{4c}$$

and an energy equation (see below), where ρ is the *plasma density* (the mass per unit volume), $\boldsymbol{v}$ the *plasma velocity*, p the *plasma pressure*, T the *temperature*, $\mathcal{R}$ the *gas constant*. The operator $\mathrm{d}/\mathrm{d}t = \partial/\partial t + \boldsymbol{v} \cdot \nabla$ is the total (or material) derivative and represents the time rate of change moving with an element of plasma, in contrast to $\partial/\partial t$ which represents the time rate of change at a fixed point of space.

Equation (4a) is the *equation of motion*, which says that the mass times acceleration of a moving element of plasma equals the sum of the forces acting on the element. Here we have included just the pressure gradient $(-\nabla p)$. Equation (4b) is the *equation of mass continuity* and is simply a mathematical expression of the physical fact that no plasma is being created or destroyed: thus, if for example mass is flowing outwards away from an element (so that the flow is 'diverging' and the divergence $\nabla \cdot \boldsymbol{v}$ is positive), then the density of the element must be decreasing so that from (4b) $\mathrm{d}\rho/\mathrm{d}t$ must be negative. Equation (4c) is the *perfect gas law*, stating that the pressure of a plasma is proportional to its density and temperature. In principle (4a) determines the velocity $\boldsymbol{v}$, (4b) the density ρ, while (4c) and an energy equation determine the pressure p and temperature T.

The (internal) energy equation may be written

$$\rho \frac{\mathrm{d}e}{\mathrm{d}t} + p \nabla \cdot \boldsymbol{v} = \nabla \cdot (\boldsymbol{\kappa} \cdot \nabla \boldsymbol{T}) - Q_v + Q_r$$

where

$$e = \frac{p}{(\gamma - 1)\rho}$$

is the internal energy density, $\boldsymbol{\kappa}$ is the thermal conductivity tensor, Q_v is the heating by viscous dissipation, Q_r is the radiative energy loss and γ is the ratio of specific heats. In

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

many astrophysical and solar applications the (optically thin) radiative loss term can be expressed as

$$Q_r = \rho^2 Q(T)$$

where $Q(T)$ is a function describing the temperature variation of the radiative loss.

In a neutral gas the electromagnetic (1)–(3) and fluid dynamic (4) equations are decoupled and so the electromagnetic and fluid properties are independent. However, in MHD we modify the above equations in four ways:

(a) A plasma feels an extra force, the so-called Lorentz force ($\boldsymbol{j} \times \boldsymbol{B}$), which is added on to the right-hand side of (4*a*). It is this term which couples the fluid equations to the electromagnetic equations. It is well known that an element $\mathrm{d}\boldsymbol{l}$ of wire carrying a current J in a magnetic field feels a force $J\,\mathrm{d}\boldsymbol{l} \times \boldsymbol{B}$ perpendicular to the wire and to the field, and so it is natural that a plasma element of volume $\mathrm{d}V$ carrying a current of density $\boldsymbol{j}$ per unit volume should feel a force $\boldsymbol{j}\,\mathrm{d}V \times \boldsymbol{B}$.
(b) The presence of the electric current adds an ohmic heating term (j^2/σ) to the energy equation.
(c) Ohm's law states that the electric field in a frame moving with the plasma is proportional to the current, but the total electric field on moving plasma is $\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B}$, where $\boldsymbol{E}$ is the field seen in a frame where the observer is at rest, so (3) is modified by adding $\boldsymbol{v} \times \boldsymbol{B}$ to the left-hand side. This too couples the electromagnetic equations to the fluid equations.
(d) We consider processes with plasma and wave speeds much slower than the speed of light ($v \ll c$), so that the displacement current ($\partial \boldsymbol{D}/\partial t$) in (1) is negligible. This in turn means that we don't need to consider $\nabla \cdot \boldsymbol{D} = \rho_c$ since it just determines ρ_c if needed.

There are at least a dozen different approximations that are commonly used for the MHD system of equations. Some of the more well-known ones are: incompressibility (when ρ is constant following the motion or $\nabla \cdot \boldsymbol{v} = 0$), which requires that the flow speed be much smaller than the sound speed and Alfvén speed; a *steady state* ($\partial/\partial t = 0$ for all variables); the Boussinesq approximation (filtering out sound waves by including density variations only in the gravitational term in the equation of motion); an *isothermal state* (when T = constant); an ideal MHD state (when $\eta = \nu = 0$, $R_m = R_e = \infty$, see below); an inviscid state (when the viscous effects are negligible); an irrotational (potential) flow (when the vorticity, $\nabla \times \boldsymbol{v}$, vanishes); an isentropic state (when the entropy is constant); a force-free field ($\boldsymbol{j} \times \boldsymbol{B} = 0$); a potential magnetic field ($\boldsymbol{j} = 0$); a strong magnetic field ($\beta \ll 1$); a weak magnetic field ($\beta \gg 1$, where β is defined by equation (15) below); a supersonic flow regime (plasma velocity larger than sound speed); a subsonic flow regime (velocity smaller than sound speed).

Validity of MHD in collisionless plasmas

Many cosmic plasmas are collisionless, where the mean free-path for binary collisions between particles is much greater than the characteristic length-scale of the system. MHD ignores particle interactions, and so the reader may at first think that it is of little use in collisionless plasmas. In practice, however, MHD and its two-fluid variants often describe the behavior of collisionless plasmas surprisingly well. For instance, the solar wind beyond 10 solar radii is completely collisionless, but MHD models describe its global velocity, temperature and density quite well, including such time-dependent aspects as shock waves, stream interactions and turbulence. In principle, the appropriate theory for collisionless plasmas is kinetic plasma theory derived from Vlasov's equation. However, due to its mathematical complexity, it is rarely used to construct a global model of the solar wind and is instead confined mainly to calculating effective transport coefficients and modeling localized effects such as shock structure.

MHD has been successful in describing collisionless plasmas for several reasons. Firstly, conservation of mass, momentum and energy are principles common to both ideal MHD and collisionless systems. It is only when dissipation processes are considered that classical MHD becomes problematical. Secondly, ionized particles undergo a gyro-motion about the magnetic field which prevents them from traveling unimpeded in the direction perpendicular to the field. Thus, long-range interactions occur only along the field, while short-range interactions across the field may be described by MHD-like equations. Finally, many plasmas are perturbed by waves which interact with particle motion, even along the field, scattering them in all directions and so re-introducing some form of 'effective' collisionality.

In ideal MHD the magnetic field is frozen to the plasma, but this is also a natural consequence of gyro-motion in a collisionless plasma whenever the $\boldsymbol{E} \times \boldsymbol{B}$ drift of the gyro-centers dominates all other drifts. Thus, if a collisionless plasma contains particles undergoing gyro-motion and the $\boldsymbol{E} \times \boldsymbol{B}$ drift dominates, it will obey the ideal MHD Ohm's law.

The MHD Lorentz force ($\boldsymbol{j} \times \boldsymbol{B}$) is recovered in a collisionless plasma whenever the particle gyro-velocity is much smaller than the speed of light. When the Lorentz force on individual particles is added together it gives a net force per unit volume of

$$\boldsymbol{F} = \rho_c \boldsymbol{E} + \boldsymbol{j} \times \boldsymbol{B}$$

where ρ_c is the electric charge density. However, the ratio of the two terms on the right is

$$\frac{|\rho_c \boldsymbol{E}|}{|\boldsymbol{j} \times \boldsymbol{B}|} \approx \left(\frac{V}{c}\right)^2$$

which is much less than unity when the particle speed (V) is non-relativistic. In other words, $\rho_c \boldsymbol{E}$ is usually

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

negligible compared with the ($\boldsymbol{j} \times \boldsymbol{B}$) force for the low-energy particles.

In a collisionless plasma, the most important new effect arises in the pressure and viscous terms in the momentum equation, since the gas pressure is generally anisotropic relative to the magnetic field. The plasma exerts a pressure ($p_\parallel$) along the field which is usually different from the pressure ($p_\perp$) perpendicular to the field. Similarly, the viscous stress tensor is also anisotropic and dependent on the magnetic field. If $p_\parallel$ and $p_\perp$ can be expressed in terms of the local bulk properties of the plasma, then the MHD equations can still be applied by just adding the appropriate forms of the pressure and viscous stress tensors.

In a collisionless plasma equation (6*a*) in the next section is replaced by the generalized Ohm's law. For a fully ionized plasma it takes the form

$$\boldsymbol{E} = -\boldsymbol{v} \times \boldsymbol{B} + \frac{\boldsymbol{j}}{\sigma} + \frac{m_e}{ne^2}\left(\frac{\partial \boldsymbol{j}}{\partial t} + \nabla \cdot (\boldsymbol{vj} + \boldsymbol{jv})\right) - \frac{\boldsymbol{j} \times \boldsymbol{B}}{ne} - \frac{\nabla \boldsymbol{p}_e}{ne}$$

where $\boldsymbol{vj}$ and $\boldsymbol{jv}$ are dyadic tensors and $\boldsymbol{p}_e$ is the electron stress tensor. The first term on the left-hand side of this equation is the convective electric field, while the second term is the field associated with Ohmic dissipation caused by electron–ion collisions. The next three terms describe the effects of *electron inertia*, while the penultimate term is the *Hall effect* and the last term includes the *electron gyroviscosity*. For a partially ionized plasma, collisions between charged particles and neutrals lead also to ambipolar diffusion.

Induction equation

With the above assumptions, equations (1)–(3) become

$$\boldsymbol{j} = \nabla \times \boldsymbol{B}/\mu \tag{5a}$$

$$\frac{\partial \boldsymbol{B}}{\partial t} = -\nabla \times \boldsymbol{E} \tag{5b}$$

$$\boldsymbol{E} = -\boldsymbol{v} \times \boldsymbol{B} + \boldsymbol{j}/\sigma \tag{6a}$$

where

$$\nabla \cdot \boldsymbol{B} = 0 \tag{6b}$$

We may therefore eliminate $\boldsymbol{j}$ and $\boldsymbol{E}$ by substituting for $\boldsymbol{j}$ from (5*a*) in (6*a*) and for $\boldsymbol{E}$ from (6*a*) in (5*b*), with the result that $\partial \boldsymbol{B}/\partial t = \nabla \times (\boldsymbol{v} \times \boldsymbol{B}) - \eta \nabla \times (\nabla \times \boldsymbol{B})$, where $\eta = 1/(\mu\sigma)$ is the magnetic diffusivity, here assumed uniform. By expanding out the triple vector product in the last term and using (6*b*), we obtain finally

$$\frac{\partial \boldsymbol{B}}{\partial t} = \nabla \times (\boldsymbol{v} \times \boldsymbol{B}) + \eta \nabla^2 \boldsymbol{B} \tag{7}$$

which is known as the induction equation.

This is the basic equation for the magnetic behavior in MHD: it determines $\boldsymbol{B}$ once $\boldsymbol{v}$ is known. In electromagnetism the electric current and electric field are primary variables, with the current driven by electric fields, and then the magnetic field is a secondary variable produced by currents. However, in MHD the basic physics is quite different, since the plasma velocity ($\boldsymbol{v}$) and magnetic field ($\boldsymbol{B}$) are the primary variables, determined by the induction equation and the equation of motion, while the resulting current ($\boldsymbol{j}$) and electric field ($\boldsymbol{E}$) are secondary and may be deduced from (5*a*) and (6*a*) if required.

If V_0, L_0 are typical velocity and length-scale, the ratio of the first to the second term on the right-hand side of (7) is, in order of magnitude, the magnetic Reynolds number

$$R_m = \frac{L_0 V_0}{\eta}.$$

Thus, for example, in a solar active region where $\eta \approx 1\ \mathrm{m^2\ s^{-1}}$, $L_0 \approx 10^5$ m, $V_0 \approx 10^4\ \mathrm{m\ s^{-1}}$ we find $R_m \approx 10^9$ and so the second term on the right of (7) is completely negligible. In turn, equation (6*a*) reduces to $\boldsymbol{E} = -\boldsymbol{v} \times \boldsymbol{B}$ to a very high degree of approximation. This is the case in almost all of the solar atmosphere, indeed in almost all of the universe—the only exception is in regions (such as current sheets) where the length-scale is extremely small, so small that $R_m \leq 1$ and the second term on the right of (7) becomes important.

If $R_m \ll 1$, the induction equation reduces to

$$\frac{\partial \boldsymbol{B}}{\partial t} = \eta \nabla^2 \boldsymbol{B} \tag{8}$$

and so $\boldsymbol{B}$ is governed by a diffusion equation, which implies that field variations (irregularities) on a scale L_0 diffuse away on a time-scale of

$$\tau_d = \frac{L_0^2}{\eta}$$

which is obtained simply by equating the orders of magnitude of both sides of (8). The corresponding speed at which they diffuse is

$$v_d = \frac{L_0}{\tau_d} = \frac{\eta}{L_0}.$$

With $\eta \approx 1\ \mathrm{m^2\ s^{-1}}$, the decay time for a sunspot is (with $L_0 = 10^6$ m) 10^{12} sec = 30 000 yr, so that the process whereby sunspots disappear in a few days cannot just be diffusion (and is probably instead decaying by the convection away from the spot of many small flux tubes). Similarly, the diffusion time for a magnetic field pervading the Sun as a whole (with $L_0 = 7 \times 10^8$ m) is 5×10^{17} s = 10^{10} yr. This is of the order of the age of the universe, so a magnetic field in a star at its formation has not had time to diffuse much.

Consider, for example, a one-dimensional magnetic field ($B(x,t)\hat{\boldsymbol{y}}$) satisfying

$$\frac{\partial B}{\partial t} = \eta \frac{\partial^2 B}{\partial x^2} \tag{9}$$

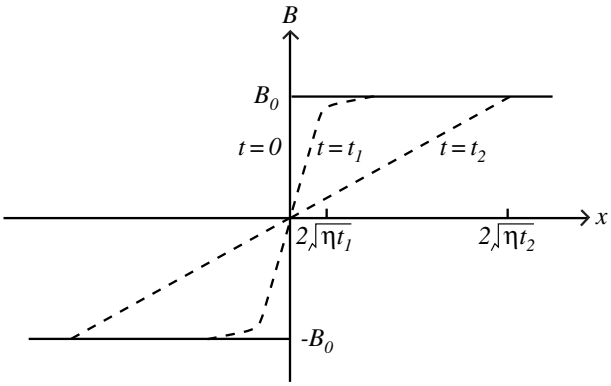

Figure 3. The magnetic field (B) in a diffusing one-dimensional current sheet as a function of distance (x) for times $t = 0, t_1, t_2$.

and suppose that initially the field is $B(x, 0) = B_0$ for $x > 0$ and $B(-x, 0) = -B(x, 0)$, as shown in figure 3. Physically, what do we expect to happen? Since (9) has the form of a heat conduction equation and we know that heat tends to flow from a hot region to a cool one and smooth out a temperature gradient, we expect the same diffusive process to occur for our magnetic field and for the initially steep magnetic gradient at $x = 0$ to smooth out, as shown in figure 3.

Mathematically, the required solution of (9) turns out to be, in terms of the *error function* (erf(ξ))

$$B(x,t) = B_0 \operatorname{erf}\left(\frac{x}{\sqrt{(4\eta t)}}\right) = \frac{2B_0}{\sqrt{\pi}} \int_0^{x/\sqrt{(4\eta t)}} \mathrm{e}^{-u^2}\, \mathrm{d}u.$$

This solution does indeed have the form shown in figure 3 and it may be verified *a posteriori* by substituting back into (9). The resulting field lines diffuse through the plasma and cancel at $x = 0$.

The main reason for variations in R_m from one phenomenon to another is variations in the appropriate length-scale (L_0). If $R_m \gg 1$, the induction equation becomes

$$\frac{\partial \boldsymbol{B}}{\partial t} = \nabla \times (\boldsymbol{v} \times \boldsymbol{B})$$

and Ohm's law reduces to $\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B} = \boldsymbol{0}$ so that the total electric field in a frame of reference moving with the plasma vanishes. Then, if we consider a curve $\mathcal{C}$ (bounding a surface $\mathcal{S}$) which is moving with the plasma, in a time $\mathrm{d}t$ an element $\mathrm{d}s$ of $\mathcal{C}$ sweeps out an element of area $\boldsymbol{v}\,\mathrm{d}t \times \mathrm{d}\boldsymbol{s}$. The rate of change ($\mathrm{d}/\mathrm{d}t \int \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S}$) of magnetic flux through $\mathcal{C}$ then consists of two parts, namely

$$\int_{\mathcal{S}} \frac{\partial \boldsymbol{B}}{\partial t} \cdot \mathrm{d}\boldsymbol{S} + \int_{\mathcal{C}} \boldsymbol{B} \cdot \boldsymbol{v} \times \mathrm{d}\boldsymbol{s}.$$

As $\mathcal{C}$ moves, so the flux changes partly because the magnetic field is changing with time (the first term) and partly because of the motion of the boundary (the second term). Then, by putting $\boldsymbol{B} \cdot \boldsymbol{v} \times \mathrm{d}s = -v \times B \cdot \mathrm{d}\boldsymbol{s}$ and applying Stokes' theorem to the second term, we obtain

$$\frac{\mathrm{d}}{\mathrm{d}t} \int \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} = \int_{\mathcal{S}} \left(\frac{\partial \boldsymbol{B}}{\partial t} - \nabla \times (\boldsymbol{v} \times \boldsymbol{B}) \right) \cdot \mathrm{d}\boldsymbol{S}$$

which vanishes in the present approximation.

Thus, the total magnetic flux through $\mathcal{C}$ remains constant as it moves with the plasma. In other words we have proved magnetic flux conservation (figure 4(*a*)). It follows that plasma elements that form a flux tube initially do so at all later times (figure 4(*a*)). There is also magnetic field line conservation (or conservation of magnetic connectivity), namely that, if two plasma elements lie on a field line initially they will always do so (figure 4(*b*)). At $t = t_1$, say, suppose elements P_1 and P_2 lie on a field line, which may be defined as the intersection of two flux tubes. Then, at some later time ($t = t_2$) by magnetic flux conservation P_1 and P_2 will still lie on both tubes, and so they will lie on the field line defined by their intersection. We interpret the above results by saying that the magnetic field lines move with the plasma—we say that they are frozen into the plasma—and plasma can move freely along field lines, but in motion perpendicular to them they are dragged with the plasma or vice versa.

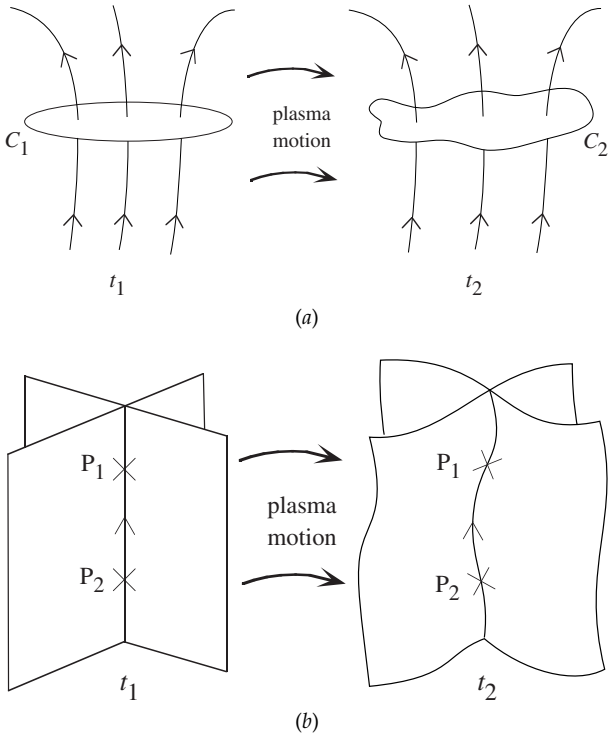

Figure 4. (*a*) Magnetic flux conservation—if a curve $\mathcal{C}_1$ is distorted into $\mathcal{C}_2$ by a plasma motion, the flux through $\mathcal{C}_1$ at t_1 equals the flux through $\mathcal{C}_2$ at t_2. (*b*) Magnetic field line conservation—if plasma elements P_1 and P_2 lie on a field line at t_1, then they will lie on the same line at t_2.

The Lorentz force

One equation relating our fundamental variables $\boldsymbol{v}$ and $\boldsymbol{B}$ is the induction equation; the other is the equation of motion, whose most common form is

$$\rho \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = -\nabla p + \boldsymbol{j} \times \boldsymbol{B} \tag{10}$$

although other forces such as viscous or gravitational may sometimes be important too. The term $-\nabla p$ is the plasma pressure gradient: it acts from regions of high plasma pressure to low pressure and is perpendicular to the isobars (curves of constant pressure).

The magnetic force ($\boldsymbol{j} \times \boldsymbol{B}$) is perpendicular to the magnetic field, and so any plasma acceleration parallel to the magnetic field must be caused by other forces. By substituting for $\boldsymbol{j}$ from Ampère's law (5*a*) and using an identity for the triple vector product, we can write it as

$$\boldsymbol{j} \times \boldsymbol{B} = (\nabla \times \boldsymbol{B}) \times \boldsymbol{B}/\mu = (\boldsymbol{B} \cdot \nabla)\frac{\boldsymbol{B}}{\mu} - \nabla\left(\frac{B^2}{2\mu}\right).$$

The two terms on the right-hand side have important physical interpretations. Since the second term has the same form as $-\nabla p$, we can say that it represents the effect of a *magnetic pressure* of magnitude $B^2/(2\mu)$. It gives a force when B^2 varies with position, and the direction of the force is from regions of high magnetic pressure to low magnetic pressure.

The first term represents the effect of a *magnetic tension* parallel to the magnetic field of magnitude B^2/μ per unit area. It gives a force when the field lines are curved, just like an elastic band or rope. By writing $\boldsymbol{B} = B\hat{\boldsymbol{s}}$ in terms of the unit vector ($\hat{s}$) along the magnetic field, the tension term ($(\boldsymbol{B} \cdot \nabla)B/\mu$) may be written

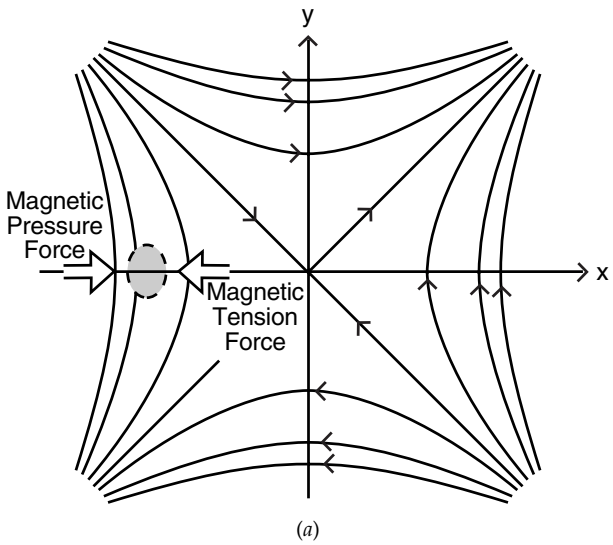
$$\frac{B}{\mu}\frac{\mathrm{d}}{\mathrm{d}s}(B\hat{\boldsymbol{s}}) = \frac{B^2}{\mu}\frac{\mathrm{d}\hat{\boldsymbol{s}}}{\mathrm{d}s} + \frac{B}{\mu}\frac{\mathrm{d}B}{\mathrm{d}s}\hat{\boldsymbol{s}} = \frac{B^2}{\mu}\frac{\hat{\boldsymbol{n}}}{\mathcal{R}} + \frac{\mathrm{d}}{\mathrm{d}s}\left(\frac{B^2}{2\mu}\right)\hat{\boldsymbol{s}}$$

where $\hat{\boldsymbol{n}}$ is the principal normal and $\mathcal{R}$ is the radius of curvature. The second term on the right of this equation is irrelevant, since it cancels with the component of $-\nabla(B^2/2\mu)$ parallel to $\boldsymbol{B}$, as it must since $\boldsymbol{j} \times \boldsymbol{B}$ is perpendicular to $\boldsymbol{B}$. However, the first term on the right is the magnetic tension term, which shows that when the radius of curvature is small the tension force is large.

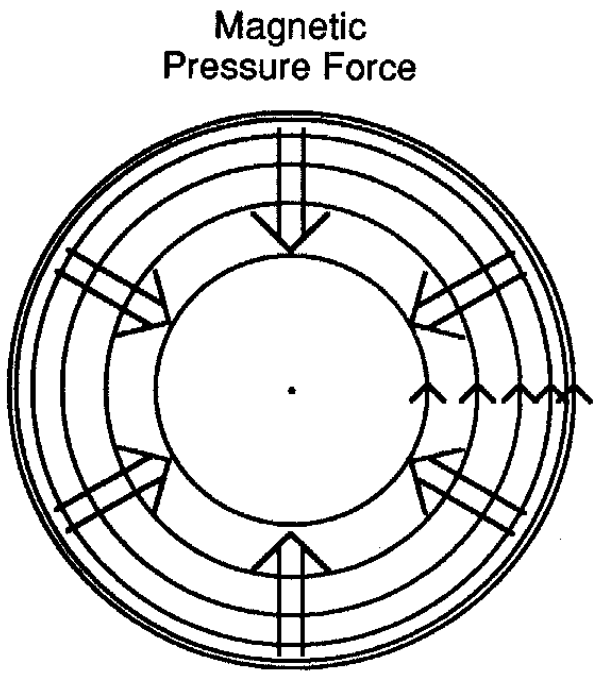
Thus, we have shown that the magnetic force has two distinct effects: the magnetic pressure tries to compress the plasma and produces a net force if B varies with position; the magnetic tension tends to make the field lines shorten themselves like elastic bands and gives a net force if the field lines are curved.

As an example, consider the field with components $B_x = y$, $B_y = x$, with X-type field lines shown in figure 5(*a*). At a point on the positive x-axis, the curvature of the field lines suggest a magnetic tension force to the right, while the fact that the magnetic pressure is increasing (like x^2) away from the origin suggests a magnetic pressure force to the left. However, from the field lines alone, it is not evident which dominates. Now

$$(\boldsymbol{B} \cdot \nabla)\frac{\boldsymbol{B}}{\mu} = \left(y\frac{\partial}{\partial x} + x\frac{\partial}{\partial y}\right)\left(\frac{y}{\mu}\hat{\boldsymbol{x}} + \frac{x}{\mu}\hat{\boldsymbol{y}}\right) = \frac{x}{\mu}\hat{\boldsymbol{x}} + \frac{y}{\mu}\hat{\boldsymbol{y}}$$



(*a*)



(*b*)

Figure 5. Magnetic forces due to the fields (*a*) $\boldsymbol{B} = y\hat{\boldsymbol{x}} + x\hat{\boldsymbol{y}}$ and (*b*) $\boldsymbol{B} = r\hat{\theta}$.

which becomes $x\hat{\boldsymbol{x}}/\mu$ on the x-axis and so does indeed act away form the origin. Also, the magnetic pressure force is

$$-\nabla\left(\frac{B^2}{2\mu}\right) = -\nabla\left(\frac{x^2+y^2}{2\mu}\right) = -\frac{x}{\mu}\hat{\boldsymbol{x}} - \frac{y}{\mu}\hat{\boldsymbol{y}}$$

which becomes $-x\hat{\boldsymbol{x}}/\mu$ on the x-axis and so does act towards the origin. We find therefore that the tension and pressure forces are in precise balance, as they must be since the electric current is

$$\boldsymbol{j} = \frac{1}{\mu}\left(\frac{\partial B_y}{\partial x} - \frac{\partial B_x}{\partial y}\right)\hat{\boldsymbol{z}} = 0$$

and so the Lorentz force $\boldsymbol{j}\times\boldsymbol{B}$ vanishes everywhere.

Also, consider next the field $\boldsymbol{B} = r\hat{\theta}$, for which the field lines are the circles r = constant, becoming more closely spaced as one moves outwards (figure 5(*b*)). Thus, physically the magnetic tension and pressure forces are expected both to act inwards. Mathematically, we find the magnetic pressure force is

$$-\nabla\left(\frac{B^2}{2\mu}\right) = -\nabla\left(\frac{r^2}{2\mu}\right) = -\frac{r}{\mu}\hat{\boldsymbol{r}}$$

which does indeed act inwards. Also, the magnetic tension is

$$(\boldsymbol{B}\cdot\nabla)\frac{\boldsymbol{B}}{\mu} = \left(\frac{B_\theta}{r}\frac{\partial}{\partial\theta}\right)\left(\frac{B_\theta\hat{\boldsymbol{\theta}}}{\mu}\right) = \frac{\partial}{\partial\theta}\left(\frac{r\hat{\boldsymbol{\theta}}}{\mu}\right)$$

and now r/μ does not vary with θ but $\hat{\theta}$ does! In fact $\partial\hat{\theta}/\partial\theta = -\hat{\boldsymbol{r}}$ and so $(\boldsymbol{B}\cdot\nabla)\boldsymbol{B}/\mu = -r\hat{\boldsymbol{r}}/\mu$, which again acts inwards, as expected.

Magnetohydrostatics

Consider the equation of motion when pressure, magnetic and gravitational forces are acting

$$\rho\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = -\nabla p + \boldsymbol{j}\times\boldsymbol{B} + \rho\boldsymbol{g} \tag{11}$$

where

$$\boldsymbol{j} = \nabla\times\boldsymbol{B}/\mu. \tag{12}$$

If L_0, v_0, L_0/v_0 are typical values for the length-scale, plasma velocity and time-scale respectively, the order of magnitude of the current from (12) is $j_0 = B_0/\mu L_0$. Then, in terms of the typical density (ρ_0), pressure (p_0) and magnetic field (B_0), the sizes of each term in equation (11) are $\rho_0 v_0^2/L_0$, p_0/L_0, $B_0^2/\mu L_0$, $\rho_0 g$, respectively.

Now, provided the magnetic term is of the same order as the largest force term, we have force balance if the first term is much smaller than the third, namely

$$v_0^2 \ll \frac{B_0^2}{\mu\rho_0} \equiv v_A^2$$

where v_A is known as the *Alfvén speed*. Then (11) reduces to the equation *for magnetohydrostatic force balance*

$$0 = -\nabla p + \boldsymbol{j}\times\boldsymbol{B} + \rho\boldsymbol{g} \tag{13}$$

where $\boldsymbol{j} = \nabla\times\boldsymbol{B}/\mu$, $\nabla\cdot\boldsymbol{B} = 0$ and $\rho = p/(\mathcal{R}T)$.

In this equation, when gravity is negligible we have magnetostatic balance

$$0 = -\nabla p + \boldsymbol{j}\times\boldsymbol{B} \tag{14}$$

if the fourth term in (11) is much smaller than the third, namely $L_0 \ll B_0^2/(\mu\rho_0 g) = 2H/\beta$, where

$$H = \frac{p_0}{\rho_0 g} = \frac{\mathcal{R}T_0}{g}$$

is the pressure scale-height and

$$\beta = \frac{p_0}{B_0^2/(2\mu)} \tag{15}$$

in the plasma beta, namely the ratio of plasma to magnetic pressure.

In turn, in (14) the magnetic force dominates if $2\beta \ll 1$, and then (14) reduces further to the equation

$$\boldsymbol{j}\times\boldsymbol{B} = \boldsymbol{0} \tag{16}$$

for a FORCE-FREE MAGNETIC FIELD, in which the magnetic field is in equilibrium with itself under a balance between magnetic pressure and magnetic tension forces.

Suppose now that gravity is directed vertically downwards in the negative z-direction ($\boldsymbol{g} = -g\hat{\boldsymbol{z}}$). Then the component of (13) parallel to a particular magnetic field line is $0 = -\mathrm{d}p/\mathrm{d}s - \rho g\cos\theta$, where s is measured along the field, or, since $\mathrm{d}s\cos\theta = \mathrm{d}z$, we have $0 = -\mathrm{d}p/\mathrm{d}z - \rho g$. After putting $\rho = p(\mathcal{R}T)^{-1}$ this becomes

$$\frac{\mathrm{d}p}{\mathrm{d}z} = -p\frac{g}{\mathcal{R}T}$$

which may be integrated to give

$$p = p_0\exp\left(-\int_0^z \frac{g}{\mathcal{R}T}\,\mathrm{d}z\right)$$

where p_0 is the pressure at the base ($z = 0$) of the field line. If the variation ($T(z)$) of the temperature with height is known, this determines the pressure and therefore the density.

If, in particular, the temperature is uniform ($T = T_0$) then

$$p = p_0\,\mathrm{e}^{-z/H}$$

so that the pressure (and density) decrease exponentially with height, with the scale-height H being the vertical distance over which the pressure falls off by a factor e.

Down in the solar photosphere, where $T_0 = 6000$ K, the scale-height is about 150 km or less and so, over for instance a vertical distance of 1.5 Mm, the pressure and density would fall off by a factor of $\mathrm{e}^{10} \approx 20\,000$. By contrast, in the solar corona where $T_0 = 2\times10^6$ K, say, the scale-height is about 100 Mm, and so the density falls off much more slowly. Indeed, for many purposes, in the corona we can neglect the effect of gravity, i.e. when the vertical scales of interest are 100 Mm or less.

Potential fields

If the pressure gradient and gravitational force are negligible, (16) holds and a particular case of interest is when the current vanishes, so that

$$\nabla \times \boldsymbol{B} = \boldsymbol{0} \tag{17}$$

where

$$\nabla \cdot \boldsymbol{B} = \boldsymbol{0}. \tag{18}$$

Equation (17) may be satisfied identically by putting $\boldsymbol{B} = \nabla\psi$ and then (18) gives Laplace's equation

$$\nabla^2\psi = 0.$$

Thus, many of the general results of potential theory may be applied and the magnetic field is said to be current-free or potential.

Magnetic reconnection

MAGNETIC RECONNECTION is a fundamental process in a plasma, whereby the magnetic connectivity of plasma elements changes and magnetic energy is converted into other forms such as heat, kinetic energy and fast-particle energy. It involves a localized breakdown of ideal MHD in a small region due to, for example, resistive effects. It is responsible for many dynamic processes in the universe, such as SOLAR FLARES and GEOMAGNETIC STORMS and probably solar coronal heating (see CORONAL HEATING MECHANISMS).

Magnetic helicity

For a perfectly conducting plasma in a closed volume (V), the MAGNETIC HELICITY is

$$K = \int_V \boldsymbol{A} \cdot \boldsymbol{B}\, \mathrm{d}V$$

where $\boldsymbol{B} = \nabla \times \boldsymbol{A}$, and the state of minimum energy for fixed K is a linear force-free field. K is a measure of the sum of the twist and the linkage of flux tubes. Thus, for two linked tubes

$$K = \Theta_1 F_1^2 + \Theta_2 F_2^2 + 2L F_1 F_2$$

where Θ_1 and Θ_2 are the twists of the two tubes F_1, F_2 their magnetic fluxes and L the linking number. Reconnection can convert linkage helicity to twist helicity, but it produces only a small change in the total helicity in a plasma of large global magnetic Reynolds number.

Magnetohydrodynamic waves and shock waves

In a gas there are sound waves which propagate equally in all directions at the sound speed

$$c_s = \left(\frac{\gamma p_0}{\rho_0}\right)^{1/2}.$$

In a plasma there are also waves, but they are of several types. Waves are very important in the solar atmosphere and throughout the cosmos. For example, they may be seen propagating out of sunspots or away from large solar flares. They are also a prime candidate for heating the solar atmosphere.

In MHD there is an incompressible mode known as the Alfvén wave, which propagates at the Alfvén speed along the magnetic field. Also, there are two compressible modes known as slow and fast magnetoacoustic waves, which propagate slower and faster respectively than the Alfvén speed. These MHD waves have propagation characteristics that depend on the direction of propagation relative to the magnetic field.

Small-amplitude sound waves propagate without change of shape, but when the amplitude is finite the crest can move faster than its trough, causing a progressive steepening. Ultimately, the gradients become so large that dissipation becomes important, and a steady *shock wave* shape may be attained with a balance between the steepening effect of the nonlinear convective term and the broadening effect of dissipation. The dissipation inside the shock front converts the energy being carried by the wave gradually into heat. The effect of the passage of the shock is to compress and heat the gas.

In MHD the slow magnetoacoustic wave can steepen to form a slow-mode shock and the fast wave to form a fast-mode shock.

Magnetohydrodynamic instabilities

Equilibrium magnetic fields in the universe can go sometimes unstable to a wide variety of instabilities. Sometimes the effect is to create fine-scale structure and at other times it is to produce dynamic events such as solar flares and dramatic eruptions from the Sun called SOLAR CORONAL MASS EJECTIONS. The two main ways of analysing stability are by investigating the natural (or normal) modes of variation or by an energy (or variational) method.

The instabilities that commonly occur include: the *Rayleigh–Taylor instability*, when heavy fluid is supported above light fluid; *kink instability* or sausage instability of a magnetic flux tube when its twist is too large; *resistive instability* such as the tearing-mode instability of a current sheet or a sheared structure; convective instability of a plasma that is heated sufficiently from below; and flow instabilities that occur when the shear in a flow is too great (such as the *Kelvin–Helmholtz instability* and in accretion discs the *Balbus–Hawley instability*).

Conclusion

It is important to recognize that magnetohydrodynamics builds on the tools of both fluid dynamics and electromagnetism, but it possesses many new features that are present in neither. Furthermore, it is advisable to build both a physical and mathematical understanding of magnetic field behavior, since they both complement one another and together give a deeper understanding than either alone.

In the following articles, various aspects and applications of MHD theory are developed in detail. In a companion article, Parker describes the key physical

processes involved in LARGE-SCALE PLASMA DYNAMICS. Then basic DYNAMO THEORY for the generation and maintenance of cosmical magnetic fields is developed by Moffatt and in particular for the GEODYNAMO by Proctor and for solar and stellar dynamos by Rosner. Then several important aspects of MHD theory are described, including FORCE-FREE MAGNETIC FIELDS (Low), MAGNETIC HELICITY (Berger) and MHD WAVES (Roberts). The theory for MHD INSTABILITIES is set up by Hood and applied in particular to MAGNETIC BUOYANCY by Hughes and to MHD: MAGNETOCONVECTION by Cattaneo. The key process of MAGNETIC RECONNECTION is reviewed by Schindler and Hörnig and its role in MHD: MAGNETIC RECONNECTION AND TURBULENCE is described by Matthaeus. Finally, two astrophysical environments where MHD plays a crucial role are discussed, namely the MHD OF ACCRETION DISKS by Brandenburg and the MHD OF ASTROPHYSICAL WINDS by Heyvaerts.

Magnetohydrodynamics of Accretion Disks

An ACCRETION DISK is a flat formation of gas and dust rotating about a central object and accreting matter inwards by transporting angular momentum outwards, so that the centrifugal support is gradually removed from the fluid parcels. There are three main classes of accretion disks: (i) disks around accreting compact stars (white dwarfs, neutron stars or black holes) in binary systems, (ii) disks around protostars and (iii) disks around active galactic nuclei. In several cases the existence of disks has been verified observationally with the Hubble Space Telescope. Images can be found at http://www.stsci.edu/pubinfo/pictures.html. An example of an image of a disk around a young stellar object together with an associated jet is given in figure 1.

Accretion disks form because matter generally has angular momentum and therefore cannot fall directly onto the central object. In the disk midplane the gravitational acceleration, GM/R^2, at distance R from the central object of mass M is balanced mainly by the centrifugal acceleration, $\Omega^2 R$. Here G is the gravitational constant and Ω is the angular velocity. Except in a few systems the disk mass is negligible and so this balance leads to the rotation law

$$\Omega(R) = (GM/R^3)^{1/2} \tag{1}$$

which is essentially Kepler's third law. In the vertical direction, i.e. parallel to the rotation axis, gravity is balanced by a pressure gradient, so that the mass is concentrated towards the midplane. There is usually some energy dissipation caused by turbulence and magnetic fields. The heat released during this process can be radiated away at the two disk surfaces. The corresponding removal of rotational energy causes matter gradually to spiral towards the central object. Large-scale fields and winds from the disk surfaces can also remove angular momentum from the disk, and would thus contribute to the accretion mechanism directly.

Accretion disks around young stellar objects are only transient phenomena because they provide essentially just a waiting queue for matter before it can fall onto the central object. The disk will disappear once all the available material has been consumed, which could be after about 10^7 yr in the case of protostellar disks.

Energy conversion in disks

The kinetic and potential energy of accreted matter in the disk is constantly being converted into heat and then radiation by dissipative processes. In disks around neutron stars or white dwarfs the luminosity of the disk can by far exceed the luminosity of the central object. The total orbital energy per unit mass is $\frac{1}{2}(R\Omega)^2 - GM/R = -\frac{1}{2}GM/R$. The mass accretion rate $\dot{M}$ is controlled by the rate of dissipation, giving a disk luminosity of

$$L = \frac{GM\dot{M}}{2R}. \tag{2}$$

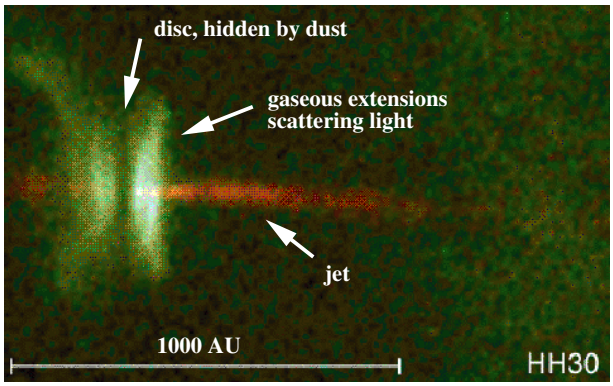

Figure 1. Image of a disk around a young stellar object together with a jet emanating from the disk center along the rotation axis. The length of the horizontal bar is 1.5×10^{11} km. (Adapted from Burrows *et al* (1996).)

This formula is essentially independent of the efficiency of the mechanism that accomplishes the energy conversion. If the central object is a white dwarf or a neutron star there will be a boundary layer at the star's surface, where as much energy can be dissipated as in the disk itself.

Equation (2) assumes that all the heat is radiated away instantaneously. In recent years it has been found that in some disks the luminosity is much lower, because significant amounts of energy can be advected radially towards the center. If the central object is a black hole the advected energy may never appear as radiation.

In the case of a black hole at the center the disk can extend down to three Schwarzschild radii, i.e. $r_{\min} = 6GM/c^2$, or less in the case of rotating black holes (c is the speed of light). The energy that is released by an accreted mass m is $\frac{1}{2}GMm/r_{\min}$. Using for $r_{\min}$ the expression above, this becomes ηmc^2, where $\eta \approx 0.1$ is an efficiency factor relative to the maximum possible value permitted by Einstein's famous formula $E = mc^2$. Note that the efficiency of hydrogen fusion in stars is only $\eta = 0.007$. For this reason the rate of energy release by accretion, $\eta\dot{M}c^2$, of a disk around a supermassive black hole of 10^8 solar masses with $\dot{M}$ of a few solar masses per year can be as large as 10^{40} W. This is believed to be the mechanism that powers quasars.

The role of magnetic fields

In the absence of turbulence a purely laminar shear motion would be totally insufficient to explain the dissipation and corresponding heat release of real disks. Thus, turbulence is necessary to produce small enough scales where microscopic viscosity and ohmic diffusion can act to dissipate kinetic and magnetic energy into heat.

It has been a long-standing debate as to what causes turbulence in disks. In the absence of magnetic fields differentially rotating disks are unstable when the specific angular momentum, ΩR^2, increases inwards (Rayleigh's criterion). Indeed, purely hydrodynamic mechanisms such as (nonlinear) instabilities and convection have

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

proved unsuccessful so far. Numerical work and theoretical arguments indicate that nonlinear instabilities do not operate in astrophysical disks and that convection produces accretion torques that are probably even of the wrong sign; furthermore, this process would not be self-sustained. For a comprehensive review of those issues see Balbus and Hawley (1998). The issue of purely hydrodynamical instabilities is not fully settled, however, because this would require direct simulations at Reynolds numbers of at least 10 000, which cannot be achieved with present computers.

In the presence of magnetic fields, however, there is a powerful linear instability, the magneto-rotational instability, which prevents the gas flow in the disk from being laminar. In 1991 Balbus and Hawley pointed out its importance in driving turbulence in accretion disks. Their papers have spawned a lot of work attempting to quantify the properties of the resulting turbulence and the related angular momentum transport. The magneto-rotational (or Balbus–Hawley) instability is a consequence of the shear, which causes a destabilization of the slow magnetosonic waves. The instability exists regardless of the orientation of the magnetic field. In the special case of a magnetic field parallel to the rotation axis the instability is axisymmetric.

In the absence of magnetic fields, or when the electrical conductivity is too low to make the magnetic field important, the disk would be purely hydrodynamic, in which case rotation would have a strongly stabilizing effect. Still, variation of the angular velocity in the vertical direction would lead to a linear hydrodynamic instability, but its growth rate is much smaller than that of the magneto-rotational instability. The vertical shear instability could be important if the conductivity is low.

The magneto-rotational instability

The magneto-rotational instability exists already in an incompressible, unstratified fluid that is differentially rotating provided that the shear parameter

$$q \equiv -\partial \ln \Omega / \partial \ln R \tag{3}$$

is positive. For thin accretion disks we have $q = +3/2$; see equation (1). In that case the dispersion relation is

$$\omega^4 - \omega^2(2v_A^2 k^2 + \Omega^2) + v_A^2 k^2 (v_A^2 k^2 - 3\Omega^2) = 0 \tag{4}$$

where $v_A = B/(\mu_0 \rho)^{1/2}$ is the Alfvén speed, B is the vertical field strength, ρ is the unperturbed density, μ_0 is the permeability, k is the wavenumber along the magnetic field and ω is the frequency. There are two solutions for ω^2, an upper branch corresponding to Alfvén waves and a lower branch corresponding to slow magnetosonic waves. The fast magnetosonic waves have been filtered out by the assumption of incompressibility. On the lower branch ω^2 becomes negative when

$$v_A < \sqrt{3}\Omega / k. \tag{5}$$

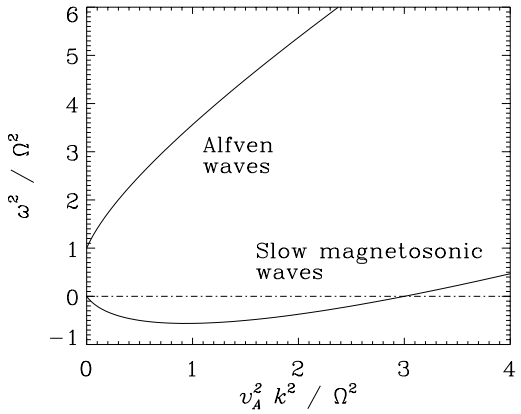

Figure 2. Dispersion relation for slow magnetosonic and Alfvén waves in an incompressible medium. For Alfvén waves ω^2 is always positive. However, for not too large values of k the slow magnetosonic waves become unstable when $v_A^2 k^2 < 3\Omega^2$, so $\omega^2 < 0$, that is ω is imaginary.

In that case ω is purely imaginary and small perturbations grow exponentially with a maximum growth rate

$$\max(\mathrm{Im}\,\omega) = \tfrac{3}{4}\Omega \tag{6}$$

at scale $\ell = 2\pi/k_{\max}$, where

$$k_{\max} \approx \Omega / v_A. \tag{7}$$

It is clear from equation (5) that the instability works only if the field is not too strong. The largest possible field strength depends on the smallest admissible k, i.e. the largest scale available to the system. One such scale would be the disk height.

The disk is formally unstable even in the limit of vanishing magnetic field strength, $v_A \to 0$. However, maximum growth would then occur for perturbations whose scale would become progressively smaller, as given by equation (7). At larger scales the growth of the instability would be so slow that viscous effects would render the instability irrelevant for driving hydromagnetic turbulence.

In figure 2 we have plotted the two branches of the dispersion relation, equation (4), corresponding to slow magnetosonic and Alfvén waves. There are also the fast magnetosonic waves that result if the assumption of incompressibility is relaxed (see Balbus and Hawley 1998). However, when the sound speed c_s is much larger than v_A, the two lower branches are nearly independent of the neglect of the fast magnetosonic branch.

There is a mechanical analogue to the magneto-rotational instability, which can be helpful in understanding the nature of the instability. The following example applies to the nonaxisymmetric case that is relevant in the presence of a toroidal magnetic field. Consider two particles, A and B, on a gravitationally bound orbit around a central object (figure 3). Assume that the two particles have the same distance from the central object but

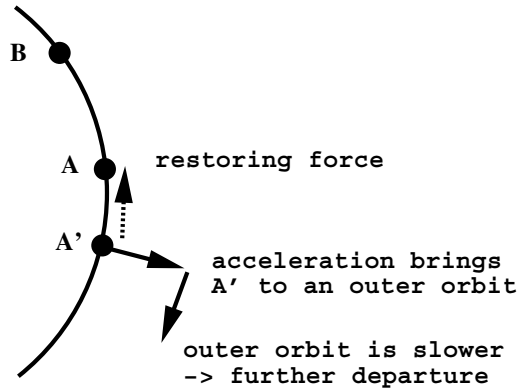

Figure 3. Mechanical analogue of the magneto-rotational instability.

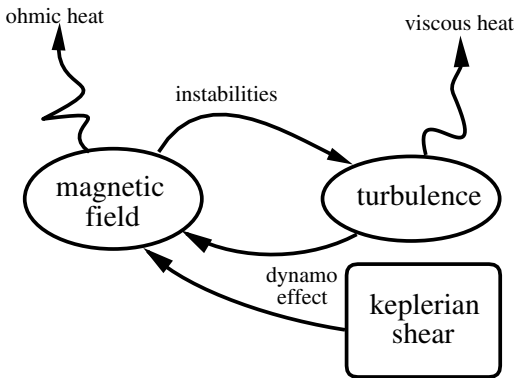

Figure 4. The energy in the Keplerian shear motion is converted into thermal energy via ohmic and viscous heating. Magnetic fields are needed as a catalyst to keep the system turbulent.

are separated azimuthally by a small amount. Interesting behavior occurs when the two particles are coupled elastically. Assume that the particle at position A is perturbed to position A′. The separation between the two particles is then increased and there is a restoring force trying to return the particle to its original position. This accelerates the particle from A′ back towards A. However, this leads to a gain in its angular momentum which then forces the particle onto an outer orbit. There, however, the orbital speed is slower, see equation (1), so the particle will separate from its original position A even further. This is the cause of an instability.

There are some parallels with the phenomenon of tidal disruption of a star passing near a black hole. In that example the restoring force is the gravitational attraction that holds the star together. In the case of the magneto-rotational instability the restoring force is the magnetic tension force. If the field is too strong, however, the fluid parcels stay in their original position, suppressing the instability.

If the conductivity in the disk is poor, there will be significant slippage between the field and the fluid. The magneto-rotational instability ceases when the collision frequency of neutral atoms with ions becomes less than the rotational frequency. This can happen in some parts of protostellar disks which have temperatures below 1000 K. At those temperatures the degree of ionization is very low and the fraction of charge carriers can be as small as 10^{-10}. In the protosolar nebula, out of which the solar system was formed, this may have been the case in a broad ring near the Earth's orbit.

Intrinsic magnetism of disks

It has long been suspected and now been confirmed by local simulations of rotating shear flow that the resulting turbulence is capable of maintaining the field by DYNAMO action. (See Schramkowski and Torkelsson (1996) for a review.) Dynamo action is a process by which kinetic energy can be converted into magnetic energy. In disks the energy comes from the kinetic energy in the shear. Most of it goes into the magnetic field which, in turn, keeps the instability going, thereby feeding the turbulence. All the energy that is removed from the shear is constantly being dissipated (see figure 4). In that sense the magnetic field acts effectively like a catalyst that enables kinetic energy to be tapped from the shear motion and then to be released as heat and radiation via viscous and ohmic heating.

The magnetic fields can contribute directly to exerting a torque that leads to an accretion flow and to angular momentum transport outwards. Any radial field component, B_R, will be sheared out by the differential rotation. This enhances the azimuthal field component, B_ϕ. The resulting torque, which is proportional to the product $B_R B_\phi$, is such that there is an inward mass flow in the disk and an outward transport of angular momentum. If the field was perfectly frozen into the gas (no magnetic diffusion) the field lines would eventually be parallel to the flow and would have no effect.

The strength of the dynamo-supported magnetic field is limited by various nonlinear feedbacks. On the one hand, when the field is too strong the magneto-rotational instability is suppressed, see equation (5), but there are other mechanisms, such as magnetic buoyancy, which can also limit the field strength.

A nondimensional measure for the total stress is

$$\alpha \equiv \langle \rho u_R u_\phi - B_R B_\phi / \mu_0 \rangle / \langle p \rangle \qquad (8)$$

which is found from numerical simulations to be typically between 0.01 and 0.1. Here, $\boldsymbol{u}$ is the velocity, and p is the pressure. The precise value of α depends on the magnetic field strength, which may vary with time. Furthermore, since the gas pressure drops faster with height than the magnetic field, α can increase away from the midplane; see equation (8). However, there are at present no global simulations that include the region far outside the disk, where the field must eventually fall off.

Knowing the value of α the radial disk structure can be calculated in closed form, by neglecting the vertical disk structure. In terms of the accretion rate $\dot{M}$ the vertically

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

integrated disk density, $\Sigma = \int \rho \, dz$, is given as a function of radius by

$$\Sigma \approx 2000 \alpha_{-2}^{-4/5} \dot{M}_{13}^{7/10} M_1^{1/4} R_8^{-3/4} \text{ kg m}^{-2} \quad (9)$$

where $\alpha_{-2} = \alpha/10^{-2}$, $\dot{M}_{13} = \dot{M}/10^{13}$ kg s^{-1}, M_1 is the central mass in solar masses and $R_8 = R/10^8$ m (e.g. Campbell 1997).

The disk structure is not always steady. In fact, in some parameter regimes, for example where ionization and recombination become important, the disk can become viscously unstable and undergo limit cycle oscillations (CATACLYSMIC BINARIES). Similar phenomena are also known to occur in disks around young stars. In that case the steady solution would still be described by an equation similar to equation (9), but with different coefficient and exponents, because of the different radiative processes involved.

External magnetic fields

External magnetic fields are maintained by currents outside the disk, for example by currents in the central object (typically a neutron star or a white dwarf, but not a black hole), or in the environment in which the disk is embedded (molecular cloud or host galaxy).

If the magnetic field comes from a star at the center, angular momentum can be transferred to the star from those parts of the disk whose local angular velocity exceeds the stellar angular velocity. This is the case inside the corotation radius, i.e. the radius where the angular velocity of the disk coincides with that of the star. If the part of the disk inside the corotation radius contains sufficient angular momentum, this process can lead to a noticeable spin-up of the central star itself. Otherwise, if the disk does not extend sufficiently far inside the corotation radius most of the field lines of the star couple with the slowly rotating outer parts of the disk which then leads to spin-down of the star. It is often difficult to say whether spin-up or spin-down will occur; this depends on the field strength and field geometry that results from the presence of a central star with a magnetic field, all of which affect the precise location of the inner radius of the disk. Indeed, there are stars where spin-up and spin-down phases are observed to alternate on a timescale of months and years. This could be explained by changes of the location of the inner edge of the disk.

The star's magnetic field increases sharply towards the star (as r^{-3} for a dipole field) and the strong field in the inner parts causes the disk to disrupt. The precise disruption mechanism and hence the precise location of the inner disk radius are still controversial. Possible mechanisms include a viscous instability of the disk (Campbell 1997) or simply a loss of hydrostatic equilibrium. Somewhere near that radius the field will also become too strong for the magneto-rotational instability to operate; see equation (5). Near the inner edge of the disk gas is thought to be channelled along the stellar magnetic field lines towards the central star.

Outflows and jets

The outer layers, away from the disk midplane, are probably heated by MAGNETIC RECONNECTION (Joule dissipation). This plausibly leads to the formation of a hot CORONA. As in the Sun, this layer can then no longer be in hydrostatic equilibrium and therefore some gas must be blown off continuously in the form of a wind. Large-scale magnetic fields can also directly contribute to accelerating outflows. This may be possible if there is a large-scale poloidal field tilted away from the rotation axis by at least 30°. In that case the component of the centrifugal force along the field will dominate over the corresponding component of the gravity force and so gas can be driven along field lines away from the disk.

At larger distances from the disk surface these outflows are seen to be strongly collimated towards the rotation axis. There is at present no clear consensus as to what causes this collimation into jets (see ASTROPHYSICAL JETS). Perhaps the most plausible mechanism is based on magnetic forces, in particular the radially inward pointing component of the Lorentz force (i.e. the hoop stress), which results from the presence of a strong toroidal field. This toroidal field is partly advected from the disk by a slow wind and partly generated just outside the jet by shearing the poloidal field. Today most models assume an externally maintained magnetic field. It is still unclear whether dynamo-generated magnetic fields can be responsible for the launching and collimation of a jet. Other topics of current research concern the variability and knottedness of jets.

Magnetohydrodynamics of Astrophysical Winds

Stellar mass loss became an issue when Parker (1958) first introduced the concept of the solar wind. Such a thermal wind results from coronal heating processes indirectly associated with the existence of a convection zone, also responsible, with rotation, for the star's dynamo action (see articles on SOLAR WIND: THEORY, CORONAL HEATING MECHANISMS, SOLAR INTERIOR: CONVECTION ZONE and MAGNETOHYDRODYNAMIC WAVES). So, mass loss of this type also exists for a large class of main sequence stars. Magnetized winds affect, by Lorentz torques, the angular momentum budget of the rotating objects from which they emanate. The rotation of solar-type stars at their formation is much larger than that of the Sun, although not close to the break-up velocity (at which the centrifugal force balances gravity at the equator). By this mechanism, a single star emitting an MHD wind progressively spins down. Its rotation-associated activity declines in time, as is in fact observed (see article on SOLAR–STELLAR CONNECTION). Stars of a type earlier than F2 which have no such activity remain fast rotators when aging, as observed. For active stars in synchronized binary systems, such as RS CVn, the loss of spin angular momentum by wind emission is converted into a loss of orbital angular momentum, which, unlike single stars, causes them to spin up and become more active, as observed. Newly born solar-type stars of the T Tauri class rotate typically at only one-tenth of their break-up velocity (Bertout 1989). Some spin-down mechanism must be active during the protostellar accretion phase, probably also due to winds emanating from the star and from the protostellar accretion disk. The structure of MHD winds has been first explored by *a priori* assuming some shape for the flow surfaces (Weber and Davis 1967). Pulsar winds called for relativistic extensions of these studies (Michel,1969 Goldreich and Julian 1970). In the past two decades new objects have been discovered which emit winds which are so strongly directive as to be named jets. Relativistic bulk velocities are reached in some of these flows, associated with active galactic nuclei or galactic micro-quasars (see article on JETS). Most often the jet phenomenon is associated with accretion, i.e. the capture of external material by intense gravitational pull to some central, usually compact, object. These jetting winds raised again the question of the two-dimensional structure of MHD flows and of wind acceleration mechanisms, by MHD or other forces.

Angular momentum and accretion

Accretion cannot proceed as direct fall to the accreting object because the matter to be accreted initially possesses too much angular momentum. In the absence of angular momentum loss, each plasma element would simply orbit the accreting object without ever falling on it. It is crucial to the accretion process that at least part of this gas gets rid of excess angular momentum.

In friction between neighboring orbiting gas elements one gas parcel loses and the other gains angular momentum. The one which loses descends on an orbit closer to the accreting object, while the other recedes to a broader one. Viscosity due to friction between atoms is by far insufficient to achieve observed accretion rates but instabilities in the disk, mediated by a weak magnetic field, have been shown to supply turbulence causing a large enough equivalent viscous effect (Balbus and Hawley 1991). A gaseous turbulent disk orbiting the accreting object forms. In its inner regions matter slowly spirals down to the center (Shakura and Sunyaev 1973) while the disk's outskirts slowly expand as a growing reservoir of angular momentum. Tidal torques from a companion eventually limit this growth.

An alternative possibility is that winds or jets convey the excess angular momentum of accreting matter to infinity. The process is similar to the one which torques down stars which emit a wind.

How are winds and jets propelled?

The solar wind is accelerated by the pressure of the hot solar corona. The innermost regions of some accretion disks may be very hot too and emit a wind that could be made directive by hydrodynamical interaction with an anisotropic environment, such as the disk itself. Flow refraction at oblique radiative shocks could add to this effect for forming bipolar anisotropic outflows (Mellema and Frank 1997), but the most extreme focusing is unlikely to be of a purely hydrodynamic origin.

The intense radiation field in the environment of some of these objects could cause radiative acceleration. For the radiative force on a completely ionized plasma to exceed the gravitational one, the luminosity of the radiating object should exceed a rather high threshold proportional to its mass, the Eddington luminosity. This, however, does not seem to be the actual situation for most active galactic nuclei. Intense radiation could still efficiently boost a leptonic component of the plasma to relativistic bulk velocities in jets where such motions and high-energy radiation are observed. More on this can be read in papers by O'Dell (1981), Dermer and Schlickeiser (1993) and Markowith *et al* (1995).

The Lorentz force density $\vec{j} \times \vec{B}$, $\vec{j}$ being the electric current density and $\vec{B}$ the magnetic field, could very well play a role in plasma acceleration, as discussed below. In relativistic dynamics, ignored here for simplicity, the electric force density should be considered as well.

Stationary, axisymmetric MHD flows

Magnetized plasma winds are often discussed assuming axisymmetry, stationarity and perfect MHD. The basic concepts of MHD are reviewed in the article on MAGNETOHYDRODYNAMICS. If, as is often envisaged, the wind source is an accretion disk, it should be effectively dissipative, for otherwise the magnetic flux threading the disk would be advected with the accreting matter and pile up near the accreting object or in it. The necessary

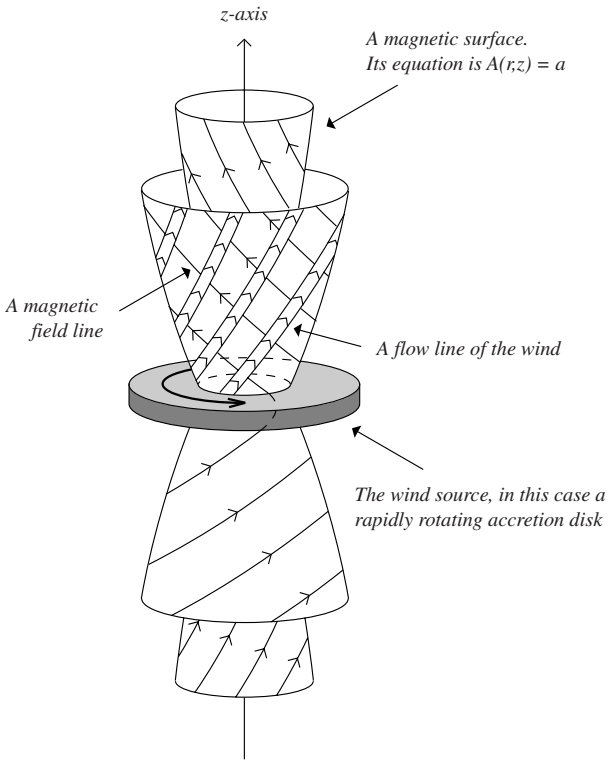

Figure 1. Geometry of a stationary, axisymmetric MHD flow.

magnetic diffusivity could be provided by some form of turbulence or, in partially ionized plasmas, by ambipolar diffusion (Königl 1989).

General properties

In axisymmetric and stationary MHD flows, field lines lie on axially symmetric surfaces, the magnetic surfaces, with equation $A(r, z) = a$ in cylindrical coordinates r, ϕ, z. $A(r, z)$ is the flux through the circle of radius r centered on the axis at position z. Each value of a defines one such surface. Stationarity and perfect MHD imply that the plasma flow lies on magnetic surfaces. This geometry is represented in figure 1. The fluid velocity is the superposition of a field-aligned motion and of a rigid-body rotation of the magnetic surface, at angular velocity $\Omega(a)$. The ratio of mass flux to magnetic flux is a constant, $\alpha(a)$, on a surface a. The motion also conserves the ratios, $E(a)$ and $L(a)$, of total energy and angular momentum flux to mass flux. There is a magnetic contribution to these quantities since the energy flux has a Poynting part, while the azimuthal component of the Lorentz force exerts a torque on the plasma. If a polytropic approximation is made to the actual thermal energy balance, the ratio $P/\rho^\gamma = Q(a)$ is also constant on each magnetic surface. The rates of mass, energy and angular momentum loss in the wind are integrals from pole to equator of $\alpha(a)$, $\alpha(a)E(a)$ and $\alpha(a)L(a)$. It is important to note that the specific angular momentum per escaping particle, $L(a)$, can be significantly larger that the specific angular momentum of the matter at the root of the magnetic surface a on the wind source, situated, say, at an axial distance $r_0(a)$, which is almost exactly Ωr_0^2. The Alfvén radius on magnetic surface a, defined by $r_{\rm A}^2(a) = L(a)/\Omega(a)$, is the effective lever arm of escaping matter, typically the distance up to which the magnetic field remains strong enough to impose corotation of escaping plasma with the wind source. For strong enough magnetization it may be larger than r_0, the loss of angular momentum of the wind source being then dominated by the torques exerted by electric currents induced in the wind. This is how single stars with a convection zone, and thus dynamo action and winds, can be spun down. A calculation of this evolution is, however, difficult because it involves the time history of the star's magnetic flux and of the distribution with a of $r_{\rm A}(a)$. There are two ways by which the magnetic field can accelerate the plasma in the wind zone. One is by centrifuging it away, the other is by the upward push of the magnetic pressure of the azimuthal field.

Centrifugally driven winds

For perfect MHD conditions, magnetic field lines behave like rigid structures wherever the magnetic energy density exceeds the kinetic and rotational energies. Regions on a field line where such conditions are met are closer to the source than the Alfvén point. In a rest frame accompanying the rotation of a given magnetic field line, the constrained plasma elements can glide on the 'rigid' field lines like beads on a wire in response to the centrifugal force and gravitational pull. The combined force density vanishes on the accretion disk surface if the latter is in Keplerian rotation and the net field-aligned force is oriented outwards if the angle of the meridional field with the direction of the axis exceeds 30°. Under these conditions a plasma flow can be centrifugally driven along the field lines threading the accretion disk (Blandford and Payne 1982). An exactly similar process at the surface of a star is not possible because this would imply that it rotates near breakup, but some gas pressure could push the plasma over the initial potential barrier, the flow becoming centrifugally driven further out. It takes adequate plasma conditions in the disk for favorable conditions for such acceleration to be realized at the disk's surface. If the field is too stiff or the magnetic diffusivity too large, the poloidal field lines cannot be sufficiently bent to meet the minimum 'launching angle'. If the field is too flexible, plasma cannot be efficiently centrifuged away. Detailed analysis has shown that, for this whole process to work, the plasma β parameter in the disk should be of order unity, and the disk magnetic Reynolds number based on radius and radial accretion velocity should be much larger than unity (Ferreira and Pelletier 1993; Li 1995). It is not yet known whether such conditions can indeed be achieved.

Coiled spring acceleration

When the magnetic field is not dynamically dominant, inertia bends the field lines backwards to rotation and

an azimuthal field component appears. The vertical component of the associated Lorentz force is opposite to the gradient of B_ϕ^2 and can lift the plasma up if this quantity decreases with altitude. This is the 'plasma gun' force (Contopoulos 1995), which can be described also pictorially as the force exerted by a coiled spring: a field line, which is more 'coiled' where B_ϕ is larger, acts as a locally overtwisted spring which pushes on the plasma to relax its stresses. Since B_ϕ is zero, by symmetry, on the equatorial plane of the disk, this force has an unfavorable sense there, pinching the disk's plasma. Favorable conditions would usually be met further away from the source, past the Alfvén point, where this effect may provide continued acceleration relaying the centrifugal force described above. For the 'coiled spring' force to be effective close to the disk's surface, the Alfvén point must be close to it, which means that the field needs to be relatively weak, as opposed to the situation where centrifugal acceleration operates. Numerical calculations have proved the effectiveness of this process although possibly in an intrinsically time-dependent regime (Shibata and Uchida 1986; Ouyed and Pudritz 1997).

MHD torque and accretion

The Lorentz force has an azimuthal part which exerts a torque on the plasma. When B_z is an even function of z, it acts close to the disk's equatorial plane to decelerate the rotation. The angular momentum extracted from the disk's plasma is transferred to the outflowing wind which brings it to infinity. Plasma ejection thus appears as a means of getting rid of the excess angular momentum of accreting matter, a fraction of it being diverted out for ejection. Accretion and ejection then form together a self-consistent global machine in which the accretion flow causes wind ejection, while the torque exerted by the wind on the disk allows accretion to proceed. This can be achieved at the expense of a minor mass loss if the specific angular momentum of escaping wind material is much greater than the specific angular momentum of accreting material, which implies that the Alfvén radius r_A is much larger than the radial distance r_0 of the foot point of the field line in the disk. Centrifugally driven winds would meet this requirement more easily. The mechanical energy lost by accreting matter in wind-driven accretion, unlike in viscosity-driven accretion, does not reappear on the spot as radiation due to local dissipation but mostly escapes as wind kinetic energy, undetectable until its eventual dissipation at intermediate or terminal shocks.

What focuses jets?

Evidence for focusing

There is considerable direct evidence for focusing of mass ejection from active galactic nuclei as well as from galactic microquasars (see article on JETS). Young stellar objects in the protostellar evolution stage also have anisotropic outflows which come in the form of weakly collimated molecular outflows, with a much faster and more focused central stream visible in optical lines (Mundt 1985) and containing Herbig Haro objects which are cold condensations formed in these flows. Outflows from planetary nebulae also show, in a rather large subclass, considerable evidence for focused outflows (Livio 1997).

The hoop stress

By which physical mechanisms can such winds be turned into well-focused outflows? The extreme focusing observed in jets from active galactic nuclei and similar objects of stellar size calls for some explanation that could be sought in MHD forces. Indeed, one particular component of the Lorentz force, $\vec{j}_z \times \vec{B}_\phi$, which is radial, should have the required sign for focusing, for it can be expressed in terms of the total current $J(r, z)$ through the circle of radius r centered at the point z on the z-axis as $(-\mu_0/2\pi r)Jj_z$, which is indeed negative, hence pinching, if J and j_z are of the same sign. Since j_z is the surface density of J, this must necessarily be so in at least some central part of the flow.

The transfield equation

Assuming stationarity, axisymmetry and perfect MHD the shapes of the magnetic surfaces, and flow surfaces, are determined by the projection of the equation of motion perpendicular to them. The resulting transfield equation (Okamoto 1978) is a partial differential equation for the function $A(r, z)$ which also involves the density $\rho(r, z)$. All other quantities can be eliminated using the first integrals provided by the other MHD equations which integrate once, and so would it be for ρ itself if the Bernoulli equation, expressing conservation of the total specific energy $E(a)$, were explicitly solvable for ρ in terms of $|\nabla A|$ and A. A transfield–Bernoulli system can be established not only in classical MHD but also for special relativistic flows and for flows in a Kerr space–time appropriate for describing general relativistic effects near rotating black holes (Beskin 1997; Camenzind 1986). The transfield equation is of second order, linear in the second-order derivatives of $A(r, z)$ but non-linear in the function and its first derivatives. Its properties depend on the ratio of fluid velocity to characteristic propagation speeds, described in the article on magnetohydrodynamic waves. It is singular at the Alfvén surface, the locus of points where the meridional flow velocity v_P equals the meridional Alfvén speed, at the slow critical surface, the locus where v_P equals the slow-mode speed in its direction, and at the fast critical surface, the locus where v_P equals the fast-mode speed. The latter two surfaces are associated with singularities of the Bernoulli equation, regular solutions of which require special conditions to be satisfied at these surfaces. They determine those first integrals which are not simply given by boundary conditions (Weber and Davis 1967; Heyvaerts and Norman 1989). The character of the second-order derivative part of the equation changes from elliptic to hyperbolic at the cusp surface, from hyperbolic to elliptic at the slow surface and from elliptic to hyperbolic again at the fast surface. In each hyperbolic region, a double set of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

characteristics can be defined in the meridian plane. It has been shown that one such set has a limiting characteristic, a line to which characteristics of the considered family become tangent. The limiting characteristics represent the border of one region of the hyperbolic domain which cannot communicate with the other one by the considered mode. In particular, the fast limiting characteristic surface, not the fast critical surface, is the boundary at which MHD influence of the downstream regions on the upstream ones is shut off.

Asymptotics

The asymptotics of MHD flow, as expressed by the transfield–Bernoulli system, must be studied to see whether indeed the hoop stress causes its progressive alignment with the polar axis. General exact results have been obtained for polytropic flows (Heyvaerts and Norman 1989). An upper bound on the value of $r|\nabla A|$ in the asymptotic domain is obtained from the obvious requirement that the Poynting flux cannot exceed the total energy flux, which has been used to prove that, as r approaches infinity following a magnetic surface, z/r can only approach a non-zero limit or diverge. Far from the polar axis in the asymptotic domain the potentially dominant force perpendicular to magnetic surfaces is the hoop stress, except in the vicinity of exceptional magnetic surfaces where it must vanish and can therefore not dominate over other forces (Heyvaerts and Norman 1997). The asymptotic form of the transfield equation simply reduces to the statement that, except in thin boundary layers, the hoop stress vanishes. Between these boundary layers, the total asymptotic meridional electric current enclosed in the magnetic surface, $J_\infty(a)$, becomes a constant J_∞ independent of a, implying a vanishing meridional current density. If J_∞ is zero the quantity z/r diverges following magnetic surfaces which asymptotically become nested paraboloids. If, on the other hand, J_∞ is non-zero, no current can flow between pairs of magnetic surfaces on which r can approach infinity. It must flow in some central core consisting of asymptotically cylindrical magnetic surfaces on which r remains finite. The current which reaches infinity in this peri-axial core returns to the wind source through one of the boundary layers forming around those magnetic surfaces on which the meridional field, and therefore also the azimuthal field which is derived by inertial bending from it, vanishes. For a dipolar type of symmetry, the equatorial plane is one such exceptional surface. At precisely these surfaces, the hoop stress vanishes while it competes with opposing forces, such as pressure, in their close neighborhood. Such regions have the structure of a sheet pinch, as observed in the solar wind (Thomas and Smith 1981). It then seems that hoop stresses indeed have the potential to focus efficiently the rotating plasma stream and to turn asymptotically the wind into a very directive jet. This idea is also supported by numerical simulations (Sakurai 1985; Ustyugova *et al* 1995) and exact analytical solutions for several different types of self-similar flow (Blandford and Payne 1982; Chan and Henriksen 1980; Tsinganos and Sauty 1992).

Stability issues

Numerical studies have revealed that the flow regime may in fact not be stationary at all, even when the mass inflow and its rotation are kept constant at the boundary of the computing domain. Ouyed and Pudritz (1997) have shown examples of such behavior for flows propelled by the toroidal field coiling. When the back-reaction of angular momentum extraction on the wind source is taken into account, the system has been found to enter an unstable collapse behavior (Matsumoto *et al* 1996). Therefore the question of stability of such flows is particularly relevant.

Axisymmetric MHD wind flows exhibit shear motions and carry electric currents, features which are known to be potential sources of instabilities (see the article on MAGNETOHYDRODYNAMIC INSTABILITIES). This important issue has been addressed up to now in simplified geometries. Differential axial motions could drive Kelvin Helmholtz (KH) instabilities, causing friction and mixing between the focused wind and the neighboring medium. The linear stability of different geometries to this type of perturbation has been rather comprehensively discussed (Birkinshaw 1991), also with an axial uniform magnetic field. Body modes, which affect the whole plasma in the jetting wind, appear to be typical of these supersonic flows and are found to be unstable on a length-scale of order a Mach number of times the jet diameter. High density in the fast-jetting wind or a strong axial field reduce the instability which may even be quenched for small enough β parameters. In current-carrying jetting winds, MHD instabilities, such as the kink one, are likely to develop because the toroidal component tends to grow much larger than the poloidal one and the Kruskal–Shafranoff instability criterion, that the field coils more than one turn about the axis, is easily satisfied even on a relatively short length along the axis. The growth rates of these modes depend on the radial current profile and can be smaller than (Appl and Camenzind 1992) or comparable with those of KH modes. However, the most significant issue concerning instabilities is their non-linear evolution. It may either lead to small-scale turbulence, giving rise to an effectively dissipative flow which may still retain its global organized character, or cause a large-scale change of the fluid motion. It appears that the KH instability of a magnetized medium tends to smooth out the axial velocity profile forming a turbulent transition layer around the jetting wind (Malagoli *et al* 1996; Min 1997) and that reconnection phenomena take place in this layer, leading to dynamical alignment between field and flow vectors (Jones *et al* 1997). It is suspected that the development of the kink MHD mode would affect the efficiency of the confinement by the hoop stress forces, having the effect of limiting the ratio of the toroidal to poloidal field to a value of a few (Eichler 1993). Exactly how much depends on the elastic current profile. This would induce effective dissipation, the energy that would be otherwise stored in the form of azimuthal fields being ultimately transformed into pressure which opposes efficient collimation by the

hoop stress. The poloidal field could then become, in the wind acceleration zone, the most significant agent for collimation which would then be ballistically conserved (Spruit *et al* 1997).

Magnetohydrodynamics: Magnetic Reconnection and Turbulence

Magnetic reconnection is a distinctive dynamical phenomena by which neighboring parcels of magnetized plasma communicate with one another. It is thought to to be important in the dynamics of SOLAR FLARES, and in the magnetopause and tail regions of the magnetosphere (see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE; GEOMAGNETIC TAIL). Reconnection is also thought to be an important element of low frequency plasma turbulence in the SOLAR WIND, the interstellar medium and in other astrophysical plasmas. Reconnection may influence heating, plasma flows and transport of charged particles including COSMIC RAYS.

Examples of MAGNETIC RECONNECTION are typically portrayed in highly idealized contexts. For example, special assumptions are made regarding the choice of a model for plasma dynamics, e.g. MAGNETOHYDRODYNAMICS (MHD), as well as imposition of steady-state conditions. Other assumptions are often made regarding geometrical symmetries, including reduction to a two-dimensional (2D) model, or assumption of reflectional symmetry in quadrants about the X-type NEUTRAL POINT around which reconnection activity is centered. All of these are perfectly reasonable special cases to be employed in demonstrations of the essential physics of reconnection. However, reconnection can also occur in situations that are unsteady in time, and that are much less ordered than in the simplest models. Fluctuations in MHD variables (see SOLAR WIND TURBULENCE) are likely to occur in relatively messy 'real' scenarios that involve reconnection, and can be expected to have significant effects on the reconnection process. Reconnection occurs readily as one facet of complex MHD activity, and it appears to be an essential feature of MHD turbulence.

Models and broad definition

The traditional 2D models of reconnection (Sweet–Parker and Petschek models) describe a set of dynamical phenomena that occur when blobs of plasma containing oppositely directed magnetic field $\boldsymbol{B}$ are either pressed together or encounter each other spontaneously. Since there is a region of low field strength between the blobs, there is an excess magnetic pressure outside the central region that drives plasma towards the boundary between the blobs, at a point determined by a perturbation. This pressure causes the plasma to flow toward the center with a speed $V_{\rm in}$ as illustrated in figure 1. If the plasma has high electrical conductivity, magnetic flux conservation implies that steep gradients of magnetic field are produced. In the standard models the process is assumed to be laminar and steady, in which case the approach of the blobs is limited by the rate at which magnetic flux can diffuse across a thin region, called the reconnection zone. This causes annihilation of matching contributions from positive and negative flux regions. This merging process relaxes the magnetic flux constraint and allows the field lines to 'break' and 'reconnect'. New magnetic islands form as plasma flows outward at a speed $V_{\rm out}$ towards the region between the blobs, sometimes called the weak field region. The flow pattern is illustrated in figure 1. The key features of the traditional laminar picture of reconnection are: (a) the approach of blobs containing opposite-signed field, (b) production of steep magnetic gradients, i.e. high electric current densities, between the blobs, (c) inflow limited by magnetic diffusivity, and (d) steady outflow at $V_{\rm out} = V_{\rm A}$ the Alfvén speed computed in the inflow or strong-field regions.

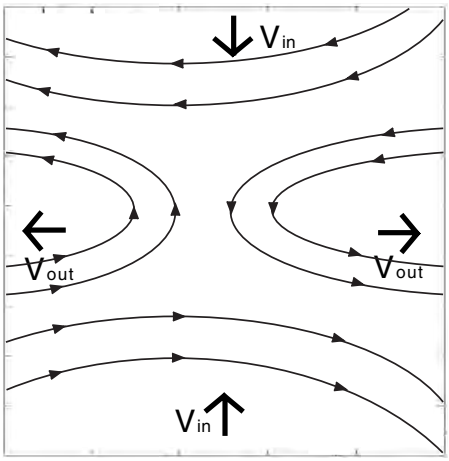

Figure 1. Diagram of two-dimensional magnetic fields in a reconnection configuration. The central reconnection zone contains an X-type neutral point. Inflow towards the reconnection zone at speed $V_{\rm in}$ is suggested by arrows in the strong field regions at the top and bottom. Outflow at $V_{\rm out}$ in weak field regions is also suggested.

Change in topology of field lines is an important by-product of the process. The rate at which topology change occurs, and the rate of Ohmic heating in the reconnection zone, is limited by the rate at which diffusivity can act to relax the limitations of flux conservation.

Most of the essential features of the traditional laminar reconnection picture remain useful in three dimensions, and when turbulent fluctuations are present. However, when reconnection is part of a complex MHD flow, carefully controlled smooth conditions far from the reconnection zone are not relevant any longer. The process may not commence from an equilibrium as is often assumed in reconnection models that invoke linear instabilities such as the tearing mode. In addition, there are many additional possibilities for types of encounters of plasma blobs in three dimensions, so a more general characterization of reconnection is needed. A widely accepted definition is that magnetic reconnection occurs in a plasma whenever an electric field $E_{\parallel}$ is present along a magnetic separator, that is, along a line of intersection of two separatrix surfaces that divide space into different magnetic cells. The separator is commonly referred to as the reconnection line, the X-line or the null line. This definition is useful for both laminar and turbulent models of reconnection.

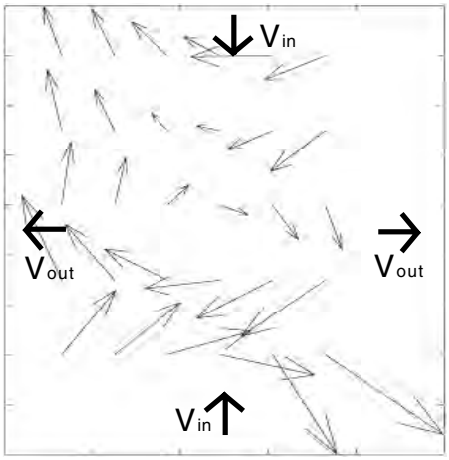

Figure 2. Map of magnetic field vectors near an active reconnection zone in the SSX experiment. Arrow length is proportional to local field strength, with longer arrows ≈1 kG. The Alfvén speed is $\approx 10^7$ cm s^{-1}. Although there is an overall X-type topology, there is evidence for multiple X-points (and at least one small island or 'bubble') near the reconnection zone. (Courtesy of M Brown and the SSX experimental team.)

Turbulent magnetic reconnection

The idealized constructs of smooth and steady magnetic islands undergoing laminar reconnection are easily extended to allow less symmetric and more active configurations. Figure 1 was intentionally constructed to be not quite fully symmetric. Simulations of MHD indicate that these types of magnetic configurations tend to experience complex undulations, involving non-steady induced electric fields that can be quite large compared with the $E_\parallel$ expected from laminar reconnection models. Fluctuations in the large-scale reconnection fields can vary in space and time in accord with the MHD equations, producing broad-band turbulence in and around the region of reconnection activity. In more complex cases in which reconnection activity is expected to occur, it may exhibit much more complex properties than in its laminar form. The reconnection geometry becomes non-steady and distorted.

Figure 2 shows an example of what is perhaps a more realistic reconnection geometry, using data taken from the SSX spheromak laboratory experiment at Swarthmore College. In SSX, two blobs of MHD scale plasma, or plasmoids, encounter each other under controlled, but not extremely symmetric or steady conditions. Experimental diagnostics indicate that reconnection occurs. Characteristic flows are detected, as suggested in figure 2, as well as changes in magnetic topology.

It may be quite a bit easier in astrophysical contexts for reconnection to arise in the presence of fluctuations than it would be in their absence. Distinctive effects that might be expected in a turbulent reconnection scenario include the possible production of multiple X-type neutral points in the reconnection zone, or the production of steep gradients and broadband fluctuations through a spectral cascade.

MHD turbulence

There is a strong similarity between MHD equations and the equations of hydrodynamics. Thus one expects that the complex dynamical motions associated with fluid turbulence at high Reynolds numbers should have a counterpart in the behavior of the fluid MHD plasma. In fact, observations of plasmas in the corona, the interstellar medium and the solar wind, as well as many laboratory plasma devices, bear out this expectation. MHD turbulence is also studied using accurate numerical simulation methods up to large-scale Reynolds numbers of a few thousand. A Reynolds number, usually defined as $R = LV_0/\nu$, with L and V_0 respectively the characteristic length and speed, and ν the kinematic viscosity, is a measure of the typical strength of nonlinear effects compared with dissipative effects. When R is large, complex nonlinear motions give rise to the irregular motions associated with turbulence, and a cascade of energy from large to small scales. In MHD the magnetic Reynolds number, $R_m = V_0 L/\eta$, for resistivity η, should be large as well, if the turbulence is to involve magnetic fluctuations as well as velocity fluctuations.

An interesting analogy exists between the dynamical behavior of the magnetic field in MHD and of the vorticity $\vec{\Omega} = \nabla \times \boldsymbol{v}$. The magnetic field obeys the induction equation. The equation for the evolution of the vorticity can be obtained formally from the induction equation under the replacements $\boldsymbol{B} \rightarrow \vec{\Omega}$ and $\eta \rightarrow \nu$. Thus the dynamics of the magnetic field in MHD are similar to the dynamics of the vorticity in ordinary hydrodynamics. The analogy is not perfect because the vorticity is related to the velocity $\boldsymbol{v}$ which appears in its dynamical equation, whereas the magnetic field is not related to the velocity $\boldsymbol{v}$ that appears in the right-hand side of its dynamical equation.

This analogy is particularly interesting from the point if view of magnetic reconnection, because it points towards an analogy with the phenomenon of 'vortex reconnection'. Vortex lines must 'break and reconnect' in order that vortices interact and merge. The vortex merger that results from this process is familiar in stirred cups of coffee, and in weather maps, and is associated with the production of large eddies from small ones. This occurs at the same time as smaller eddies are generated from large ones due to the cascade of energy to small scales.

MHD simulations indicate that reconnection, and associated magnetic flux tube merger or coalescence, are very typical in MHD turbulence. Figure 3 shows plots of magnetic field lines and intensity plots of electric current density for a simulation of two-dimensional MHD turbulence, shown at a time $t = 6$ characteristic times from the randomly generated initial state. It is apparent that of the many close magnetic islands in the top panel, many pairs are experiencing reconnection and merger. The current intensity shows the signature of

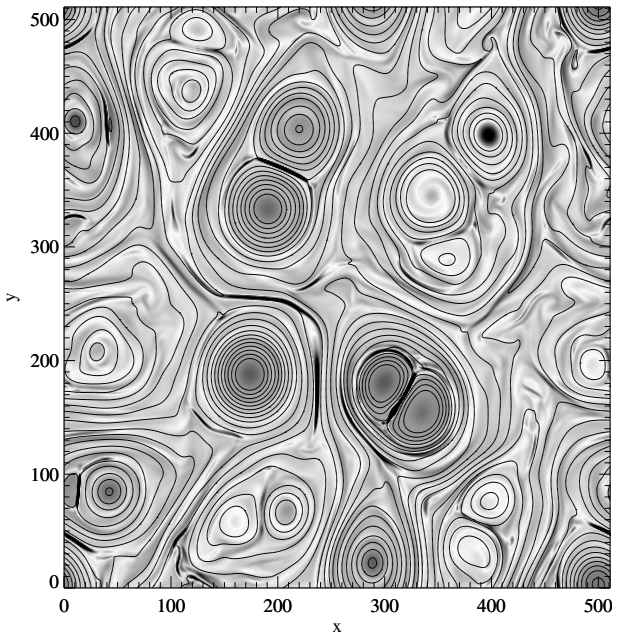

Figure 3. Magnetic field lines (contour lines) and electric current density (gray intensity scale) for a spectral method simulation of two-dimensional MHD turbulence at $R_m = 2000$, at time $t = 4$ nonlinear times from the initial state. Reconnection zones have formed between a number of adjacent islands that are coalescing, triggering localized non-steady reconnection activity throughout the periodic simulation box. Reconnection is an essential feature of the cascade process in MHD turbulence.

intense filamentation of current at X-type neutral points in the center of small, non-steady reconnection zones lying between the merging islands. Although not shown, the plasma velocity near these X-points also has the characteristic reconnection pattern of inflow and outflow near these regions, but the flow is very irregular and turbulent in general.

Turbulent dissipation and coherent structures

The effects associated with turbulence near a reconnection zone lead to a higher effective resistivity, called a turbulent resistivity or turbulent magnetic diffusivity. This is a property of MHD turbulence in general and is directly related to the analogous phenomenon of turbulent viscosity in hydrodynamic turbulence. (Note that turbulent resistivity may be supplemented by so-called *anomalous resistivity* associated with plasma instabilities of non-fluid, kinetic origin.) In general turbulence is expected to increase both the rate of reconnection and the rate of energy dissipation relative to estimates based upon laminar theories. Turbulence near an active reconnection zone also induces non-steady fluctuations in the measurable MHD variables, rendering more complex the plasma flow, electric field and magnetic field associated with reconnection.

As a consequence of turbulent reconnection, energy is directly cascaded to small scales, producing turbulent heating through a direct cascade. At the same time, larger magnetic field structures are produced through merger of magnetic islands, sometimes called an inverse cascade. The transfer of a significant amount of magnetic excitation to large scales is sometimes discussed in terms of negative temperature statistical mechanics, or the phenomenon of 'self-organization.' The characteristic structures of MHD reconnection, magnetic islands at the larger scales, and electric current filaments at small scales, can be thought of as preferred MHD coherent structures, and are possible sources of intermittency in plasma dynamics at MHD fluid scales.

Magnetohydrodynamics: Magnetoconvection

Convective motions occur naturally in layers of fluid heated from below. In the Sun turbulent convection carries most of the luminosity over the outer 30% by radius of the star. Because of the high electrical conductivity of the solar plasma convective motions interact with magnetic fields. The modified form of convection that occurs in a conducting fluid when externally imposed magnetic fields are present is referred to as magnetoconvection. The interaction of convection and magnetic fields is believed to be responsible for such diverse phenomena as the darkness of SUNSPOTS, the oscillation of SUNSPOT PENUMBRAE, the formation of the magnetic network (see CHROMOSPHERE: NETWORK), and the amplification of magnetic fields in SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES.

The nature of the interaction between convective motions and magnetic fields depends on several physical parameters. Of particular importance is the strength of magnetic forces relative to the strength of the convective driving due to buoyancy. If magnetic forces are strong the convection can be greatly inhibited or in extreme cases even suppressed. If, on the other hand, magnetic forces are weak, the magnetic field can be strongly distorted by the motions. It is customary to organize the study of magnetoconvection into different regimes defined by the vigour of the resulting motions. The *linear regime* studies the conditions under which buoyancy forces just overcome magnetic forces and the convection develops to infinitesimal amplitude. In the *weakly nonlinear regime* the amplitude of the convection is assumed to be small but still of sufficient magnitude to lead to appreciable nonlinear effects. In the *fully nonlinear regime* the motions are vigorous, possibly even turbulent, and there is a strong interaction between the convection and magnetic fields.

The linear regime

The conditions under which infinitesimal convection develops can be simply estimated by considering the forces acting on a fluid parcel displaced vertically a small distance δz from its equilibrium position in a superadiabatic atmosphere. A small fluid element will experience a destabilizing buoyancy force of magnitude $g\rho\alpha\Delta\delta z$, where g is the acceleration due to gravity, ρ the fluid density, α the coefficient of thermal expansion and Δ the local temperature gradient. If the displacement causes a distortion of wavelength ℓ in an otherwise uniform ambient magnetic field, there will be a magnetic restoring force of magnitude $B^2\delta z/\mu_0\ell^2$, where B is the field intensity and μ_0 is the magnetic permeability. If the buoyancy force exceeds the restoring force the fluid element once displaced will continue to move and a state of overturning convection will develop. If, on the other hand, the magnetic restoring force is stronger than buoyancy the parcel will eventually return to its initial equilibrium position. Both buoyancy and magnetic forces are weakened by diffusion at rates proportional to κ, the thermal diffusivity, and η, the magnetic diffusivity. If $\kappa > \eta$, buoyancy forces will be weakened more rapidly than magnetic forces and the fluid parcel will return to its equilibrium position with a greater velocity than that with which it left it, thus causing the fluid element to overshoot. In this case the convection develops as a growing oscillation. This form of instability, often called *overstability*, is characteristic of a broad class of systems—*doubly diffusive systems*—where stabilizing and restoring agents diffuse at different rates.

Some of these ideas can be made more quantitative by considering the development of convection in a layer of Boussinesq fluid (Chandrasekhar 1961). The strength of the destabilizing buoyancy force and the stabilizing magnetic force can measured by the *Rayleigh* number R and the *Chandrasekhar* number Q defined by

$$R = \frac{g\alpha\Delta d^4}{\kappa\nu} \quad \text{and} \quad Q = \frac{B_0^2 d^2}{\mu_0\rho\eta\nu} \tag{1}$$

where ν is the kinematic viscosity and d is the vertical extent of the layer. Overturning convection develops when the Rayleigh number exceed a critical value $R^{(e)}$ given by

$$R^{(e)} = R_0 + C_1 Q \tag{2}$$

where R_0 is the critical Rayleigh number for the onset of convection in the absence of magnetic effects and C_1 is a constant that depends on boundary conditions and on the geometry of the system. As we mentioned earlier, if $\eta < \kappa$ overstability is also possible provided the magnetic field is strong enough. The critical Rayleigh number for the onset of growing oscillations has the form

$$R^{(o)} = R_0(1 + C_2) + C_3 Q \tag{3}$$

where the constants C_2 and C_3 depend as before on boundary conditions and geometry, but now also on the diffusivities. In most cases $R^{(o)} \leq R^{(e)}$ so that overstability, if possible, is the first type of instability to develop in a fluid layer as the temperature gradient is gradually increased.

The weakly nonlinear regime

The weakly nonlinear regime describes magnetoconvection when the amplitude of the motions is small but finite. The existence of both overturning and oscillatory forms of convection gives rise to a rich and complex set of possible dynamical behaviors. The primary objective of weakly nonlinear theory is to classify these possibilities in terms of *amplitude equations* and their associated *bifurcation diagrams* (see, for instance, Guckenheimer and Holmes 1983).

The simplest type of amplitude equation describes the behavior of small amplitude solutions when the *bifurcation parameter*, for instance the Rayleigh number, is near its critical value for the onset of overturning convection. The dynamical behavior for typical initial conditions can be described by

$$\dot{a} = \varepsilon a + \gamma a^3 \tag{4}$$

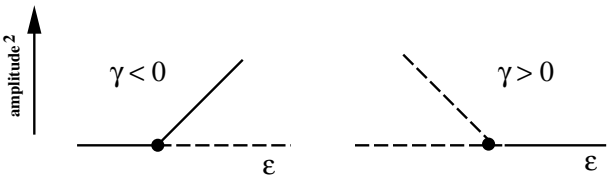

Figure 1. Bifurcation diagram describing the behavior of small amplitude solutions. The ordinate measures the (square) of the amplitude of the solutions, the abscissa the magnitude of the bifurcation parameter. Solid and dashed lines correspond to stable and unstable solutions respectively. $\varepsilon = 0$ is a bifurcation point where branches of solutions are created or destroyed.

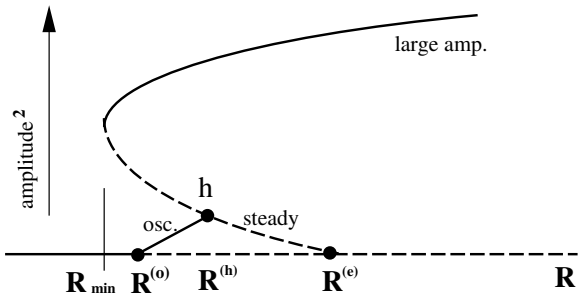

Figure 2. Bifurcation diagram describing the relationship between various branches of solutions. Solid and dashed lines correspond to stable and unstable solutions respectively.

where $\varepsilon = (R - R^{(e)})/R^{(e)}$. With this notation $\varepsilon = 0$ corresponds to a bifurcation point where branches of solutions are either created or destroyed. Here γ depends on the physical parameters specifying the problem and determines the stability of these solutions. If $\gamma < 0$ small amplitude solutions are *stable* and weak initial conditions develop into convective motions with a characteristic amplitude of $\sqrt{\varepsilon/|\gamma|}$. If $\gamma > 0$ small amplitude solutions are *unstable* and weak initial conditions develop to large amplitude. These two cases are represented schematically by the two bifurcation diagrams in figure 1.

More complicated diagrams can be used to represent more complex situations. For instance, the interplay between overturning and oscillatory convection is described by the diagram in figure 2. In this case the static solution (no motion) becomes unstable to oscillatory convection at $R = R^{(o)}$. A branch of unstable overturning convection is destroyed at $R = R^{(e)}$ so that no small amplitude solutions exist for $R > R^{(e)}$. For $R_{\min} \le R \le R^{(o)}$ convection is possible at large but not at small amplitude. As R approaches $R^{(h)}$ the period of the oscillations increases, eventually to become infinite at $R = R^{(h)}$ where the branch of oscillatory solutions collides with the unstable branch of overturning convection. In the vicinity of such points, called *homoclinic points*, solutions can become aperiodic and even chaotic. Other complex dynamical behavior is possible in (horizontally) unbounded domains where the possibility of oscillatory convection leads to solutions in the form of traveling, modulated and pulsating waves.

All these different dynamical possibilities can be described by amplitude equations analogous to, but in general more complex than, (4) (see, for instance, Proctor and Weiss 1982). Formally such equations are only valid when the amplitude of the motion is small, but in many circumstances the predictions of weakly nonlinear theory appear to remain qualitatively correct even when the solutions grow to larger amplitudes. Thus weakly nonlinear theory is often used as a starting point for the systematic study of magnetoconvection in the fully nonlinear regime.

The fully nonlinear regime

The study of the interaction of large amplitude convection with an externally imposed magnetic field divides naturally into two approaches, *kinematic* and *dynamical*. Kinematic theory can be regarded as the limiting case of magnetoconvection for very weak fields. In this limit the Lorentz force can be neglected and the momentum equation decouples from the induction equation. It is then possible to study the induction equation alone for prescribed velocity fields. In the dynamical regime the Lorentz force is important and the induction and momentum equations must be solved simultaneously. Because of the difficulties in obtaining analytical solutions in this regime, dynamical theory has particularly benefited from numerical work.

The most important parameter in kinematic theory is the *magnetic Reynolds number*, $R_{\rm m} = Ud/\eta$, where U is a characteristic amplitude of the velocity. It measures the relative efficiencies of convective to diffusive processes, i.e. the time it takes to diffuse the magnetic field over a distance d divided by the time it takes to *advect* the magnetic field over the same distance. The magnetic Reynolds number is huge in most astrophysical circumstances.

The simplest kinematic problem considers the structure of a unidirectional field near a stagnation point flow. If the velocity is axisymmetric and given in cylindrical coordinates (r, z) by the stream function $\Phi(r, z) = Ur^2 z$ then the steady-state magnetic field has a Gaussian profile of the form

$$B_z(r) = B^* \exp(-\tfrac{1}{2} R_{\rm m} r^2) \qquad B^* = \tfrac{1}{2} B_0 R_{\rm m} \qquad (5)$$

where B_0 is the amplitude of an initial uniform field. This shows that the steady state is determined by a balance between advection and diffusion which occurs when the magnetic field is concentrated on structures with characteristic scale of order $R_{\rm m}^{-1/2}$. More realistic calculations show that in general the magnetic field is amplified by straining motions and expelled from regions of closed circulation.

The above example shows that within kinematic theory magnetic fields can be amplified arbitrarily provided $R_{\rm m}$ is arbitrarily large. In a realistic situation one expects an eventual breakdown of the kinematic assumption and a modification of the velocity due to the action of the Lorentz force. Of direct physical interest

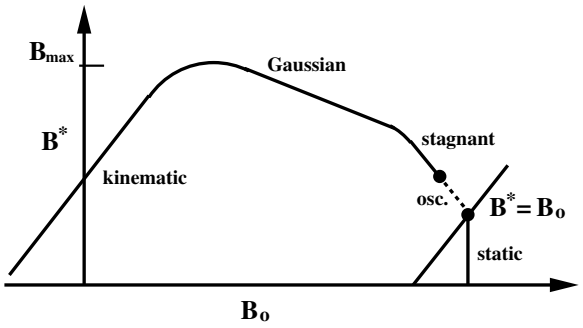

Figure 3. Limits of kinematic amplification. Peak field B^* as a function of initial filed B_0. After Galloway and Moore (1979).

is the determination of the strongest field that can be obtained by convective amplification. In particular, how it compares with an equipartition field, i.e. one whose energy density is comparable to the kinetic energy density. For very weak initial fields the above example indicates that the maximum field strength $B^* \approx B_0 R_\mathrm{m}$ for a nearly axisymmetric configuration. For very strong initial fields linear theory predicts that the convection becomes suppressed, in which case $B^* = B_0$. It is reasonable to assume that the maximum value is obtained for some intermediate value of B_0.

We envisage a sequence of experiments where convection at a fixed Rayleigh number develops in the presence of an initially uniform field of strength B_0. In each experiment B^* is the maximum field strength obtained in the final steady or statistically stationary state. The behavior of B^* as a function of B_0 is shown schematically in figure 3. For weak initial fields B^* increases linearly with B_0, the slope of the line being precisely R_m. Eventually the curve turns over when the vorticity generated by magnetic curvature forces becomes comparable to the vorticity generated by horizontal temperature gradients. At this point B^* attains its maximum value B_max given by

$$B^2_\mathrm{max} \approx \frac{U^2}{\log(R_\mathrm{m})}(\nu/\eta). \qquad (6)$$

To the right of the peak B^* decreases slowly with B_0 and the magnetic field profile remains approximately Gaussian. For stronger initial fields the convection is no longer capable of confining the magnetic field and B^* decreases more rapidly with B_0. If B_0 is increased further there is a transition to oscillatory convection terminating with the eventual suppression of the motions. Clearly the above considerations suggest that convective motions can indeed amplify magnetic fields to values exceeding the equipartition strength U provided that the ratio ν/η is sufficiently large.

If compressibility becomes important the above arguments must be modified. In particular, another critical field strength B_ev must be considered corresponding to a magnetic field whose pressure is comparable to the thermodynamic pressure of the ambient fluid. The significance of B_ev can be appreciated by noting that an isolated flux tube of this strength in thermal and mechanical equilibrium with its surroundings must be *evacuated*. There is substantial numerical evidence that partially evacuated flux structures can indeed be generated by convective processes in strongly stratified layers. It is as yet unclear whether the extreme case of a completely empty tube can be maintained by convection.

Magnetosphere of Earth: Bow Shock

The bow shock (figure 1) is the nonlinear wave which stands in the SOLAR WIND flow upstream of the Earth's magnetosphere, at which the solar wind plasma is heated and decelerated in preparation for diversion around the magnetosphere. The dissipation processes at the shock depend on the properties of a collisionless plasma and lead to a rich range of energetic particles and plasma waves.

Why and where?

In an ordinary gas, a shock wave forms when an obstacle is placed in a flow which is supersonic, i.e. the relative speed between flow and obstacle is greater than the sound speed. For example, a supersonic aircraft has an associated shock wave. In a PLASMA, such as the solar wind, the situation is complicated by the existence of other wave modes in addition to sound waves. However, the principle remains true, and the solar wind flow speed is greater than the sound speed and the Alfvén speed, so that a plasma shock is formed, owing to the obstacle created by the MAGNETOSPHERE OF EARTH.

Shock waves can arise in a number of different situations in astrophysics. For example, an explosive event may generate supersonic flows which impact the surrounding gas, and this leads to a blast shock wave, where there is a limited amount of energy associated with the shock (e.g. SUPERNOVA REMNANT or SOLAR FLARE). In the case of the magnetized planets in the solar system, the magnetosphere presents an essentially impermeable obstacle (see PLANETARY MAGNETOSPHERES), and a steady shock wave is formed which stands at a relatively constant distance from the planet in the upstream flow. This is called a bow shock, in analogy to the bow wave in water ahead of a ship.

What is a shock wave? It is a wave through which the plasma flows, and in doing so it increases its characteristic wave speed (e.g. sound speed). This is accomplished by an increase in the temperature, and a corresponding decrease in the flow speed, so that the sound speed increases relative to the flow speed. The shock wave is thus the transition from supersonic flow upstream to subsonic flow downstream. The shock acts to transform some of the kinetic energy of the upstream flow into an increase in the thermal energy of the downstream flow. There is no return to the initial upstream state of the flow, so there also has to be an increase in the entropy of the flow at the shock (i.e. dissipation) so that the changes there are irreversible.

Now consider a supersonic flow. By definition sound waves produced by a source are immediately swept downstream; they cannot propagate upstream against the flow. An obstacle in a supersonic flow, without a bow shock, could never disturb the upstream flow so that it is diverted around the obstacle. The necessary deflection must be accomplished by pressure-like forces, which are communicated into the upstream flow to warn, as it were, the incoming plasma that there is an obstacle ahead. However, such forces are the same as the restoring forces that lead to the characteristic wave modes of the plasma. For example, in sound waves the restoring force is provided by the particle pressure, and hence the pressure force can only be propagated at the speed of sound. Thus, in order for the obstacle to affect the flow upstream, there must be a surrounding layer of subsonic flow (the magnetosheath), and it is this that the bow shock provides.

At the bow shock the magnetic field, density and temperature all increase as the solar wind transits the shock. This is similar to what happens in a fast magnetosonic wave (i.e. fast-mode MHD wave). Thus the bow shock is an example of a fast-mode collisionless shock, and the governing characteristic wave speed is that of the fast magnetosonic wave.

In an ordinary gas the dissipation necessary at a shock is provided by collisions between the gas molecules, so that the width of the shock is associated with the dissipational scale length which is of the order of the collision mean free path. In space plasmas the mean free path between collisions is so large that the system is essentially collisionless. Consequently the dissipation is supplied by plasma processes related to the gradients at the shock, particularly changes in the electric and magnetic field. The plasma shock processes consequently govern the width and internal structure of the shock layer. The Earth's bow shock has a width of between roughly 100 km and 1000 km, depending on the shock and plasma parameters.

The bow shock surrounds the magnetosphere on its upstream side, and is about $15R_E$ from the Earth at the 'nose' of bow shock, i.e. at the subsolar point. However, the position of the shock is highly variable (from $12R_E$ to $20R_E$) and depends on the solar wind parameters, most importantly the ram pressure. The shock position changes on the time scale of minutes in response to changes in the solar wind, and the motion of the shock can be in the range 10–100 km s^{-1}. One important consequence is that observations of the bow shock are usually due to the shock moving over a spacecraft, rather than to the motion of the spacecraft around its orbit. The motion of the shock allows a translation from a time series of measurements to a cross-section through the shock giving its spatial structure. This can obviously become impossible if the shock is unsteady.

The overall shape of the bow shock has been investigated by collating large sets of shock crossings determined from measurements of the magnetic field. Most models used to fit the observations are cylindrically symmetric conic sections (i.e. the surface generated by rotating a parabola or hyperbola around its symmetry axis), with suitable scaling to take into account variation of the solar wind ram pressure. Locating the bow shock at any given time is not yet a precise operation, since the magnetospheric obstacle is not rigid, but also responds to changes in the solar wind pressure and magnetic field orientation.

The bow shock is important for different reasons. The solar wind flow is processed by the shock before it hits the magnetosphere, so the coupling between solar wind and

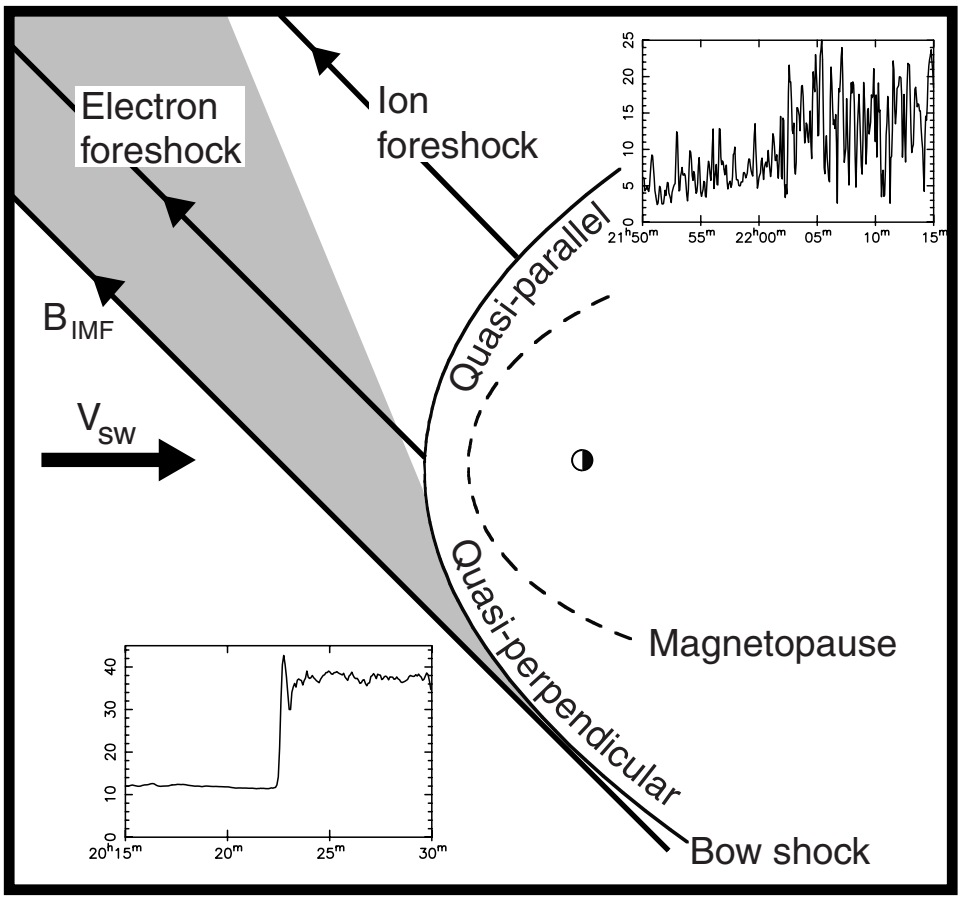

Figure 1. A schematic view of the Earth's bow shock in the equatorial plane. The direction of the upstream solar wind flow is indicated by V_{SW}. The upstream IMF direction for typical solar wind conditions is shown by three representative field lines, including the tangent field line which defines the upstream edge of the foreshock. For clarity the field lines are shown ending at the bow shock; in reality they pass into the magnetosheath and drape around the magnetosphere. The regions of quasi-perpendicular and quasi-parallel shock regimes are indicated. Examples of the corresponding different types of shock crossing are shown as time series of the magnetic field magnitude in nT (data from ISEE spacecraft—see www.igpp.ucla.edu). The typical zones of the electron and ion foreshocks are shown upstream of the bow shock.

magnetosphere is mediated by the shock and its downstream region (the magnetosheath). More importantly the bow shock is an accessible example of an astrophysical shock in a collisionless plasma. Such shocks are believed to be common in a wide range of astrophysical situations, and the Earth's bow shock allows us to study in detail shock processes such as dissipation, wave generation and particle acceleration. A spacecraft crossing the shock takes between seconds and minutes, and in that time instrumentation can record the electric and magnetic fields and particle distribution functions at high resolution. This has allowed an analysis of the plasma processes producing the necessary dissipation at the shock and how these processes, and hence the shock structure, are controlled by variations in the solar wind parameters. Observations of the bow shock show that it is a rich source of waves and energetic particles, and *in situ* observations have provided something like a plasma laboratory, so that much of the physics of collisionless shocks has been deciphered.

Different kinds of shock

From the earliest spacecraft observations it became clear that there are different types of collisionless shock, and that these correspond to different solar wind parameters (see SOLAR WIND SHOCK WAVES AND DISCONTINUITIES). These parameters include the speed, density and temperature, but also, and most importantly, the direction of the upstream interplanetary magnetic field (IMF). Observed crossings of the bow shock are generally divided into two broad classes, depending on the so-called shock normal angle θ_{Bn}, between the upstream magnetic field and the normal vector to the shock surface. If the magnetic field upstream of the shock is more nearly perpendicular to the shock normal (i.e. parallel to the shock surface) then the shock is called quasi-perpendicular. If the field is more parallel to the shock normal, then the shock is termed

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

quasi-parallel. Usually the dividing line between these two classes is taken as 45°, so that a quasi-perpendicular shock has $\theta_{Bn} > 45°$, and a quasi-parallel shock has $\theta_{Bn} < 45°$. The dividing line is slightly arbitrary, it is sometimes difficult to accurately assign a value of θ_{Bn} in the case of a quasi-parallel shock. There are other divisions to be made when categorizing shock crossings. The Mach number (the ratio of the upstream flow speed normal to the shock to the characteristic wave speed) also plays an important role. For typical solar wind conditions the bow shock has a high Mach number (e.g. an Alfvén Mach number 5–10).

Quasi-perpendicular and quasi-parallel shocks have very different structures, as is evident from, for example, profiles of the magnetic field through a shock crossing. Quasi-perpendicular shocks have a single sharp gradient, relatively smooth upstream flow, although with waves in the downstream region caused by the shock. Such shocks most closely resemble the laminar flow discontinuity that would be expected at an ordinary gas shock. Quasi-parallel shocks are much more convoluted: the shock transition is embedded in large amplitude waves both upstream and downstream, and it is often very difficult to assign an exact moment for the shock crossing. The shock crossing appears much thicker than in the quasi-perpendicular shock, but even within the extended quasi-parallel shock transition one can find abrupt changes with sharp gradients similar to the quasi-perpendicular shock. The presence of waves in the solar wind upstream of the quasi-parallel shock can make it difficult to assign an accurate value for the θ_{Bn} of the shock, since the waves are convected into the shock by the flow and produce an ever-changing shock normal angle.

As discussed above, the bow shock forms a curved surface shrouding the Earth's magnetosphere, and the interplanetary field, over the scale length of the bow shock, is typically uniform. Consequently, the shock normal angle varies over the surface of the bow shock, and the locations of quasi-perpendicular and quasi-parallel portions of the bow shock are controlled by the direction of the IMF. Thus, observationally, as well as rapid traversals of the shock because of its motion in response to changing solar wind ram pressure, the type of the shock crossing can change because of changes in the IMF direction.

The fundamental differences in structure between the major shock classes can be explained by the effect of the magnetic field geometry on the motion of particles (mainly protons) at, and immediately upstream of, the shock. The two important components of particle motion are motion along and gyration perpendicular to the field direction. At a high Mach number shock, such as the bow shock, the magnetic field increases by a factor of about four, from upstream to downstream, although peaks at the shock ramp itself can be greater. The field jump at such shocks can produce reflection of some of the protons in the incoming flow. This process depends completely on the kinetic properties of forces on individual protons, and so can never be included properly in a fluid model of a plasma shock. Ion reflection seems to be a ubiquitous property of high Mach number shocks, irrespective of their θ_{Bn} value. Ion reflection is observed using particle instruments which can measure not just particle density but also the particle velocity space by simultaneously recording particle energy and arrival direction.

The ion reflection process occurs at the location of high gradient in the field and is approximately specular, i.e. the component of velocity normal to the shock is reversed. The resultant velocity has components away from the shock along the magnetic field direction, and also, importantly, perpendicular to the field. The latter produces gyrational motion with a gyroradius of the order of 500 km, which is greater than the thickness of the shock ramp.

At a quasi-perpendicular shock the field lines are near parallel to the shock surface, so that motion along the field does not lead to rapid escape from the shock. At the same time the gyromotion about the field forces the ions to return to the shock ramp, where, on their second encounter, they are likely to pass into the downstream region. On the other hand, at a quasi-parallel shock the field-aligned motion can help guide any reflected ions away from the shock ramp before their gyration brings them back. Similar arguments show that particle motion across the shock, from downstream to upstream against the flow, is much more likely to occur at quasi-parallel shocks than at quasi-perpendicular shocks.

These fundamentally different behaviors, re-encounter with the shock or escape from it, lead to different (collisionless) heating mechanisms at the different types of shock. At the quasi-perpendicular shock the reflected-gyrating ions which re-encounter the shock pass into the downstream region where they contribute most of the ion heating. In effect, the reflection process provides a direct conversion, for a small fraction (∼15%) of the incoming ions, from upstream kinetic (flow) energy to downstream thermal (gyrating) energy. As described this process is not true dissipation, but the large temperature anisotropy of the gyrating ions makes the plasma unstable to a number of different wave modes (see MAGNETOSPHERE OF EARTH: WAVES). These waves scatter and isotropize the ions leading to true dissipation.

The foreshock

Before we consider thermalization at the quasi-parallel shock, there is a unique feature of collisionless shocks to be described. The argument concerning the θ_{Bn} control of escape from the shock actually depends on the velocity of the particles concerned. If a particle has sufficiently high velocity at even the quasi-perpendicular shock, i.e. if its motion away from the shock along the field is faster than the speed at which the field line is convected into the shock, then it will be able to escape into the region upstream of the shock. By the various mechanisms of shock acceleration the bow shock does produce both energetic electrons and ions, and with sufficient velocities to stream ahead of the shock. The region upstream of the shock populated by energetic particles and their related waves, is termed the foreshock. Because the energetic

Dirac House, Temple Back, Bristol, BS1 6BE, UK

populations have unstable velocity space distributions (e.g. beam like) they can drive a wide range of plasma waves from electromagnetic waves at radio frequencies (80 kHz), through electrostatic Langmuir waves (40 kHz), down to low-frequency MHD-like waves (50 mHz).

The foreshock only exists because of the collisionless nature of the solar wind, and the various wave types and energetic particles present there can only be explained using kinetic, as opposed to fluid, theories (see SOLAR WIND: KINETIC PROPERTIES). Furthermore, the foreshock is vital to understanding several basic phenomena at the bow shock itself, such as particle acceleration and, in the case of the quasi-parallel shock, even the shock structure. It can be seen that in some ways the existence of the foreshock undermines our discussion of the shock location as the limit of an obstacle's influence in the upstream flow. The velocities of the energetic particles are greater than the wave speeds of the plasma. On the other hand, the associated energy densities within the foreshock are small enough that the solar wind flow is only slightly affected. Indeed, if the foreshock were to strongly affect the incoming flow, then the position and nature of the bow shock would be changed drastically, which would feedback to the characteristics of the shock.

The foreshock has definite regions within it characterized by different energetic particle populations and associated waves (see SOLAR WIND: ENERGETIC PARTICLES). The upstream edge of the foreshock is the surface everywhere parallel to the solar wind magnetic field and tangential to the bow shock surface. The foreshock does not extend indefinitely upstream, since particles are eventually scattered and coupled to the solar wind flow. The foreshock global morphology is organized by the IMF direction, the bow shock shape, and, crucially, particle cross-field drift relative to particle parallel velocity. Particles energized at the shock with high speeds will tend to more closely follow a field line parallel to the tangent field line. This leads to a velocity filter which organizes the foreshock spatially, so that one can distinguish an electron foreshock and an ion foreshock. In each case one expects, and sees, the fastest beams occurring on the upstream edge. Electron distributions vary from energetic beams (up to 100 keV) near the upstream edge to a backstreaming heat flux deeper in the foreshock. Ion distributions vary from field-aligned beams (with temperatures similar to that of the solar wind), through 'intermediate', to 'diffuse' ions with near-isotropic velocity space distributions, with energies up to several hundred keV.

The coupling between the shock and foreshock is vital to understanding how the quasi-parallel shock manages to heat the incoming flow. Out of this understanding has developed what is known as a 'cyclic reformation' model. Because of the quasi-parallel field geometry, and lack of collisions, particles with moderate energies can easily stream away in front of the shock. Once there they can excite plasma instabilities, creating a region of interacting waves and particles. Since the flow is, by definition, faster than the most important wave speeds, the majority of waves in the foreshock must eventually be convected by the flow into, and through, the shock itself. Based on simulations and observations, high Mach number quasi-parallel shocks have a highly dynamic structure which alternates between a sharp transition in the field (and correspondingly the thermalization) and a longer, more gradual transition. This alternation cycles in time and is linked to the convection of upstream waves (generated by foreshock ions) into the shock layer, which modifies the local shock normal angle. Furthermore, periodic bursts of reflected ions (with $\sim$20% the incident density) are observed within the shock structure. These reflected ions appear to be specularly reflected out of the incident distribution. It is the interaction of the foreshock waves, as they are swept into the shock, with the reflected ions which forms one part of the reformation cycle mechanism. This model can be taken further by admitting that that the upstream waves, which control the shock structure, are only coherent over a certain scale length. Consequently, it had been suggested that the idea of a single shock surface, in the quasi-parallel regime, has to be abandoned, and that different parts of the bow shock are at different stages in the cycle from abrupt to extended transition.

Magnetosphere of Earth: Convection

Magnetospheric convection is the process whereby ions and electrons are transported throughout the *magnetosphere*, the region of space dominated by the Earth's magnetic field (see MAGNETOSPHERE OF EARTH). Throughout much of the magnetosphere, the ions and electrons travel together with the same velocity perpendicular to the magnetic field; this is called the *convection velocity* $\boldsymbol{u}$ and is given numerically by $\boldsymbol{u}_E = [\boldsymbol{E} \times \boldsymbol{B}]/B^2$, where the local magnetic and electric fields are $\boldsymbol{B}$ and $\boldsymbol{E}$, respectively. In the absence of time variations and significant magnetic-field-aligned electric fields, magnetospheric convection patterns can be deduced from electric-field patterns in the ionosphere. At high energies and in regions of large field gradients, however, particles also exhibit energy- and charge-dependent drifts, such that they move at field-perpendicular speeds significantly different from the local convection velocity.

Particle motions

Drift velocities

The motion of a charged particle in magnetic and electric fields can be resolved into several components, with fundamental time constants relevant to each. The magnetic, or *Lorentz*, force is given by $F = q\boldsymbol{v} \times \boldsymbol{B}$, where the particle velocity perpendicular to the field line is $v_\perp$ and the particle charge (including sign) is given by q. This force results in a *gyromotion* of particles around the field line: the particle moves in circles around the field line. The particle's velocity parallel to the field line $v_\parallel$ is unchanged by the Lorentz force, so that the net motion is a helix around the field line. The angular frequency of this circular motion is called the *gyrofrequency* ω_c given by qB/m, where m is the particle mass. The radius of curvature of this gyromotion is called the *gyroradius* and is given by $v_\perp/\omega_c$, where the velocity perpendicular to the field line is $v_\perp$. Electrons move in a right-hand sense around the field direction, and ions in a left-hand sense. This is typically the fastest temporal scale and shortest spatial scale for plasma motion, and, so long as the electric and magnetic fields do not change on these scales, leads to a conservation of particle *magnetic moment* $mv_\perp^2/2B$.

Because of the strength of the Lorentz force, any other external force perpendicular to the magnetic field does not result in a free acceleration along that force direction, but instead results in a particle drift u_d perpendicular to both the magnetic field and the external force: $\boldsymbol{u}_d = (\boldsymbol{F}_{ext} \times \boldsymbol{B})/qB^2$. This drift can be visualized to result from changes in the gyroradius of the particle during one cycle (figure 1(top)). During the part of the cycle where the particle is moving along the force, its perpendicular velocity and therefore its gyroradius is increasing; during the other half of the cycle, the particle moves opposite to the external force and its velocity is decreasing. This leads to a cycloidal motion that is the sum of the simple circular motion plus a steady drift given by u_d. The center of curvature of the circular motion is called the *guiding center*. Thus the particle motion can be thought of as the sum of the circular gyration plus the drift motion of the guiding center. For the case where the external force is from a large-scale electric field $\boldsymbol{E}$, the drift velocity is given by $\boldsymbol{u}_E = [\boldsymbol{E} \times \boldsymbol{B}]/B^2$.

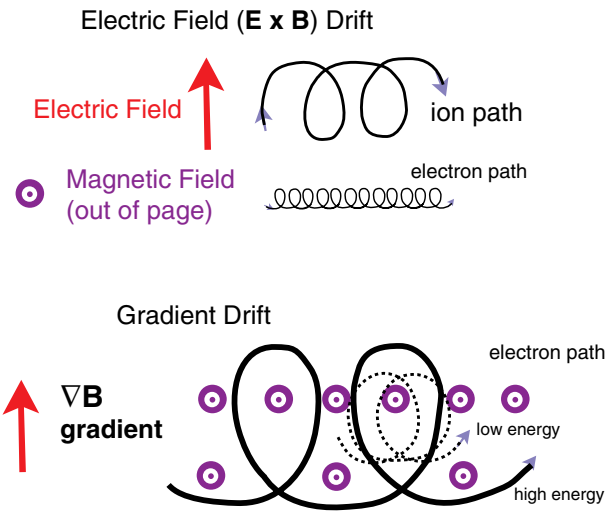

Figure 1. Top: drifts from external forces result in a drift perpendicular to the magnetic field and the force. In the case of the electric field, the drift is an $E \times B$ *drift*. Bottom: gradients in the field magnitude also result in particle drift, with the fastest drift for higher-energy particles.

Since the electric-field drift is neither mass, energy, nor charge dependent, it represents the drift of the entire low-energy plasma population and is called the *convection velocity* or $E \times B$ *drift*. A *flux tube* is a set of field lines which cross a particular area. Consider the set of particles which all have their guiding centers on the field line in the center of a flux tube. Since all of these particles drift together, their guiding centers permanently remain on the same field line as each other. Therefore, you can imagine the entire magnetic flux tube and its associated particles moving as a unit. This is the idea of *frozen-in-flux*, which was developed by HANNES ALFVÉN. This approximation breaks down if the magnetic field changes topology (as by *reconnection*, see MAGNETIC RECONNECTION) or if electric fields along the magnetic field accelerate particles along the field line, but it is a useful way to visualize the large-scale motion of low-energy plasma.

If there is no electric field aligned along the magnetic field ($E_\parallel$), and if the fields are steady state, then each magnetic-field line is an equipotential. Thus perpendicular electric fields at high altitudes are simply mapped to electric fields at low altitudes and the motion of the plasma at the high-altitude end of the field line is reflected in the motion of the plasma in the ionosphere. Each flow path is an equipotential in steady-state conditions.

The second periodic motion of a particle trapped in the Earth's magnetic field is its *bounce motion* from one

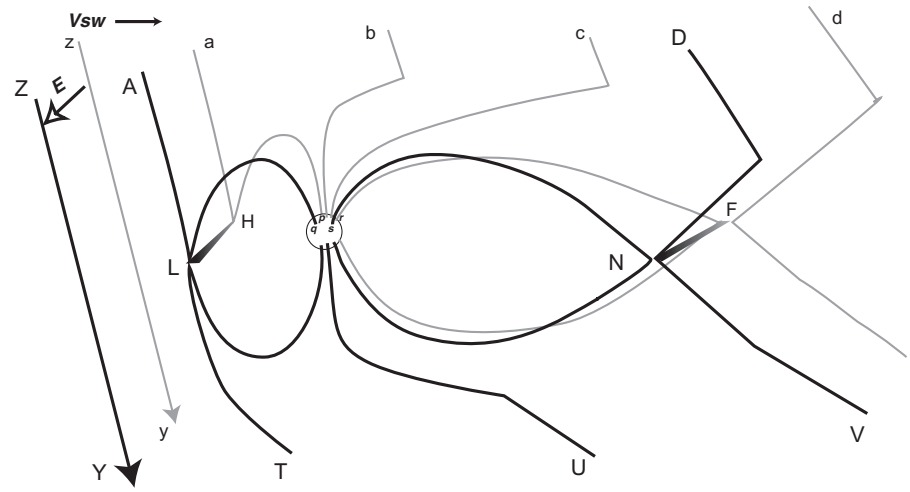

Figure 2. Schematic of magnetic reconnection. The Sun is to the left. Two southward-pointing solar-wind field lines separated in the Y direction have a potential drop across them, with line zy (gray, in background) at a higher potential than ZY (in foreground). When those field lines connect to the Earth's field at the dayside X-line (HL), the potential drop aA is mapped to HL and from thence down to the ionosphere (pq). This electric field sets the ionosphere in motion. As the solar wind convects from a to b to c to d, the ionospheric feet of those field lines move antisunward as well. The open fields reconnect at the tail X-line (FN), which maps to the ionosphere as line rs. The newly closed field lines convect back sunward (not shown) to complete the cycle.

hemisphere to the other. The particle, preserving its first adiabatic invariant (the *magnetic moment* $mv_\perp^2/2B$) and its total energy $mv^2/2$, increases its *pitch angle* $\alpha(=\sin^{-1} v_\perp/v)$ as it travels towards the Earth from the equatorial plane. When its pitch angle reaches 90°, the particle's parallel velocity goes to zero then reverses. The particle *mirrors* and returns to the other hemisphere. The integral of the parallel velocity along a bounce path leads to the second adiabatic invariant, which is also conserved if the fields change slowly compared to the bounce period.

Energy-dependent drifts

Higher-energy particles have energy-dependent drifts in addition to their convection velocity. Gradient drift is a result of a change in magnetic-field strength over the course of one gyration (figure 1(bottom)), in a manner similar to $E \times B$ drift (figure 1(top)). The effect is to move high-energy particles along a contour of constant field strength. Similarly, if the particles move along a curved field line, the centrifugal force also leads to a particle drift. In the Earth's equatorial plane, both gradient and curvature drifts lead to westward drift of ions and eastward drift of electrons. The drifts are given by $u_g = (mv_\perp^2 \boldsymbol{B}\times\nabla\boldsymbol{B})/2qB^3$ for the gradient drift, and $u_c = -(mv_\parallel^2 \boldsymbol{R} \times \boldsymbol{B})/R^2 qB^2$ (where $\boldsymbol{R}$ is the radius of curvature of the field line) for the curvature drift. These charge-dependent drifts lead to a westward current circling the Earth, the *ring current* (see MAGNETOSPHERE OF EARTH: RING CURRENT). Since the drift velocity depends on the energy of the particles, it can be shown that the intensity of the ring current is proportional to the energy density of the particles in the ring current. Since the gradient drift is perpendicular to the field gradient, energetic particles trapped in the equatorial plane move along contours of constant B. The drift cycle around the Earth leads to a third adiabatic invariant, which is less frequently conserved (because it requires field constancy on the timescale of a drift period, which is minutes to hours, depending on the energy of the particle and its distance from Earth). Again, the motion of the guiding center is a useful concept for following particle trajectories. However, because of the larger gyroradii of energetic particles, a particle can be lost from the magnetosphere even if its guiding center remains inside.

Steady-state convection

Corotation

Near the Earth, the low-energy plasma motion is dominated by *corotation*. Collisional drag between the ionosphere and the neutral atmosphere sets up currents which create an electric field which brings the less massive magnetospheric plasma into flow equilibrium with the neutral atmosphere. Mapping the electric field from the ionosphere to the magnetosphere then results in the inner-magnetosphere low-energy plasma (the *plasmasphere*) drifting around the Earth counterclockwise once per 24 h (see MAGNETOSPHERE OF EARTH: PLASMASPHERE). In rotation-dominated magnetospheres such as Jupiter's, partial corotation is observed essentially throughout the magnetosphere, although significant slippage occurs in the outer magnetosphere, and near the orbit of the satellite Io where the ionization rate is large (see JUPITER: MAGNETOSPHERE). In Earth's magnetosphere, however, corotation only dominates close to the Earth (within about 4–6 R_E). The convection electric field from corotation is given by $E_{cor} = -(\boldsymbol{\Omega} \times \boldsymbol{r}) \times \boldsymbol{B}$, where $\boldsymbol{\Omega}$ is the angular

frequency of the Earth and $\boldsymbol{r}$ the radius vector to the location in question.

Solar-wind-driven convection

Although the motion of cold plasma trapped near the Earth is dominated by corotation, the motion of the bulk of the magnetosphere is determined by its large-scale interaction with the SOLAR WIND. The Earth's magnetic field has a defined outer boundary, the *magnetopause* (see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE). The solar wind flowing past the magnetosphere sets up a convective flow inside the magnetosphere, so that the regions of the magnetosphere just inside the boundary flow antisunward (i.e. in the same direction as the neighboring solar wind), and the plasmas deeper in the magnetosphere have a return sunward flow.

This antisunward motion can either be driven by quasi-viscous forces at the magnetopause (e.g. diffusion of particles across the boundary or momentum transfer by large-amplitude Kelvin–Helmholtz surface waves), or by magnetic reconnection. Magnetic reconnection is the process whereby plasma flows across a boundary between regimes of different magnetic topology. In the case of the Earth, dayside (northward pointing) closed field lines become connected to southward-pointing interplanetary magnetic field lines, with a transfer of flux across the boundary (figure 2). The mapping of the solar-wind electric field throughout the magnetosphere leads to a large-scale convection pattern with a dawn-to-dusk electric field (figure 3). The reconnection model has had spectacular successes in predicting the variation of the convection speed and direction as a function of interplanetary conditions (see below), and is considered the dominant form of solar-wind interaction. MHD models of the magnetosphere, with their numerical resistivity, naturally yield both forms of interaction process.

Combined flows

The simplest models of convection merely added the externally driven convection electric field vectorially to the corotation electric field. However, it can be shown that, in steady conditions, electric charges on the inner edge of the plasma sheet shield the inner magnetosphere from the solar-wind-driven convection. In times of changing convection, however, this external convection electric field penetrates more easily. In times of increasing convection, the outer parts of the plasmasphere can be stripped off and convect to the dayside magnetopause, creating tongues of plasma. The combined flow is shown in the bottom panel of figure 3.

Convection for southward IMF

This transport of plasma across the magnetopause boundary in an open geometry requires an electric field along the x line. The integral of $\boldsymbol{E}$ along the x line, sometimes called the dayside reconnection rate R_D, represents the rate at which closed dayside flux becomes

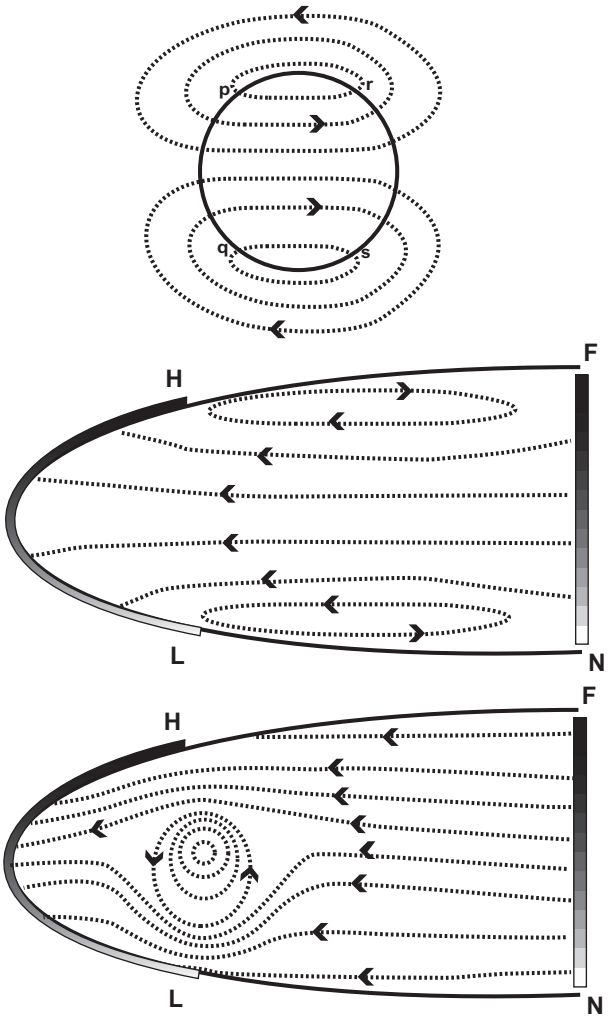

Figure 3. Schematic of convection in the ionosphere (top) and the corresponding flow paths in the equatorial plane (middle). The flow paths intersect the magnetopause at the dayside (HL) and nightside (FN) x-lines, which map to the ionosphere at pq and rs, respectively. A small convection cell from viscosity is shown on the edges of the middle panel. Adding in the corotation electric field and the plasma sheet shielding yields the bottom convection pattern.

'open', or interconnected to the interplanetary magnetic field. The dayside x line is shown as HL in figures 2 and 3, with H at the higher potential.

Similarly, the flux transfer rate across the nightside portion of the x line, denoted by R_N, represents the rate at which open magnetic flux is closed. This x line is shown as FN in figures 2 and 3. Over a long time average, $\langle R_D \rangle$ must equal $\langle RN \rangle$, but the two instantaneous rates frequently differ. When $R_D > R_N$, the amount of open flux increases and thus the size of the polar cap (the footprint of the open field line region in the ionosphere) increases. Magnetic energy stored in the tail likewise increases. When $R_N > R_D$, open flux in the magnetotail closes and the polar cap size

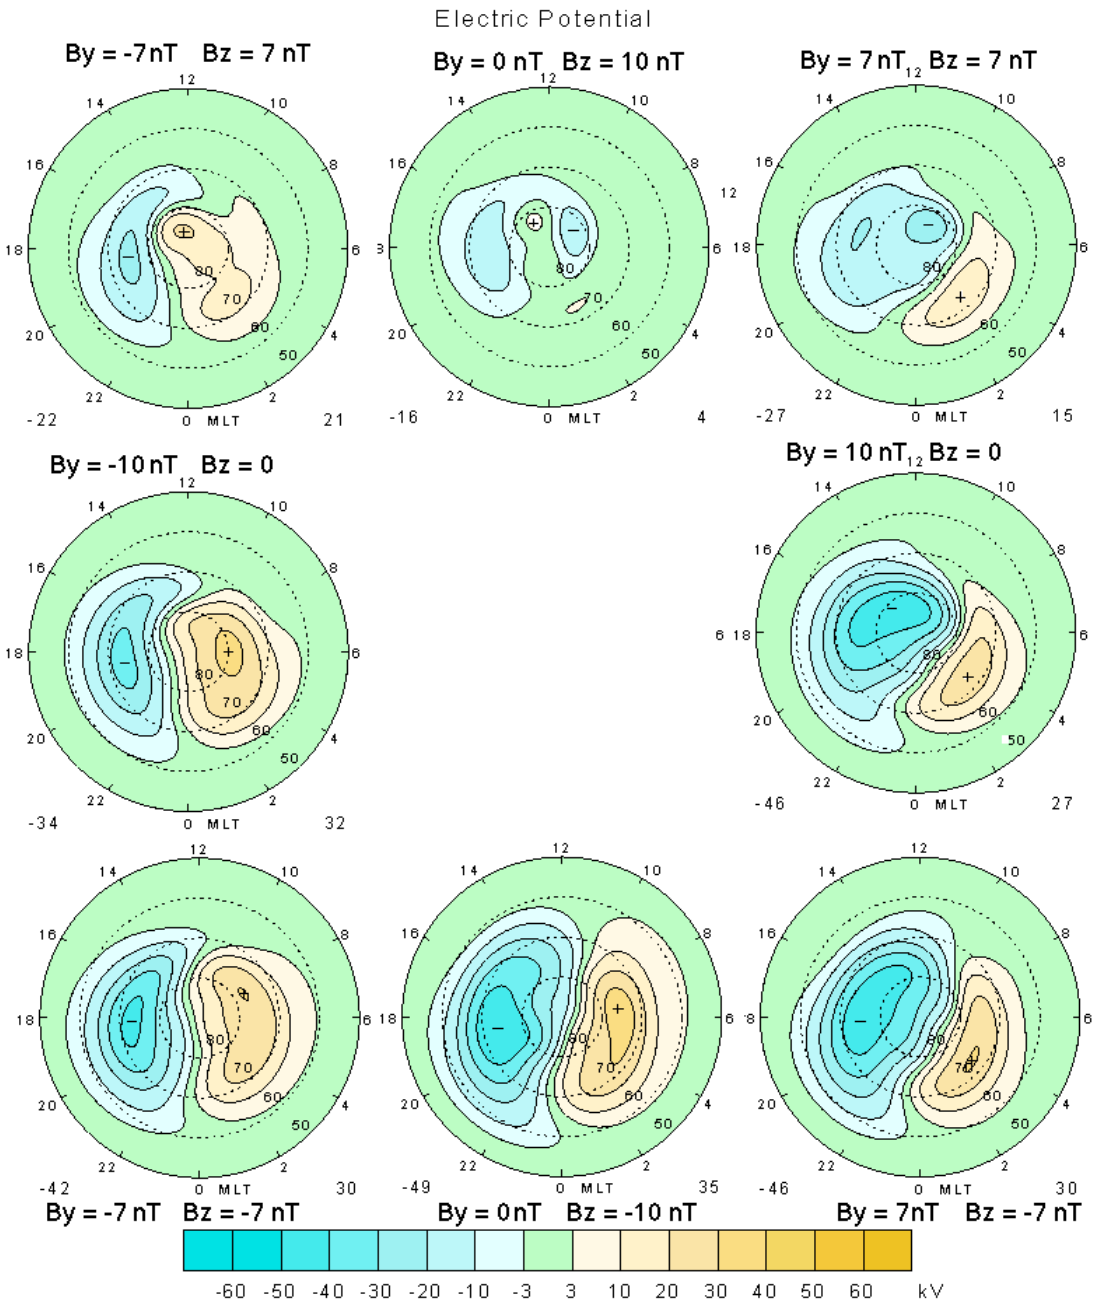

Figure 4. Ionospheric convection patterns for various orientations of the IMF (adapted from Weimer D R 1996 *Geophys. Res. Lett.* **23** 2549–52). In each case the view is from above the Earth's north magnetic pole and the Sun is towards the top. The minimum and maximum potential for each case is shown at the bottom.

decreases. The magnetic energy is released in a *substorm* (see MAGNETOSPHERE OF EARTH: SUBSTORMS). In a steady state, $R_D = R_N = \Phi_{pc}$, the electric potential drop across the antisunward flowing part of the ionosphere. This polar cap potential drop Φ_{pc} thus characterizes the global rate of convection, both in the ionosphere and in the magnetosphere. Polar cap potentials range from a minimum near 20 kV in quiet times to 200 kV, or more in very active times, with a median value near 50 kV.

In the ionosphere, the flow lines (which are equipotentials) form closed contours and a convection pattern can be discerned, with generally antisunward flow on the field lines inside the polar cap (connected to the antisunward-flowing solar wind), with sunward return

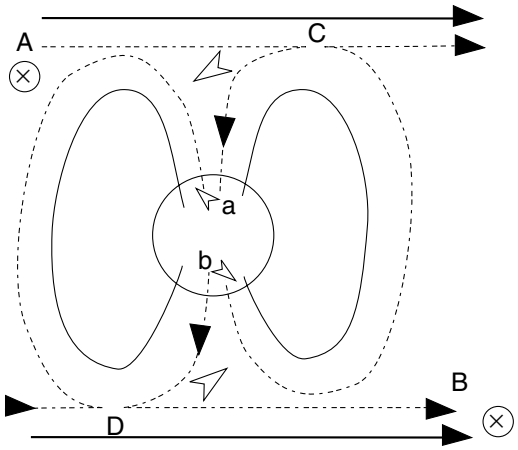

Figure 5. Schematic of reconnection of the Earth's field (light lines) with an IMF with a positive B_y component (heavy lines; view from the sun). The merging line (not shown) runs from C to D across the dayside. Newly interconnected field lines (shown dashed) are dragged tailward by the solar wind. Tension in the field lines (A–a) and (B–b) causes the flow to cross noon from dawn to dusk in the northern hemisphere and from dusk to dawn in the southern hemisphere (open arrows).

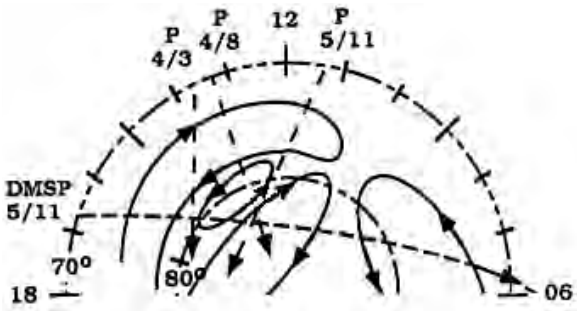

Figure 6. Four-cell convection pattern frequently observed for strongly northward IMF. In this case four spacecraft passes confirmed the location and orientation of the convection cells. (Adapted from Maynard N C *et al* 1998 *J. Geophys. Res.* **103** 29–46).

flow on closed field lines at lower latitudes (figure 3). The integral of the electric field around the polar cap boundary must (by Faraday's law) equal the negative time change of the magnetic flux enclosed. Since the Earth's magnetic field is constant, then the integral of the electric field around the boundary in the Earth's frame of reference must be zero and the convection pattern will look like closed flow contours, even in times when the merging rates differs between the dayside and the nightside. This flow pattern changes in strength and skew with the magnitude and orientation of the *interplanetary magnetic field* (IMF). The larger the southward (negative B_z) component of the IMF, the larger the polar cap potential drop. One typically uses a Geocentric Solar Magnetospheric (GSM) coordinate system for the IMF. The $+x_{GSM}$ axis is defined as pointing from the Earth to the Sun; the $+z$ axis points generally towards the ecliptic north, but is tilted so that the Earth's dipole is in the x–z_{GSM} plane; and the y_{GSM} axis completes a right-hand system, with positive y pointing generally opposite to the Earth's orbital motion.

The very strong dependence of the potential on the IMF B_z is the most compelling evidence for magnetic merging being the dominant form of momentum transfer from the solar wind to the magnetosphere. Empirical studies also indicate a background potential drop (5–15 keV) that is not related to B_z but does appear to depend on the solar-wind velocity squared. This may indicate a small diffusive or turbulent momentum transfer across the magnetopause, or it may just indicate that the best functional form for the merging momentum transfer has not yet been found.

B_y effects

The effect of the y component (dawn–dusk) of the IMF is to skew the flow pattern from dawn to dusk, with the flow asymmetry opposite in opposite hemispheres. In the northern hemisphere, for example, for IMF $B_y > 0$, the dayside flow in the polar cap crosses noon from the dusk side to the dawn side, making the antisunward flow strongest near the dawn polar cap boundary. Just below the polar cap boundary, in the closed field regions, the flow is eastward.

For $B_y < 0$ (or for $B_y > 0$ in the southern hemisphere), the flow is in the opposite sense: towards dusk below the polar cap boundary, and towards dawn above it. Convection patterns for various orientations of the IMF are shown in figure 4. These patterns, from fits to low-altitude electric-field measurements, are similar to those compiled from ionospheric flow measurements or ionospheric magnetic-field perturbations. However, being fitted functions to many passes of spacecraft data, they have smaller gradients than are typically observed in a single spacecraft pass.

The dawn–dusk asymmetry of the flow can be best explained in terms of the field tension resulting from interconnection with the IMF (figure 5). The dayside x-line is tilted along the current direction so that the component of the IMF along the x-line is constant as the magnetopause is traversed. Since the reconnected field line has one end in the duskside magnetosheath and its footpoint in the dawn ionosphere, the foot is dragged duskward.

Most published convection patterns (as in figure 4) are given with the Earth's rotation subtracted. This leads to a less-cluttered plot, since the equipotentials at low latitudes are dominated by corotation. The plasma sheet shielding effect (see above) means that convection patterns with corotation subtracted generally do not extend below about 55° invariant latitude. The lack of convection below 50° is useful in calibrating electric field and velocity measurements, which can suffer minor offsets from modest pointing errors.

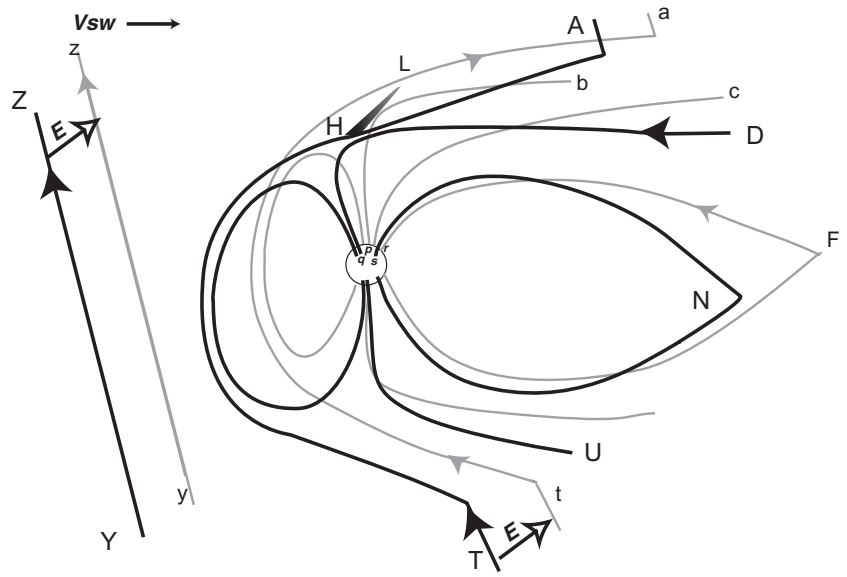

Figure 7. Reconnection of northward-pointing IMF field lines (YZ and yz) with the tail field lines tailward of the cusp. The magnetosheath flow causes the IMF to bend, having a tendency to follow the curvature of the magnetopause (TA and ta). Dipole tilt or the x-component of the IMF will favor reconnection in one hemisphere or another (here shown in the north). After reconnection at the x-line FN, dusk to dawn electric field in the magnetosphere gets mapped down to the ionosphere, creating sunward flow on the dayside. Tension then swings the flow to the dawn or dusk, depending on the sign of B_y. (Gray field lines are farther away; black field lines are closer).

Convection for northward IMF

In times of northward IMF, the polar cap convection is more complicated. Since the dayside reconnection rate R_D decreases, the polar cap has a tendency to shrink. Furthermore, since less magnetic flux connects to the solar wind, the electric potential across the polar cap also decreases. Effects of the y component of the IMF (see above) become more pronounced.

The most dramatic difference from southward IMF conditions is the appearance within the polar cap of substantial regions of sunward flow. If the IMF B_y is large, the polar cap convection can exhibit a single large convection cell with, e.g., sunward flow on the dawn side and antisunward flow on the dusk side, as occurs for B_y large and negative in the northern hemisphere (see figure 4). When the northward component of the IMF is larger than the B_y component, the convection can show a four-cell pattern: there is a central pair of cells with sunward flow in the central part of the polar cap and antisunward flow around the edges, which is similar to but opposite in sense to the normal convection pattern, and lower latitude cells of the normal sense. Although the driving mechanism for this kind of convection is still controversial, the existence of the pattern is well established, both by multiple spacecraft passes (e.g. figure 6) or from arrays of velocity measurements from ground-based radar.

The driving mechanism for the higher-latitude reverse cell is considered to be 'reverse reconnection': connection of high-latitude field lines with the IMF tailward of the magnetospheric cusps (figure 7) (see also MAGNETOSPHERE OF EARTH: DAYSIDE CUSP). Reconnection can occur in just one hemisphere (as is shown here), or in more unlikely circumstances, can occur in both hemispheres simultaneously, leading to the creation of newly closed magnetic flux. In addition, there exists a lower-latitude pair of cells in the forward sense (antisunward at higher latitudes) which persists even when the higher-latitude cells reverse direction. The driving mechanism for these lower-latitude cells could either be small-scale magnetopause reconnection, closure of open field lines (in cases where $R_N > R_D$), or quasi-viscous processes at the magnetopause.

Time-dependent convection

Increasing reconnection

The difference between the dayside and nightside merging rate results in an expansion (if $R_D > R_N$) or contraction (if $R_D < R_N$) of the open field region, while maintaining closed flow contours in the ionosphere. The merging rate is the integral of the electric field along the x-line in the *moving* frame of reference. The difference between the electric field in the x-line's frame of reference and in the Earth's frame of reference is just $\boldsymbol{v}_{\rm pc} \times \boldsymbol{B}$, where $\boldsymbol{v}_{\rm pc}$ is the speed of the polar cap boundary in the Earth's frame of reference.

The dayside convection pattern is observed to change very rapidly in response to changes in the IMF, with the information propagating to the ground at approximately the Alfvén speed (a few minutes from the magnetopause). The changes in the dayside flow get communicated to

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the nightside portion of the ionosphere more slowly (5–10 min), but still significantly faster than the convection time from the dayside to the nightside along the magnetopause (30–60 min).

During times of increasing reconnection, the shielding currents do not have time to be set up and strong sunward flows can be observed at relatively low latitudes. It is in these times that plasmas in the outer portions of the plasmasphere can be stripped away.

Bursty bulk flows

Nightside reconnection results in newly-closed field lines which then shorten and move earthward. The flows in the magnetotail are observed to be unsteady, however, with short ($\sim$ 1 min) bursts of rapid flow separated by several minutes of slow flow. The sunward flow in the magnetotail may be choked off because, as the flux tube travels earthward, its volume decreases and the plasma pressure inside increases. This leads to a back pressure retarding the flow.

Decreasing reconnection

After a northward turning of the IMF, the dayside reconnection rate is smaller than the nightside rate. The flow across the nightside *X*-line need not stop immediately, however, and the polar cap boundary retreats poleward. Open magnetotail flux becomes closed. Northward turnings of the IMF have frequently been associated with the expansion onset of *substorm*, but the cause of that association has not been proven.

If the convection is decreasing, the pre-existing shielding currents are too strong for the new convection pattern, and an overshielding condition can occur. This can result in significant antisunward flows at low latitudes until a new steady state is established. This effect (plus the effect of continuing nightside reconnection) may be a significant driver of the lower-latitude cells observed during northward IMF conditions (see figure 7).

Summary

The convection of plasmas in the Earth's magnetosphere is becoming better understood, both from a theoretical standpoint and from *in situ* measurements. However, the magnetosphere is rarely steady in space or in time, and the effects of rapid time variations on the merging rate are still not well understood. By using multiple spacecraft measurements, coordinating with arrays of velocity measurements from ground-based radars, we can begin to elucidate better the changes in the convection in response to both changes in the IMF and from internal changes such as substorms.

Magnetosphere of Earth: Dayside Cusp

The magnetospheric cusps are the dayside, polar regions of the magnetosphere that have the first direct magnetic connection to interplanetary space as the SOLAR WIND flows past the magnetosphere. This direct magnetic connection allows solar wind and magnetosheath particles and energy to enter the magnetosphere, beginning the complex coupling between interplanetary space and Earth's environment. Because the solar wind that is continuously flowing toward Earth is highly variable, the cusps are dynamic regions, changing abruptly as the driving forces in the solar wind change. The magnetospheric cusps provide an important window to interplanetary space, and a natural laboratory to investigate the coupling of mass, momentum and energy from the flowing solar wind into Earth's magnetosphere, ionosphere and upper atmosphere.

The magnetospheric cusps extend from the dayside magnetopause into the northern and the southern polar regions of Earth (figure 1; see also figure 1(*a*) of MAGNETOSPHERE OF EARTH). The location of the cusps and their properties depend strongly on the interaction occurring on the magnetopause between the flowing magnetosheath on its outer surface and the magnetosphere that is confined within. The dominant process that facilitates the linkage across the magnetopause is MAGNETIC RECONNECTION. If magnetic reconnection were not occurring on the magnetopause, i.e. if the magnetosphere were 'closed', the magnetospheric magnetic field would lie tangent to the magnetopause everywhere along its inner surface. The magnetic field over this entire surface would trace to a vanishingly small region at the magnetic poles. Consequently, any plasma that crossed the magnetopause and flowed into the magnetosphere along the magnetic field would be focused into these narrow regions at the northern and the southern poles. The occurrence of magnetic reconnection on the magnetopause causes the magnetic field to cross the magnetopause over much of its surface, leading to a much broader volume in the polar regions into which the magnetosheath plasma will flow. The rate of reconnection and its location on the magnetopause will determine the energy transfer and the breadth of the polar regions into which magnetosheath plasma will penetrate, as well as the properties of this penetrating plasma.

Much of what we know about the cusp has been obtained from instruments on orbiting satellites, on sounding rockets and from ground instrumentation. Satellites and rockets are used to measure directly the magnetosheath and magnetospheric plasma and fields, while ground instruments measure the effects of the precipitating plasma and of the interconnection with the solar wind on the ionosphere and upper atmosphere. The observed low-altitude effects include dayside aurora, acceleration of the ionosphere and neutral atmosphere and heating of ionospheric plasma that then flows out and populates the magnetosphere.

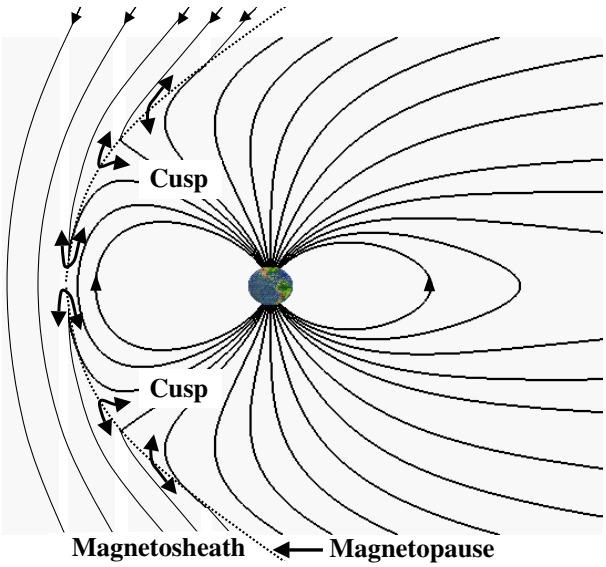

Figure 1. Location of the cusps in the magnetosphere. The cusps extend from the high-latitude ionosphere and upper atmosphere out to the dayside magnetopause. In the case when Earth's magnetic field is interconnected with interplanetary space, the magnetosheath and magnetospheric plasma freely mix across the open magnetopause (arrows crossing magnetopause).

The properties of the cusp are described here by considering the case in which the interplanetary magnetic field (IMF) is directed southward. Under these conditions, the solar wind drives the magnetospheric and ionospheric plasma mainly in the anti-Sunward direction, and the dominant source of cusp plasma is the low-latitude dayside magnetosheath. For different orientations of the solar wind magnetic field, the magnetosphere and ionosphere are pulled in different directions, and the location where the cusp is connected to the magnetopause varies. Since the IMF is typically quite variable, the cusp regions at any given time can be rather complex, reflecting a history of competing forces and magnetosheath source properties.

When the IMF is southward and reconnection occurs at low latitudes on the equatorial magnetopause, the Earth's high-latitude magnetic field becomes interconnected with the low-latitude magnetosheath (figure 1). These interconnected field lines extend from Earth out to the high-speed solar wind in interplanetary space. As a consequence of the interconnection of the field lines across the magnetopause, the magnetosheath plasma flows freely into the magnetosphere, and the magnetospheric plasma escapes out into the magnetosheath and eventually to interplanetary space. This interchange of plasma across the magnetopause is illustrated with the arrows in figure 1.

Observing the cusp

Inside the magnetosphere, the entering magnetosheath plasma and the escaping magnetospheric plasma can be clearly identified. This is due in part to the different densities and temperatures of the plasma on either side of the magnetopause, and in part to the different mass composition in the two regions. The plasma in the outer dayside magnetosphere typically has a low density (<1 cm^{-3}) and a high temperature ($\sim 10^8$ K). In the dayside magnetosheath, the density is considerably higher (1–100 cm^{-3}), and the temperature is lower (10^5–10^7 K). Consequently, when a satellite moving from low to high latitudes within the magnetosphere crosses the boundary between open and closed field lines, it will detect the entering magnetosheath plasma at the lower energies, below about 1 keV for the electrons and below about 10 keV for the ions. There will also be an abrupt decrease in the higher-energy magnetospheric plasma above these approximate energies. The plasma mass composition is also used to distinguish plasma of direct solar wind origin from plasma of ionospheric origin. Mass composition experiments detect the presence of helium nuclei (alpha particles) in the cusp with density of a few per cent of the hydrogen density. The relative abundance observed in the cusp matches well the relative abundance in the solar wind and magnetosheath, but is considerably higher than the relative abundance in the closed magnetic field portion of the outer magnetosphere.

An example of a crossing through the cusp made by NASA's POLAR satellite is shown in figure 2, obtained from the Hydra Electron and Ion Hot Plasma Instrument. A segment from the orbit of Polar is shown on the right of the figure. Over this 3 h time period, the satellite moved from low latitudes to high latitudes, remaining near local noon. At the end of this time period, Polar was located roughly over the geomagnetic pole. The gray intensity indicates electron (upper panel) and ion (lower panel) count rates as functions of particle energy for energies ranging from a few eV to about 20 keV. The ions measured here are primarily protons, with a small contribution coming from other higher-mass species. Dark regions indicate low count rates, and light regions indicate high count rates. The locations and energies where the count rates are below a threshold level of the instrument are indicated with white.

The transition from closed to open magnetic field lines can be clearly seen in figure 2 at approximately 16:48 UT. Prior to this time, Polar detected high-energy electrons and ions on the closed magnetospheric field lines, up to the highest energies measured. When the boundary between open and closed field lines was crossed, the dense, lower-energy electrons and ions that originated in the magnetosheath were abruptly observed, and the highest-energy particles were seen to no longer be present. The cusp is the region in the magnetosphere, observed on this crossing between approximately 16:48 UT and 18:00 UT, where the magnetosheath plasma has entered across the dayside magnetopause and filled a funnel-shaped region of the magnetosphere that extends down to the ionosphere and upper atmosphere.

Spatial and temporal variability of the cusp

The cusp, which is defined primarily by the density and average energy of its plasma, is observed to be localized in latitude and in longitude, and exhibits spatial and temporal structure. The spatial structure is primarily due to the large-scale magnetospheric convection and to the large-scale spatial characteristics of the magnetosheath and of the magnetopause. The temporal variability of the cusp is due primarily to temporal changes in the rate and location of magnetic reconnection on the dayside magnetopause.

One of the most consistently observed spatial features of the cusp is the variation of the average energy of the plasma with latitude. As can be seen in figure 2, the cusp ions are concentrated at high energies near the boundary between open and closed field lines (at lower latitudes), and the average energy decreases as the spacecraft moves to higher latitudes. This dependence of particle energy on latitude arises from the evolution of the plasma following magnetic reconnection. The spatial dependence of the cusp plasma depends on three main effects: (a) the travel time required for the entering magnetosheath plasma to penetrate into the magnetosphere after reconnection occurs; (b) the changes in the magnetosheath plasma as it flows over the dayside magnetopause; and (c) the spatial dependence of plasma acceleration that occurs when plasma crosses the magnetopause current sheet.

The large-scale magnetospheric convection driven by reconnection on the dayside magnetopause carries the newly interconnected magnetic field and plasma to higher latitudes over the polar regions and eventually deep into the magnetotail. This flow is directed perpendicular to the magnetic field, and carries all plasma along at a common convection speed. As time progresses, the magnetopause crossing point of a given magnetic field line moves to higher latitudes and eventually far down the tail.

When reconnection first occurs, the magnetosheath electrons and ions begin to flow into the magnetosphere across the magnetopause. As the particles travel along the magnetic field toward the ionosphere, the large-scale convection carries the plasma and the magnetic field to higher latitudes. Consequently, the particles that have very high velocities parallel to the magnetic field will quickly penetrate deep into the magnetosphere prior to appreciable convection to higher latitudes. Particles with low parallel velocities will penetrate more slowly into the magnetosphere, and therefore will be convected to higher latitudes in the time required for them to penetrate a given distance into the magnetosphere.

Therefore, at the low-latitude edge of the cusp, i.e. on magnetic field lines that reconnected only a brief time ago, the only magnetosheath particles that can be observed are those that have a sufficiently high parallel velocity to reach the observation locations in the time since reconnection of the field line occurred. As an observer moves to higher latitudes, i.e. onto magnetic field lines that reconnected progressively longer ago, magnetosheath plasma with progressively lower energies will be observed.

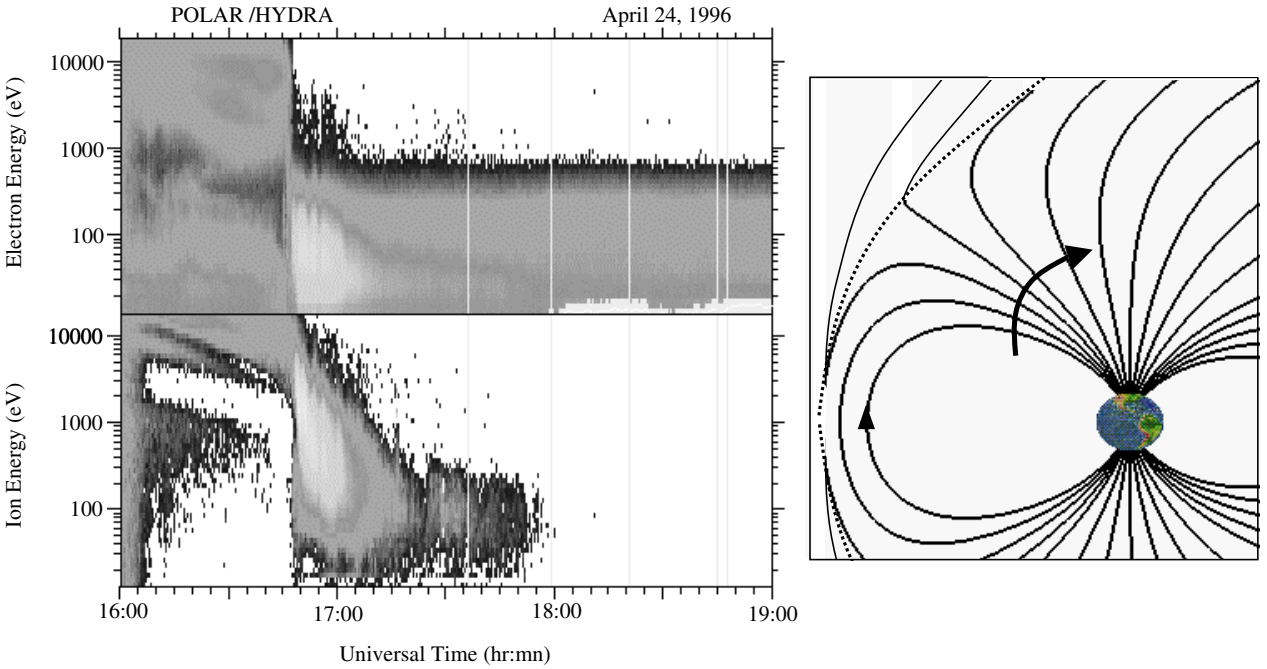

Figure 2. Segment of the orbit of the NASA Polar satellite (right) and electron (upper) and ion (lower) measurements obtained from the Hydra instrument on board the Polar satellite (left). Dark shades indicates low particle fluxes, light shades indicate high particle fluxes, and the white areas indicate where the particle fluxes are below a threshold level. The cusp is the region of intense, localized particle fluxes observed at the lower and intermediate energies for electrons and ions, respectively; in this case after 16.47 UT.

Another factor that contributes to the plasma characteristics in the cusp is the spatial structure of the magnetosheath, which is the dominant source population for the cusp plasma. At the Sunward-most point of the magnetopause, the magnetosheath is highly compressed, with a high density, a high temperature and a small flow velocity. As the magnetosheath then expands and flows over the magnetosphere, its density and temperature decrease and its velocity increases, eventually rejoining the high-speed solar wind far down tail. Therefore, when the reconnected field lines cross the magnetopause near its Sunward-most location, the magnetosheath plasma that flows into the cusp will have its highest densities and temperatures. As the plasma convects away from the reconnection site and the magnetopause crossing point of the field line moves to higher latitudes, the magnetosheath source plasma will have a lower density and temperature and higher flow velocity that eventually becomes directed away from the cusp. Consequently, the density and temperature of plasma entering the cusp will be lower at the higher latitudes, as seen in figure 2.

As the magnetosheath accelerates around the magnetosphere, it eventually becomes supersonic, with its downtail bulk flow speed becoming much larger than the thermal speed of the ions. Within the thermal distribution of the ion velocities, only a very small number of ions will then have velocities directed back toward Earth. Although the high-latitude magnetospheric field lines are still interconnected with the magnetosheath, which still has an appreciable density and temperature, no magnetosheath ions will be detected deep within the magnetosphere on these field lines. This effect contributes to the disappearance of the magnetosheath ions at high latitudes.

Finally, the spatial characteristics of the cusps are affected to some extent by the acceleration of the magnetosheath plasma as it crosses the open magnetopause. The acceleration that particles receive is related to the strength and relative orientation of the electrical current and the electric field at the magnetopause. On the low-latitude dayside magnetopause, the current is parallel to the large-scale electric field (see figure 1(*d*) of MAGNETOSPHERE OF EARTH), causing the particles to be accelerated and gain energy as they cross the magnetopause. At high latitudes, the magnetopause current reverses direction, becoming anti-parallel to the large-scale electric field. Particles that cross the magnetopause at these locations will be decelerated. This acceleration and deceleration across the magnetopause tends to enhance the entry of magnetosheath plasma in the low-latitude portion of the cusp, and inhibit magnetosheath entry at high latitudes.

Note, however, that even in the absence of magnetosheath ions, the magnetosheath electrons are detected continuously throughout the cusp and polar cap on the open field lines. Because the electrons have much higher speeds than the ions, due to their smaller mass, the electron thermal speed remains higher than the tailward magnetosheath bulk flow speed. The thermal distribution

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of magnetosheath electrons will, therefore, always contain a large fraction of the total electron density with velocities directed earthward along the interconnected magnetic field. Because the magnetosheath electrons entering the magnetosphere are flowing into a region where magnetosheath ions do not have access, the charge balance must be accomplished by a background population of magnetospheric ions, probably of ionospheric origin. Some deceleration of the electrons is likely to occur at the magnetopause to maintain charge balance with the less dense background ions. The steady entry of magnetosheath electrons throughout the entire open polar cap is referred to as polar rain. Polar rain electrons are a direct tracer of the solar wind electrons that flow rapidly along the magnetic field and freely penetrate into the open magnetosphere.

The cusp has been described so far as a steady region, whose properties depend on location within the region. The cusp, however, is a dynamic region that responds rapidly to the changing solar wind conditions and to the rate of energy coupling between the solar wind and the magnetosphere. Because of the direct link between the cusp and the dayside magnetopause, the measurements in the cusp are valuable for studying magnetic reconnection and its role in energy transfer processes in the magnetosphere as well as more generally in space and laboratory plasma.

With steady reconnection, the spatial structure measured by a satellite passing through the cusp should progress smoothly as it moves from low to high latitudes, as described above. At each new latitude, the plasma will have slightly different characteristics, reflecting the slightly different time that the magnetic field line has been open to magnetosheath plasma entry. When the reconnection rate is not steady, there will be regions in the cusp which underwent reconnection some time ago that directly neighbor regions that only recently reconnected. In this case, there will be discontinuous jumps in the observed cusp plasma between two spatially contiguous regions reflecting an abrupt change in the length of time that the magnetic field lines have been open. The changes in the plasma characteristics across these jumps have been used to estimate quantitatively the variations in rate of reconnection. It has been found that reconnection often occurs in short bursts, of order 1 min or less, separated by roughly 10 min.

Issues for the future

The cusp is a dynamic region in the magnetosphere that directly connects the flowing solar wind with Earth's ionosphere and upper atmosphere. Although the dominant processes that form the cusp and determine its interaction with neighboring regions are understood at a basic level, many important issues remain unresolved. One important feature of the cusp is that the observed plasma often shows considerably more spatial and/or temporal structure than the basic picture presented here can describe. For example, measurements of the cusp particles, such as those illustrated in figure 2, at times show multiple, overlapping bands of particles, rather than a single band. It is not known what processes at the magnetopause or within the magnetosphere cause this structuring in energy. Also, the measurements typically become more complex as a spacecraft moves away from local noon. It is often unclear if the cusp particles crossed the magnetopause on open magnetic field lines, resulting from reconnection, or if they crossed closed magnetic field lines through some other process. Finally, from measurements by a single satellite, there is always an ambiguity between temporal and spatial changes as a region is traversed. The properties of magnetic reconnection or the structure of the magnetopause and magnetosheath that are inferred from cusp measurements depend critically on our ability to differentiate temporal and spatial variability. These issues are topics for future research, where multisatellite missions, theoretical analyses and numerical simulations will play key roles in advancing our understanding of the cusps.

Magnetosphere of Earth: Geomagnetic Storms and Solar Wind Origins

In the mid-1800s extraordinary disturbances accompanied by a great decrease in the horizontal component of the Earth's magnetic field were termed 'GEOMAGNETIC STORMS', or simply 'magnetic storms'. The challenge facing modern space physics in understanding the electromagnetic structure and dynamics of the solar–terrestrial plasma environment originated historically in the study of geomagnetic storms. The effects of geomagnetic storms in the ionosphere and thermosphere are the result of energy inputs from a chain of processes involving kinetic, chemical and electrodynamic coupling between the magnetosphere, ionosphere and thermosphere. The importance of predicting magnetic storms lies not only in its 'academic' value in tracing the way the magnetosphere and ionosphere extract solar wind energy, but also in its practical aspects, influencing human and societal problems such as the effects on communications and satellite anomalies.

Geomagnetic storms are multifaceted phenomena that originate at the Sun and occur in the solar wind, the magnetosphere, the ionosphere and the thermosphere. What causes storms, how is the ring current formed and intensified during magnetic storms, what are the effects of the storm in the ionosphere, how do changes in the magnetosphere–ionosphere system affect the Earth's upper atmosphere, and how can we predict the occurrence and intensity of the storms? These are some of the major questions relating to magnetic storms (Kamide *et al* 1998, Tsurutani *et al* 1997). Magnetic storms must be understood as a chain of processes from the Sun to the Earth when considering the many different aspects of magnetic storms and testing different scenarios on the cause-and-effect relationship of a variety of magnetic storm phenomena.

What is a geomagnetic storm?

Geomagnetic storms at low latitudes

Geomagnetic storms were first detected by using ground magnetograms. The characteristic signature of a magnetic storm is a depression in the magnetic field lasting more than some tens of hours. This depression is caused by the ring current in the magnetosphere encircling the Earth and flowing westward at a geocentric distance of 2–7 R_E (where R_E is the Earth's radius) (see MAGNETOSPHERE OF EARTH: RING CURRENT). A general picture of a typical magnetic storm is shown in figure 1 in terms of variations in the *Dst* index constructed from *H* component magnetograms at low and middle latitudes, where *H* is the horizontal component of the Earth's vector magnetic field. Note that *Dst* is the average of magnetic perturbations at mid- and low-latitude stations distributed in longitude.

A geomagnetic storm customarily involves three phases, beginning with a sudden increase in the *H* component (storm sudden commencement or SSC),

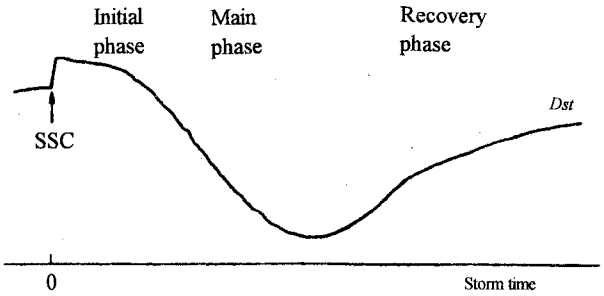

Figure 1. Schematic diagram of a typical geomagnetic storm in terms of the *Dst* index. For the definition of the initial, main and recovery phases, see text.

followed by a period of arbitrary length in which the elevated field does not change very much. This period is called the *initial phase*. The sudden increase in the geomagnetic field is caused by an interplanetary shock. The initial phase is followed by the *main phase* where the development of a depressed *H* component occurs, enduring over a period of a few to several hours. The storm typically concludes with a slow recovery toward the pre-storm level over hours to tens of hours, i.e. the *recovery phase*.

Energy of the ring current

The occurrence of a magnetic storm can most clearly be identified by the existence of the main phase, during which the magnetic field on the Earth's surface is significantly depressed. The depression has a strong latitudinal dependence, being maximum at the equator and minimum at the poles. The intensity of a magnetic storm is commonly defined by the minimum *Dst* value, or the maximum depressed *Dst* magnitude, at the main phase. The depression of the magnetic field during the main phase is explained as the effect of the ring current in the magnetosphere. The ring current is carried primarily by energetic (20–200 keV) ions (see MAGNETOSPHERE OF EARTH). During the recovery phase, the ring current decays due to charge exchange, Coulomb interaction and wave–particle interaction processes in the volume of space occupied by the ring current particles.

The magnitude of a magnetic storm, measured by the *Dst* index, is approximated by the total energy of ring current particles, *E*, through the so-called Dessler–Parker–Sckopke relationship:

$$Dst^*/B_0 = 2E/3E_m$$

where Dst^* is the *Dst* value after a correction for magnetopause currents due to solar wind pressure, B_0 is the magnetic field at the equator on the Earth's surface and $E_m (= 8 \times 10^{17}$ J) is the total magnetic energy of the geomagnetic field outside the Earth. Note that *Dst* includes the magnetic effects not only of the symmetric ring current but of other currents, such as ionospheric, field-aligned and tail currents. According to the above

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

relationship, the *Dst* value is, to a first approximation, linearly proportional to the total energy of the ring current particles. This is the reason why the *Dst* index is used practically as a measure of the intensity of geomagnetic storms.

What is the minimum level in *Dst* is required for a geomagnetic storm? In fact, assigning a threshold serves only an operational purpose in arranging 'storm-time' data and has no physical basis. Small storms can be substorms (see MAGNETOSPHERE OF EARTH: SUBSTORMS). It is understood that intense storms are those with the peak *Dst* value of −100 nT or less.

Geomagnetic storms at high latitudes

During a magnetic storm, defined by the magnetic depression at low and mid latitudes, intense substorms take place successively at high latitudes. A magnetospheric substorm is a transient phenomenon initiated on the night side of the Earth in which a significant amount of energy is deposited into the auroral ionosphere and the inner magnetosphere (Rostoker *et al* 1980). A basic question remains unanswered involving whether a magnetic storm is a superposition of intense substorms, each of which constitutes an elementary storm. That is, it is not clear whether the occurrence of substorms is a necessary condition for a magnetic storm or merely coincidental (Siscoe 1997).

Magnetic storms in interplanetary space

When spacecraft observations of solar wind properties became available, it was discovered that the solar wind magnetic field, i.e. the interplanetary magnetic field (IMF), plays a major role in generating magnetic storms. The primary cause of magnetic storms is an intense, long-duration, southward IMF. In fact it became possible to model successfully the growth of the ring current using, as input, only the dawn–dusk component of the interplanetary electric field in the ecliptic plane normal to the Sun–Earth line. By that time it was recognized that an SSC is not a necessary condition for a storm to occur, and hence the initial phase is not an essential feature. The only essential feature of a geomagnetic storm is the significant development of a ring current and its subsequent decay. Note also that if an interplanetary shock is not followed by southward magnetic fields, the sudden increase in the geomagnetic field is called an SI (sudden impulse).

Solar origins of geomagnetic storms

It has long been known that geomagnetic storms start at the Sun. In fact, geomagnetic storms begin when disturbances in the solar wind reach the Earth's magnetosphere. Solar flares and coronal mass ejections (CMEs) are the most energetic of various types of coronal disturbances, although a number of geomagnetic storms are also generated by CORONAL HOLES.

It is important to understand how CMEs are created at the Sun and how they interact with interplanetary structures. Considerable uncertainties exist, however, regarding their magnetic configuration, which must play a key role in unveiling the physics for different sizes of interplanetary CMEs (ICMEs) and such changes as the dimming of coronal features, which is known to be crucial for generating intense geomagnetic storms. One of the major problems is that it is difficult at present to visualize the three-dimensional structure of CMEs and the corresponding magnetic field lines extending into interplanetary space.

Flares and CMEs

The dominant solar events that occur near the maximum sunspot phase of the solar cycle are impulsive ejecta, often called solar flares and CMEs, although how these two elements of solar activity are interrelated is not well understood (see SOLAR CORONAL MASS EJECTION: OBSERVATIONS). CMEs, distinct particle and field structures with field orientations not generally favoring the typical spiral equatorial orientation, are most numerous near the solar maximum and have been demonstrated to cause major geomagnetic storms at that phase of the solar cycle, and at other phases as well.

These events occur on a wide variety of spatial scales and have a variety of speeds, but the ones that are most effective in creating magnetic storms are statistically shown to be rapid, with speeds exceeding the ambient wind speed, so that a forward shock is formed. The fast ejecta are in general associated with flares. There are three essential features of CMEs near the Sun: bright outer loops, a dark region and filamentary structures near the coronal base. It is not well understood, however, whether all these propagate efficiently into interplanetary space.

Coronal holes

During the declining phase of the solar cycle, another type of solar event is shown to dominate, in which the coronal holes emerge from polar regions and extend into, and sometimes far across, the equatorial regions. Coronal holes represent low-temperature regions and the areas of 'open' magnetic field lines. Fast (750–800 km s^{-1}), tenuous plasma is continuously emitted from these solar regions.

When the coronal holes expand effectively toward the equator during the declining phase of the solar cycle, high-speed streams escaping from them create geomagnetic storms. Because these hole regions are long-lived and evolve relatively slowly, they appear to 'corotate' with the Sun over a 27 day period as observed from Earth, leading to the so-called recurrent geomagnetic storms.

Solar wind causes of geomagnetic storms

The causes of geomagnetic storms are strong dawn-to-dusk electric fields in the solar wind, which directly transport solar wind energy into the magnetosphere, driving plasma convection in the magnetosphere. These electric fields are caused by a combination of two factors: solar wind velocity and the southward IMF. Of the two, the southward field is probably more important because of its greater variability, while the solar wind velocity is empirically found to be a minor factor. Solar wind ram

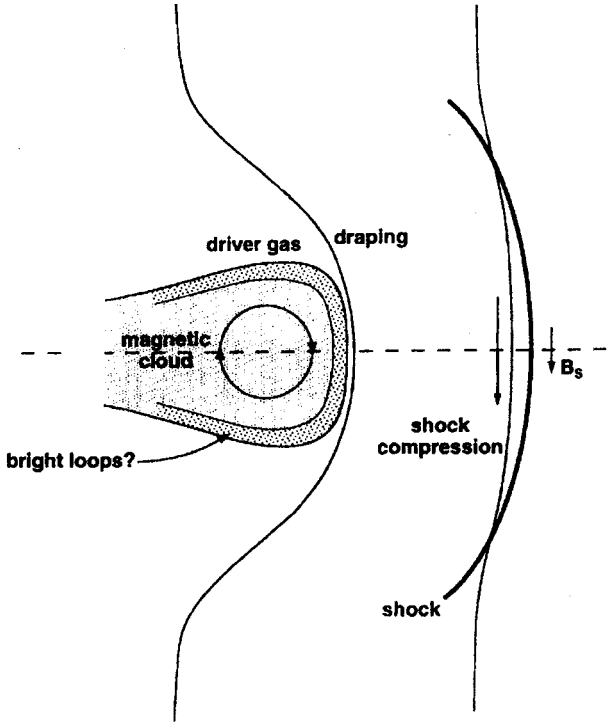

Figure 2. Schematic diagram of regions of intense interplanetary magnetic fields in solar ejecta typically seen near solar maximum. After Tsurutani and Gonzalez (*J. Atmos. Terr. Phys.* **57** 1369 (1995)).

pressure is also important in ring current energization. The specific circumstances or solar wind conditions typically leading to enhanced dawn–dusk electric fields (a B_s magnitude greater than 10 nT) of substantial duration (longer than 3 h) were identified to generate intense geomagnetic storms. There can be a variety of causes of enhanced southward IMF of long duration in the high-speed stream region.

Solar ejecta

Figure 2 shows schematically the regions of possible intense IMF of such solar ejecta, i.e. driver gas, detected at 1 AU. As a fast plasma and field structure propagates from the Sun through interplanetary space, it tends to compress the slower plasma ahead, creating a 'sheath' between the shock and the interplanetary manifestation of the ejecta. The sheath fields leading the rapid ejecta often contain substantial north–south field components, possibly due to compression and draping of the ambient IMF over the ICMEs. Both the remnant fields and plasma in the ejecta proper and those of the sheath can generate intense geomagnetic storms, if the IMF is directed southward.

Most 'geoeffective' ICMEs, giving rise to the largest geomagnetic storms, are magnetic clouds, a subset of ejecta characterized by high IMF magnitude, low field variance and large-scale coherent field rotations, often including large north–south components. This high-field region is typically a low-β ($\sim$0.1) plasma, where β is defined as the ratio of plasma pressure to magnetic pressure. The field reversals within magnetic clouds feature magnetic field reconnection with the Earth's field during the period of the southward field and a lack of reconnection during the northward field. The storm initial phase is caused by increased ram pressure behind the fast shock. The higher plasma density and higher velocity combine to form a much larger solar wind ram pressure. This pressure compresses the Earth's magnetosphere considerably, increasing the field magnitude near the equator. Since interplanetary shocks are thin discontinuities, they create an abrupt onset of the initial phase, which has been called an SSC.

If there are large-amplitude, long-duration southward field intervals in either the sheath or the ejecta proper, a main phase will follow. The storm recovery usually begins as the magnetic field in the magnetic clouds becomes less southward and gradually rotates to a northward direction. However, there is no guarantee that southward magnetic field events will follow the shock, and therefore a storm main phase may not follow the shock.

There are numerous mechanisms that can lead to north–south variations in the sheath, such as shock compression and draping around the ejecta (see figure 2). Intense southward fields can be found in each of the ejecta itself and the sheath. When they are found in both regions simultaneously, the resultant geomagnetic storm should have a two-step main phase.

Corotating interaction region

If a coronal hole is at lower latitudes, the Earth's magnetosphere will be bathed in this stream once each solar rotation. High-speed streams emanating from the coronal hole can create a geomagnetic storm. Typically the solar wind containing low-speed (less than 400 km s^{-1}) and high-density (tens $\times$ 10^6 of particles/m^3) streams lies ahead of the fast stream in interplanetary space. The interaction of the rapid stream with the slow stream ahead tends to create a plasma and field compression. This is called a corotating interaction region (CIR; see SOLAR WIND: COROTATING INTERACTION REGIONS). CIRs are bounded on the leading and trailing edges by forward- and reverse-propagating compressional waves respectively.

Figure 3 shows schematically the formation of CIRs in which magnetic field fluctuations are present in the high-speed stream proper. The magnetic fields of the lower speed tend to be more curved and those of the higher speed more radial. The stream–stream interface (IF) is formed at the boundary between the rapid and slow-speed plasmas. CIRs are characterized normally by intense magnetic fields that reach 30 nT.

A 27 day modulation in geomagnetic activity has been noted since the nineteenth century. This periodicity was later discovered to arise from high-speed solar wind streams originating in coronal holes. Although the high-speed wind from coronal holes generally carries

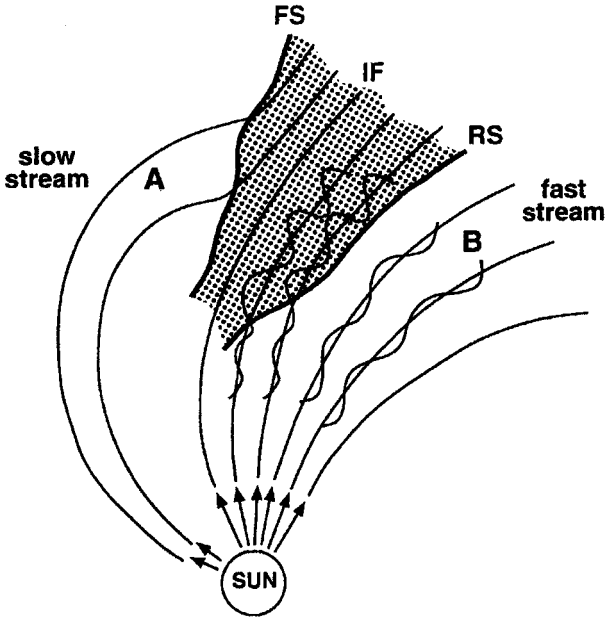

Figure 3. Schematics of the formation of corotating interaction regions (CIRs) during the declining phase of the solar cycle. The interaction between a high-speed stream (B) and a slow-speed stream (A) are shown together with the CIR (shaded). The forward shock (FS), interface surface (IF) and reverse shock (RS) are also indicated. After Tsurutani *et al* (*Geophys. Res. Lett.* **22** 3397 (1995)).

relatively low field magnitude and a radial orientation not conductive to production of steady and substantial north–south fields, CIRs resulting from the interaction of this rapid wind with slower, denser streamer wind produce geoeffective field compressions and deflections. Geomagnetic storms associated with CIR-like plasma signatures generally lack the sudden commencements. These storms are termed gradual geomagnetic storms.

Enhancement/modulation effects of geomagnetic storms

One remarkable characteristic of the solar wind escaping from coronal holes is the presence of continuous Alfvénic activity, consisting of large-amplitude, quasi-periodic fluctuations in the IMF orientation with periods from tens of minutes to a few hours. This activity is generally in phase with similar fluctuations in the solar wind flow direction. Thus, in the interplanetary medium following CIRs, the southward field components associated with these Alfvén waves cause reconnection with the Earth's magnetic field and small injections of plasma into the inner magnetosphere. Because of such persistent substorm activity, prolonged recovery phases of the storms will result. Events of this type are known as 'high-intensity, long-duration, continuous auroral electrojet (*AE*) activity' (HILDCAA) events. The average north–south (B_z) component in HILDCAA intervals is nearly zero, but the induced reconnection in the magnetospheric response results in a continuous occurrence of substorms of almost equal intensity.

Another mechanism which can modulate storm activity is based on the simple geometric mapping from the solar equatorial system, in which the prevailing IMF is ordered, into a magnetospheric system which then orders the magnetospheric response. This mapping, from GSEQ (solar equatorial) to GSM (solar magnetospheric) coordinates, was described by Russell and McPherron (1973). The result of the offsets between the solar equatorial, ecliptic and terrestrial rotational planes is to create a modulation in the rotation from the transverse solar equatorial IMF component (GSEQ B_y) into the north–south field in the magnetospheric system (GSM B_z). The tilt of the terrestrial dipole adds a diurnal component as well. The combined effect is such that negative GSEQ B_y, corresponding to the 'toward sector' IMF, maps most directly to negative GSM B_z at 2200 UT on 5 April, while positive GSEQ B_y ('away sector') maps most directly to negative GSM B_z at 1000 UT on 5 October.

This modulation, called the Russell–McPherron effect (see section on solar cycle distribution below), has been shown to increase in amplitude with increasing activity thresholds and to persist even for very disturbed geomagnetic conditions. Figure 4 shows a seasonal variation of the number of intense storms with clear maxima at the equinoxes.

Storm/substorm relationships

Successive occurrence of substorms

Intense substorms occur frequently during the main phase of magnetic storms. Many researchers believe, or tacitly assume, that magnetic storms develop as a result of the frequent occurrence of substorms. There are certainly good reasons to believe that a geomagnetic storm consists of intense substorms. During episodes of substorm activity, energy can be deposited into the inner magnetosphere, leading to the formation of the so-called partial ring current, which is connected to the substorm electrojet through field-aligned currents. If intense substorms occur successively when the effects of previous substorms still remain in terms of the partial ring current, the local time extent of that partial ring current could increase and evolve into a complete ring. In other words, an individual substorm may cause only a 'mini' ring current, but if substorms occur frequently enough, the injected ring current particles accumulate in the trapping region, forming the symmetrical ring current as a geomagnetic storm.

Is the successive occurrence of many intense substorms a necessary condition for a magnetic storm? We should refocus on the question of why some large substorms are associated with significant increases in the ring current, while other equally large substorms have little effect on it. The main question which then arises regarding the storm/substorm relationship involves the nature of the physical processes which lead to the growth of the ring current during magnetic

storms. Substorms were in some way thought to be responsible for the growth of the ring current. In fact, early studies of 'injections' of energetic particles into the inner magnetosphere suggested that the occurrence of substorms led to the acceleration of particles to energies which allowed them to be effective current carriers in the ring current. However, it later became clear that the storm-time ring current was carried by energetic ions with energies typically in excess of several tens of keV. The question of how ring current particles attain their energies and whether substorm disturbances play an integral role in that process is still open.

Ring current composition

Questions continue with regard to the formation, population and composition of the ring current during magnetic storms, as well as the loss mechanism of ring current particles during the storm recovery phase that sometimes takes only several hours, but occasionally several weeks. The relative importance of the solar wind and the ionosphere as the origin of ring current ions in the 20–200 keV energy range seems to have been identified recently. The ionospheric component has been shown to be most abundant during the main phase of intense magnetic storms. This implies that ionospheric ions are accelerated upward by parallel electric fields or by perpendicular heating (involving plasma waves) leading to ion conic distributions, both of which are associated with the onset

of substorm expansion.

Observations of field-aligned ionospheric ions indicate that injection occurs over a broad range of geocentric distances. These ions are trapped through an efficient magnetospheric process, becoming the main contributors to the storm-time ring current. Therefore, the successive occurrence of intense substorms appears to be a necessary condition for the main phase of magnetic storms. This in fact supports the classical notion that a magnetic storm consists of continual substorm activity.

On the other hand, an enhanced solar wind electric field of sufficient duration directly drives magnetospheric convection, which, in turn, enhances the ring current at the same time. Substorms are often triggered in the course of this process of extraction of power from the solar wind required to build up the storm-time ring current. In this scenario, the action of substorm activity is merely a byproduct of the overall energy process in the magnetosphere–polar ionosphere coupling.

Although the ring current as expressed by Dst can be reproduced mainly by changes in the large-scale electric field driven by southward IMF, the role of substorms is an issue suitable for further study in quantitative detail. In other words, the relationship between substorms and storms is currently poorly understood, and therefore basic questions remain unanswered regarding the hypothesis of whether a magnetic storm represents a superposition of intense substorms.

Solar cycle distribution of geomagnetic activity

ICMEs and CIRs are considered the primary causes of the enhanced duskward electric fields in the solar wind driving geomagnetic storms, while HILDCAAs and the Russell–McPherron effect can be modifiers which do not produce storms without an ICME or CIR, but enhance storms once they are generated. In reality, however, these four mechanisms couple differently from event to event, and even within a geomagnetic storm, from phase to phase. For example, the enhanced field in shocked solar wind can map to even a stronger or weaker southward IMF in GSM coordinates, depending on different seasons. This may be called the 'post-shock Russell–McPherron effect'. CIRs with a southward IMF can also be effective when the time of year is favorable.

ICMEs and CIRs as the primary drivers for strong geomagnetic storms may explain the strong dependence of geomagnetic activity on the solar cycle. Within a solar cycle, there are two peaks in geomagnetic activity, one somewhat before and the other following solar maximum. For two solar cycles, figure 5(*a*) shows the yearly averaged sunspot number and the hours when $Dst < -50$ and -100 nT. It is clear that the number of intense magnetic storms measured by the intervals of low Dst follow the sunspot cycle faithfully at the beginning and toward the ending of the solar cycle, but have pronounced dips during the years of solar maximum (near 1980 and 1990). The occurrence rate of ICME is shown to follow the sunspot cycle, while strong CIRs are most predominant during the declining phase due to the presence of large polar coronal holes extending into lower latitudes. Thus, a simple superposition of occurrence rates of rapid ICMEs and strong CIRs might well produce the double-peaked pattern of figure 5(*a*). Figure 5(*b*) is another example of such a dual-peak distribution, but only for solar cycle 21.

Another statistical trend in geomagnetic activity is its modulation in accordance with the 22-year cycle (Cliver *et al* 1996). The average levels in overall geomagnetic activity are shown to be highest during the rising phase of odd-numbered sunspot cycles and during the declining phase of even cycles. These 'double-solar-cycle' variations can have the following two sources: the first is a combination of the Russell–McPherron effect and the heliographic latitude dependence of the IMF strength, as well as the solar magnetic polarity. The second is an intrinsic difference in large-scale solar magnetic fields, manifested as changes in the solar wind between odd and even cycles. The odd- and even-numbered cycles have some differences in average solar wind speed profiles. A variety of evidence exists for systematic differences in solar properties between even and odd cycles. It must be noted, however, that studies to date have used the *aa* index due to its availability for over 100 years. The *aa* index reflects geomagnetic activity at sub-auroral latitudes. Evidence for a 22 year period in such an

index does not necessarily guarantee similar modulation in geomagnetic storm activity.

Space weather predictions

Throughout Earth and human history, people have stood in awe of the wildly changing colors and forms of auroras, which occur most frequently during geomagnetic storms (see AURORA). 'Space weather' refers to conditions in the solar wind, magnetosphere, ionosphere and atmosphere that can influence the reliability of space and ground-based technological systems. In other words, the aurora is one of the end results of space weather. Our reliance on technological systems, such as spacecraft missions, power systems, navigation systems and communications, is growing, and these systems are shown to be vulnerable to the unpredictability of space weather conditions. In fact, the risks for disruption of satellite operations, communications and power grids on the ground could be minimized if reliable forecasts of space weather were possible. Studies have already begun aimed at predicting the sequence of extreme conditions that occur in the solar–terrestrial coupling system.

Space weather plays an ever-increasing role in our society as human beings develop more and more delicate technologies in space and on Earth (see SOLAR–TERRESTRIAL CONNECTION: SPACE WEATHER PREDICTIONS). In view of the crucial effects of geomagnetic storms on such human-societal systems as radio communications and satellite drag, there is a strong need for prediction schemes to be continually upgraded. It is essential to integrate our observation and modelling efforts in the space weather project.

The goal of space weather studies is to be able to predict the occurrence of intense geomagnetic storms. How does one monitor the intensity of geomagnetic storms? Their intensity is commonly defined by the minimum *Dst* value during the magnetic storm, which is equivalent to the maximum *Dst* magnitude at the main phase. It may be natural to assume that when a major event is observed near the Earth, something major is also occurring throughout the chain of processes from the Sun to the Earth, seriously affecting the space surrounding the Earth. Is this assumption really correct in magnetic storms? Is a large disturbance in the interplanetary structure really necessary to generate a major magnetic storm? Is it meaningful to rely on the minimum *Dst* value to define the storm intensity?

During the largest magnetic storms, the main phase often goes through two steps. That is, well before the *Dst* decrease has fully recovered to its pre-storm level, a succeeding decrease tends to occur. If this is truly the case, the largest magnetic storms consist merely of two medium-size storms. In other words, what is perhaps needed in generating an intense magnetic storm are two separate regions of southward IMF in an interplanetary structure. One of the most important factors in generating intense magnetic storms is perhaps the slow decay rate of the ring current.

Magnetosphere of Earth: Geomagnetic Tail

The geomagnetic tail is an elongated region of the MAGNETOSPHERE OF EARTH extending from the near-Earth space in the antisunward direction. It acts as a giant energy reservoir for the magnetosphere and is therefore an important participant in dynamic processes such as GEOMAGNETIC STORMS and substorms (see MAGNETOSPHERE OF EARTH: SUBSTORMS).

The geomagnetic tail has a roughly cylindrical shape with two D-shaped lobes which contain strong magnetic fields and cool plasma lying back to back with a region of hot plasma and weak magnetic field between. The geomagnetic tail extends far beyond the lunar orbit, at least out to 1.5 million km from the Earth, and has a diameter of about 0.3 million km. The magnetic field points toward the Earth in the northern lobe and away from the Earth in the southern lobe. The field magnitude decreases from about 100 nT at the inner edge of the geomagnetic tail (at 40 000 km from the Earth) to about 10 nT reached around 600 000 km from the Earth; tailward of that distance the field magnitude is almost constant at about 10 nT. These antiparallel fields in the tail lobes are supported by a cross-tail current sheet embedded in a thicker plasma sheet roughly in the equatorial plane (see MAGNETOSPHERE OF EARTH: PLASMA SHEET). The average electric field is about $0.3\,\mathrm{mV\,m^{-1}}$ in magnitude and oriented in the dawn-to-dusk direction across the geomagnetic tail. The plasmas enter the tail either from the solar wind or from the Earth's ionized upper atmosphere, the ionosphere, and are in continuous large-scale convective motion under the electromagnetic forces (see SOLAR–TERRESTRIAL CONNECTION: COUPLING BETWEEN SOLAR WIND, MAGNETOSPHERE, IONOSPHERE, AND NEUTRAL ATMOSPHERE, MAGNETOSPHERE OF EARTH: CONVECTION).

The solar wind energy enters the magnetosphere at a variable rate proportional to the solar wind velocity and interplanetary magnetic field direction. When the interplanetary magnetic field points southward (opposite to the magnetospheric field), magnetic reconnection opens the magnetosphere allowing for energy, flux and momentum transfer from the solar wind to the magnetosphere. When the interplanetary field points northward, the magnetosphere is closed and the energy transfer to the magnetosphere is much reduced. During periods of southward interplanetary field, energy extracted from the solar wind is stored in the geomagnetic tail in the form of magnetic field energy and later explosively released in a sequence of events known as a magnetospheric SUBSTORM. During substorms, MAGNETIC RECONNECTION is initiated at the center of the geomagnetic tail about 150 000 km from the Earth. As a consequence, a portion of the plasma sheet tailward of this distance is ejected from the magnetosphere in a magnetically confined plasma bubble, a plasmoid (see figure 1). This sequence lasts 2–4 h during which about 10^{15} J of energy flows through the geomagnetic tail. The magnetosphere is continuously in a dynamic state, where this energy storage–release cycle is repeated on average 4–5 times per day. The substorm process is analogous to a dripping faucet where water (energy) is constantly fed to the water drop (geomagnetic tail), the drop grows until it falls (plasmoid ejection) and when more water is added the drop starts to grow again.

The formation of a geomagnetic tail is a characteristic of the planet–solar wind interaction: each of the solar system planets has a PLANETARY MAGNETOSPHERE and a tail. Furthermore, even smaller bodies with active plasma environments such as COMETS have a tail, although in the case of comets the magnetic forces are weak and the dynamics governed by the ion motion is quite different.

Structure of the geomagnetic tail

Magnetic fields

The structure of the geomagnetic tail is governed by the magnetospheric magnetic field. In the near-Earth region (inside $7R_E$, $1R_E \simeq 6400$ km), the magnetic field is dominated by the nearly dipolar internal geomagnetic field (giving about 30 000 nT at the Earth's surface at the equator). Further away, the magnetospheric magnetic field is a combination of the internal field and a magnetic field created by extraterrestrial current systems induced by the interaction of the solar wind and interplanetary magnetic field with the internal geomagnetic field. The solar wind pressure compresses the dipole field on the dayside. Magnetic reconnection alters the connectivity of the field lines in the polar caps creating a class of 'open' field lines, which are connected to the Earth only at one end. These open field lines created on the dayside are carried downstream in the solar wind flow and stretched into the antiparallel field structure of the tail lobes. The lobe field lines are separated by a cross-tail current sheet. Within the current sheet, at about $100R_E$ from the Earth in the tailward direction, there is another quasi-permanent reconnection region called the distant neutral line. Here the lobe field lines are again reconnected creating 'closed' field lines (connected to the Earth at both ends) Earthward of the neutral line and 'solar wind' field lines (completely disconnected from the Earth) tailward of the neutral line. This magnetic field topology is a permanent structure in the geomagnetic tail.

The Earth's orbital motion causes a small aberration from the Sun–Earth line in the solar wind velocity direction in an Earth-based coordinate system; the geomagnetic tail is aligned along the velocity direction, on average 4° from the Sun–Earth line. The Earth's dipole axis is tilted 11° relative to the rotation axis and the rotation axis is tilted 23° relative to the ecliptic plane normal. Therefore, the orientation of the dipole axis varies between ±35° during the year (pointing toward the Sun during the northern hemisphere summer and away from the Sun during the northern hemisphere winter) and ±11° daily owing to the Earth's rotation. Because the inner magnetosphere current systems follow the dipole motions, the center of the cross-tail current sheet is (3–4)R_E below the Sun–Earth

line during the northern hemisphere winter and above the Sun–Earth line during the northern summer.

During periods of northward interplanetary magnetic field, magnetic reconnection occurs at high latitudes poleward of the cusps reconfiguring already open magnetic field lines. When the interplanetary field has a component also in the cross-tail direction, reconnection occurs predominantly in two quadrants of the geomagnetic tail (northern dawn and southern dusk for dawn-to-dusk directed interplanetary field) and the reconnected solar wind field lines exert a tangential stress on the lobe field lines (proportional to the field component tangential to the magnetopause). This leads to twisting of the magnetotail such that the plasma sheet is at an angle with respect to the equatorial plane. During periods of southward interplanetary field, the twisting is weaker because the tangential stress in the reconnection-dominated quadrants is smaller. The effects of the interplanetary field are larger in the distant tail where the lobe field strength is smaller.

The large-scale extraterrestrial current systems are permanent features of the geomagnetic tail but are highly variable both in intensity and location (see figure 2). Additional, temporary current systems form during dynamic processes. The cross-tail current in the geomagnetic tail flows in the dawn-to-dusk direction and is closed by currents along the magnetospheric boundary, the magnetopause (see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE). Typical current densities are 10–100 nA m^{-2} in the inner tail (at $15R_E$) and 1 nA m^{-2} in the distant tail, the total current is roughly 2–3 MA. The ring current encircles the Earth near the equatorial plane in the inner magnetosphere (see MAGNETOSPHERE OF EARTH: RING CURRENT). The current density is less than 1 nA m^{-2} during quiet times and 1–10 nA m^{-2} during geomagnetic storms; the total current varies between 0.1 and 5 MA. Two large-scale magnetic-field-aligned current systems couple the magnetosphere and the ionosphere. The region 1 currents flow at high auroral latitudes, originating from magnetospheric boundaries and from the geomagnetic tail. These currents flow toward the ionosphere in the morning sector and away from the ionosphere in the evening sector. The region 2 currents flow at subauroral latitudes from the morning-sector ionosphere to the equatorial geomagnetic tail and from the tail to the evening-sector ionosphere. These currents carry roughly 1–3 MA; the current density is a few μA m^{-2} at the ionospheric altitudes and 3 orders of magnitude lower in the geomagnetic tail. The most important temporary current system is the substorm current wedge, which connects the geomagnetic tail and the auroral ionosphere during the substorm expansive phase carrying roughly 1 MA.

Electric fields

The solar wind–magnetosphere interaction induces an electric field in the dawn-to-dusk direction. The plasma at low altitudes in the plasmasphere co-rotates with the Earth, which gives rise to an electric field pointing radially inward (see MAGNETOSPHERE OF EARTH: PLASMASPHERE). The combination of these two components gives the large-scale tail electric field typically about 0.1–0.5 mV m^{-1}, being larger during dynamically active periods (southward interplanetary magnetic field) and smaller during quiet times (northward interplanetary field). In addition to that, electric fields induced by the magnetic field configuration changes (Faraday's law $\boldsymbol{\nabla} \times \boldsymbol{E} = -\partial \boldsymbol{B}/\partial t$), intense and strongly fluctuating small-scale electric fields, and a variety of plasma waves are present in the geomagnetic tail.

Plasmas

The geomagnetic tail has two plasma sources, the solar wind and the dense ionosphere. Both source populations are very cold: the plasma temperature in the solar wind is around 10 eV (1 eV corresponds to 11 600 K), and in the ionosphere about 0.1 eV. The solar wind plasma (or actually plasma in the magnetosheath between the magnetopause and the bow shock) enters the magnetosphere via dayside reconnection; a portion of the particles enter through the magnetospheric boundaries also along the geomagnetic tail. In this plasma mantle, the cold plasma flows tailward typically at about 200 km s^{-1} (somewhat slower than in the adjacent magnetosheath) and drifts across the tail lobes at a speed of about 20 km s^{-1} toward the plasma sheet. The ionospheric plasma rises both from the polar cap and from the auroral regions; especially the dayside cusp region is an effective source for magnetospheric plasma (see MAGNETOSPHERE OF EARTH: DAYSIDE CUSP). In the distant tail, the solar wind source dominates. The accelerated ionospheric particles form an important source for the $\geq$15 keV inner-tail population especially during geomagnetically active times.

The combination of the electric and magnetic fields in the geomagnetic tail controls the large-scale plasma motions. In the tail lobes, the dawn-to-dusk electric field and Sun–Earth-directed magnetic field cause the plasma to drift toward the plasma sheet. Plasmas in the tail lobes and plasma mantle are cool; their energies are below a few hundred eV and densities less than 0.1 particles cm^{-3}. Within the plasma sheet, the magnetic field is predominantly northward and the plasma convects Earthward. As the electric field is parallel to the cross-tail current, the plasma is energized ($\boldsymbol{j} \cdot \boldsymbol{E} > 0$) to form the plasma sheet population whose mean energy is a few keV and average density a few particles cm^{-3}. Between the lobe and the plasma sheet, the plasma sheet boundary layer is characterized by anisotropic plasma distributions and multiply streaming plasma components. In the inner magnetosphere, the outer van Allen radiation belt hosts a population of high-energy (tens of keV to several MeV) electrons, and the ring current consists of energetic ions (tens to hundreds of keV). These ions are mostly protons but also heavier elements such as ionospheric oxygen and helium and alpha particles from the solar wind are present especially during periods of high magnetospheric activity.

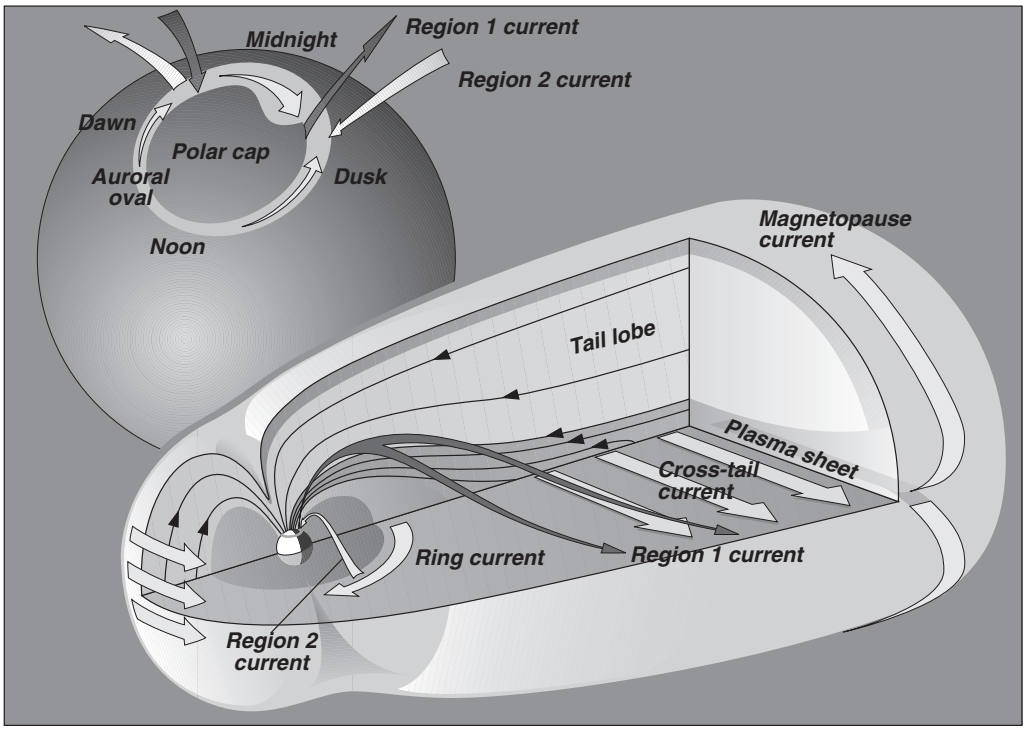

Figure 2. Magnetospheric current systems and a three-dimensional view of the inner magnetosphere and geomagnetic tail. The enlargement of the Earth shows the connectivity of the current systems to the auroral ionosphere.

At the Earthward end, the geomagnetic tail field lines all connect to the high-latitude portion of the Earth's dipolar field. The closed plasma sheet field lines connect to the auroral regions encircling the polar caps. Hence, the plasma sheet is the source region for the particles (mainly electrons) creating auroral light as they collide with the atmospheric atoms. The lobe field lines are magnetically connected to the polar caps poleward of the auroral ovals.

Dynamics of the geomagnetic tail

The geomagnetic tail is a remarkably stable and coherent structure, with distinct plasma regions identifiable from observations out to the distance of $240R_{\rm E}$ covered by *in situ* measurements. Current sheets, such as the cross-tail current sheet, are often the locations where instabilities can grow in space plasmas, and this is the case also for the geomagnetic tail. However, the magnetic field component normal to the cross-tail current sheet stabilizes the system under most circumstances so that significant energy input is required before large-scale instabilities can grow.

During the basic dynamic cycle in the magnetosphere, the magnetospheric substorm, energy stored in the geomagnetic tail is dissipated by a reconfiguration process. The process is initiated by a localized growth of a microinstability within the cross-tail current sheet and quickly expands so that its effects are observable over a large portion of the magnetosphere. Therefore, the substorm is a global reconfiguration process in the magnetosphere.

The repetition and intensity of the dynamic cycles are controlled by the rate of energy input from the solar wind roughly given by $\epsilon = 10^7 V B^2 (7R_{\rm E})^2 \sin^4(0.5\theta)$, where V is the solar wind velocity, B the interplanetary magnetic field and $\tan(\theta) = B_Y/B_Z$. Correlation analyses using solar wind velocity, interplanetary magnetic field and a magnetic activity indicator (AL) derived from ground-based magnetometer data show that the correlation between $VB_{\rm south}$ and AL has two peaks, one at 20 min corresponding to the direct solar wind driving of magnetospheric convection and another broad peak at 1 h corresponding to the substorm-associated strong energy dissipation in the geomagnetic tail.

Although the substorm energy comes from the solar wind, the location and time of the instability onset leading to the global reconfiguration are controlled by internal tail processes. The changing boundary conditions and magnetic field configuration lead to the formation of a thin current sheet that extends from the inner geomagnetic tail ($(8–10)R_{\rm E}$) out to at least $(20–30)R_{\rm E}$. This current sheet has a thickness of only a few hundred km, and the magnetic field component normal to the current sheet is very small, only a few nT. Such a thin current sheet is a required precondition before the microinstability leading to the substorm expansion phase can grow. The instability evolves like a tearing-type process breaking the magnetic topology and has a growth time of only a fraction of a minute. The details of the microphysical instability process are as yet unknown.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

The substorm cycle begins with energy extraction from the solar wind via dayside reconnection at a rate of 10^{11} W and its storage in the tail magnetic energy. This substorm growth phase typically lasts about 1 h giving about 10^{15} J of energy to the tail. Magnetic reconnection at a newly formed near-Earth neutral line (20–30)R_E from the Earth initiates the reconfiguration process, which leads to disruption of the inner tail current sheet, consequent decrease in the lobe magnetic field (Ampère's law $\nabla \times \boldsymbol{B} = \mu_0 \boldsymbol{j}$) and the formation of a plasmoid or, more generally, a flux rope, which is ejected from the geomagnetic tail in the antisunward direction (see figure 1). Because the reconfiguration process is limited in the cross-tail direction, the plasma jets Earthward at a speed higher than the convection velocity on either side. The flow shear creates a pair of field-aligned current sheets, where the current flows to the ionosphere in the morning-side leg and out of the ionosphere in the evening-side leg. This is the substorm current wedge. The stored energy is dissipated during these processes, which typically last about 30 min (substorm expansion phase). After that, the energy dissipation ceases and the neutral line moves tailward to replace the distant neutral line. The magnetosphere recovers its original state during a slow process of rebuilding the cross-tail current.

The structure and dynamics of the geomagnetic tail have been probed by several spacecraft since the beginning of the space age. The first measurements were made by the EXPLORER spacecraft in the early 1960s. These were followed by a series of ten Interplanetary Monitoring Platform (IMP) spacecraft during the 1960s and early 1970s. The first measurements from the distant geomagnetic tail were obtained from PIONEERS 7 and 8, which crossed the tail at distances of 1000 R_E and 500 R_E, respectively. A more detailed picture of the dynamics was given by the three INTERNATIONAL SUN–EARTH EXPLORER (ISEE) spacecraft in the late 1970s and early part of the 1980s. While ISEE 1 and ISEE 2 had apogees at 22 R_E, ISEE 3 was located for part of its lifetime in the distant geomagnetic tail probing it out to 220 R_E. The International Solar Terrestrial Physics (ISTP) program in the 1990s is a joint effort between all the major space agencies. While there are several spacecraft probing various regions of the geospace, the most important for the study of the geomagnetic tail has been the INTERBALL tail probe reaching out to 30 R_E and GEOTAIL, which has covered the tail from 220 R_E inward to about 10 R_E in great detail.

Magnetosphere of Earth: Magnetopause

The magnetopause is the location where the external PLASMA and magnetic field pressure of the magnetosheath balance the internal plasma and magnetic field pressure of the MAGNETOSPHERE OF EARTH. It is usually considered the boundary of the magnetosphere. The magnetic field orientation changes across the boundary from its magnetosheath to its magnetospheric orientation, implying that this boundary is a current sheet. While pressure balance and changes in the orientation of the magnetic field at a current sheet are relatively simple concepts, the structure of the Earth's magnetopause is complicated because the plasmas on both sides of the discontinuity are magnetized.

For typical SOLAR WIND conditions, the distance from the center of the Earth to the magnetopause along the Earth–Sun line, called the subsolar distance, is about 10 times the radius of the Earth, or 10 Earth radii (approximately 64 000 km). The shape of this boundary can be approximated by an ellipsoid of revolution about the Earth–Sun line with the magnetopause at the terminator about 50% further from the Earth than it is at the subsolar point. In the magnetotail, this approximation is not accurate. The magnetopause does not converge in this region; rather it extends many hundreds of Earth radii in the direction away from the Sun. Figure 1 is a cut through the magnetosphere in the noon–midnight meridian plane, showing the magnetopause. As discussed below, the magnetopause shown in figure 1 is called a 'closed' magnetopause because there are no magnetic field lines crossing the boundary.

Since the magnetopause is in pressure balance, changes in the internal or external pressure will cause the location and shape of this boundary to change. The solar wind dynamic pressure (that is, the solar wind mass density times the square of the solar wind velocity) is far from constant. This dynamic pressure is converted to plasma thermal pressure and magnetic field pressure in the magnetosheath. Thus, variations in the solar wind dynamic pressure cause the magnetopause to move toward and away from the Earth. The subsolar distance can move in to about half its nominal distance for extremely high solar wind pressure and can move out to about twice its nominal distance for extremely low solar wind pressure.

A magnetopause was hypothesized long before spacecraft observed it and measured many of its properties. In 1931, Sydney Chapman and Vincenzo Ferraro suggested that a charge-neutral plasma (composed of ions and electrons) ejected from the Sun during magnetic storms would envelop the Earth. Because the medium surrounding the Earth is a good electrical conductor, the plasma from the Sun would not penetrate the Earth's magnetic field. Instead, the plasma (and magnetic field) from the Sun would pile up and be swept around the Earth's magnetic field, forming the boundary

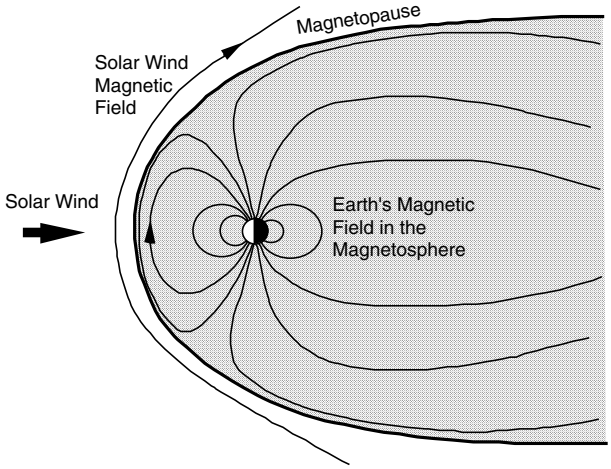

Figure 1. The Earth's magnetopause is the location where the pressure of the solar wind and the internal pressure of the Earth's magnetosphere balance. This magnetopause is closed so that no magnetic field lines cross the boundary and the plasmas on either side do not intermix.

that is now known as the magnetopause. In effect, a current system would be set up on the magnetopause surface which would shield the planetary magnetic field from the interplanetary plasma. Chapman and Ferraro were attempting to explain the initial decrease in the Earth's magnetic field during magnetic storms which were known to be associated with solar activity. They believed that the plasma ejected from the Sun was intermittent and that it did not contain a magnetic field (thus, the magnetic pressure external to the magnetopause was zero). It is now known that the charge-neutral plasma from the Sun (the solar wind) is unsteady but not intermittent and does contain a magnetic field. The continuous solar wind and the presence of the magnetic field in the solar wind (see SOLAR WIND: MAGNETIC FIELD) have important implications for the structure of the magnetopause beyond what Chapman and Ferraro envisioned. However, their pioneering work on the magnetopause was significant and is a good starting point for understanding this complex boundary.

As a first approximation, the structure of the magnetopause can be investigated by neglecting the internal plasma in the magnetosphere and neglecting the external magnetic field in the solar wind. The first assumption is a reasonable approximation because the internal plasma pressure is about 5–10 times lower than the external plasma pressure. The second assumption has more profound implications discussed below.

In this first approximation, the external, unmagnetized plasma pressure is balanced by the internal magnetic field pressure. If the external plasma has zero temperature, then the balance occurs between the external dynamic pressure (i.e. the plasma density and bulk flow velocity) and the internal magnetic field. In this case, the unmagnetized ions and electrons impinge on the magnetic field and are completely turned around. Because the ions are more

massive than the electrons, they penetrate slightly further into the Earth's magnetic field. This charge separation produces an electric field which self-consistently turns the ions and electrons around. Throughout this process, the external plasma pressure and the internal magnetic field pressure must balance. This relatively simple description of the magnetopause was formulated and solved analytically before the first observations of the Earth's magnetopause. It predicts a relatively thin current layer which is of the order of the geometric mean of the electron and ion gyroradii (for typical conditions in the magnetosheath, this mean is approximately the ion gyroradius or approximately 50–100 km). It also predicts that there is no transfer of plasma across this thin layer since all plasma incident on the layer is ejected.

While neglecting the presence of a plasma in the magnetosphere has an effect on the structure of the magnetopause, especially at the flanks or sides of the magnetopause, the major difference between this simple approximation and the Earth's magnetopause is that it neglects the external magnetic field in the magnetosheath. Although the magnetic field in the magnetosheath is weaker than its magnetospheric counterpart, it is the presence of this magnetic field that causes most of the interesting phenomena associated with the Earth's magnetopause.

The next simplest approximation of the magnetopause is to assume that it is a tangential discontinuity. The magnetic field may undergo an arbitrary rotation across this type of discontinuity but no magnetic field lines cross the discontinuity and the plasma on either side of this magnetic field rotation does not intermix. Plasma intermixing is not allowed across a tangential discontinuity because, under ideal MAGNETOHYDRODYNAMICS (MHD), the magnetic field is 'frozen in' the plasma and a group of ions or electrons that share a common field line never share that field line with another group of ions or electrons on an adjacent field line. Since no magnetic field lines thread the boundary and the plasma on either side of the discontinuity cannot intermix, the magnetopause (and magnetosphere) is considered 'closed'. A closed magnetopause has the magnetic topology in figure 1. Once again, the total pressure on either side of the tangential discontinuity must balance. At the location where the magnetic field rotates, plasma can move along the discontinuity by executing particle orbits in the layer. By virtue of the different orbits for ions and electrons, this particle motion constitutes a current which self-consistently maintains the layer. The thickness of this structure can be of the order of an ion gyroradius (or approximately 50–100 km, for typical conditions in the magnetosheath). Spacecraft observations indicate that, at least at times and over some limited areas, the magnetopause has the characteristics of a tangential discontinuity.

In the 1970s, as spacecraft observations became more detailed, it became clear that solar wind plasma regularly crossed the Earth's magnetopause. In particular, solar wind plasma was found in a layer approximately 3000 km thick inside the magnetopause. This layer is much thicker than a tangential discontinuity magnetopause that has a thickness of about 100 km. It thus became important to understand how this magnetized plasma crossed a magnetic boundary and what the implications were for the structure of the boundary. One suggestion was that the plasma diffused across the tangential discontinuity. In a magnetized plasma this diffusion must occur 'anomalously' through the action of waves which disrupt the regular particle motion about the magnetic field, thus breaking the 'frozen-in' condition. Another way to produce this diffusion would be growth of an instability such as the Kelvin–Helmholtz instability caused by shear flows of the plasma at the magnetopause. If the Kelvin–Helmholtz instability were to grow to saturation amplitudes and enter a non-linear phase, plasma elements on two sides of the magnetopause could intermix. Spacecraft observations of waves and shear flows at the magnetopause held promise for anomalous diffusion. This subject is still controversial, but the observed wave amplitudes now appear to be insufficient to produce substantial anomalous diffusion necessary to match the observations of solar wind plasma crossing the magnetopause. Similarly, most shear flows at the magnetopause do not appear to be large enough to drive the Kelvin–Helmholtz instability to saturation.

In 1961 James Dungey suggested that a breakdown of the frozen-in condition of ideal magnetohydrodynamics would cause the solar wind and terrestrial magnetic fields to diffuse into a region and interconnect. He developed these ideas from work on solar magnetic field interconnection (or reconnection) but realized that conditions favorable for MAGNETIC RECONNECTION could occur when (and where) the magnetic field in the magnetosheath was directed opposite the terrestrial magnetic field. Under magnetohydrodynamics (outside the small region where the diffusion and interconnection occurs), the tangential discontinuity magnetopause would decompose into a series of MAGNETOHYDRODYNAMIC WAVES, each performing a change in the plasma or magnetic field parameters that is required for the transition between the solar wind and magnetosheath conditions. Despite this complex structure, the total pressure remains constant through each wave front and the 'magnetopause' is still a balance between external and internal total pressure.

Computer simulations that consider kinetic effects in the plasma (as opposed to MHD theory which treats the plasma as a fluid or fluids) indicate that some of these waves merge or change characteristics, so that, at least to a reasonably good approximation, the magnetopause during reconnection has the properties of a rotational discontinuity. The primary differences between tangential and rotational discontinuities are that magnetic field lines thread a rotational discontinuity and the plasma on either side can cross this type of discontinuity. Across a rotational discontinuity, the mass, momentum and energy densities are conserved. These conservation laws give rise to a series of jump conditions for the density, velocity and

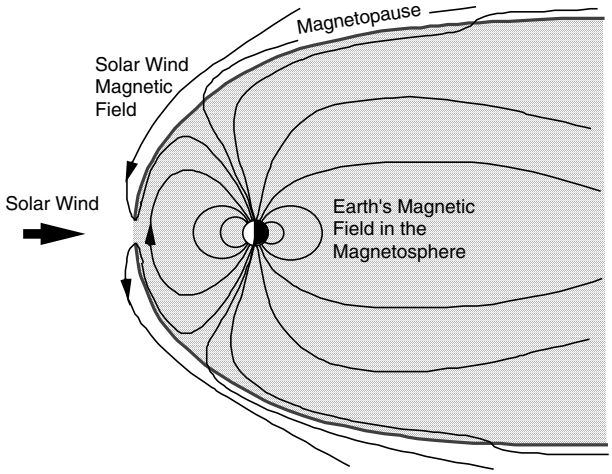

Figure 2. An open magnetopause where reconnection is occurring in the subsolar region. The magnetopause is still the location where the solar wind and magnetospheric pressures balance but magnetic field lines thread the boundary and plasmas on either side can intermix.

energy across the discontinuity. For example, the mass density and the normal velocity must be conserved across the discontinuity. Under certain assumptions, the jump conditions can be tested at the Earth's magnetopause. These tests reveal that the magnetopause is often a rotational discontinuity.

The magnetopause structure when magnetic reconnection occurs is significantly different from the magnetopause in figure 1. Figure 2 is a cut through the magnetosphere in the noon–midnight meridian plane, showing the magnetopause when reconnection is occurring in the subsolar region. Magnetosheath and magnetospheric magnetic field lines interconnect in a relatively small region (called the diffusion region) near the subsolar point. The diffusion region is very small compared with the magnetopause and, as a consequence, the probability that a spacecraft will cross through the diffusion region is also small. Even if a spacecraft crossed through the region, it might not be recognized since the distinction between this region and the magnetopause outside of the diffusion region is relatively subtle and only now beginning to be understood from a theoretical standpoint.

Under the action of the magnetosheath plasma flow around the magnetosphere and the magnetic field line tension that is released in the reconnection process, these interconnected magnetic field lines convect away from the diffusion region toward the magnetotail. More magnetic field lines convect and reconnect in the diffusion region, continuing the process. Thus, figure 2 is a snapshot in time where the magnetopause can be traced through the rotation of the magnetic field from its magnetospheric to its magnetosheath orientation. Because of the interconnection of the magnetic field and the intermixing of the plasma, the magnetopause in figure 2 is described as an 'open' magnetopause.

Although the magnetopause structures in figures 1 and 2 are significantly different, there are some features that these discontinuities have in common. The first feature is that the magnetopause is the location where the magnetic field changes from its magnetosheath orientation to its magnetospheric orientation. For the closed magnetopause in figure 1, the magnetic field rotates in a plane tangential to the magnetopause from its magnetosheath to its magnetospheric orientation and no magnetic field lines thread the boundary. For the open magnetopause in figure 2, the magnetic field undergoes the same rotation tangential to the magnetopause, but there is also a small component of the magnetic field that threads the boundary.

The second feature that remains in common with all magnetopause structures is that the total magnetic field and plasma pressure remains constant across the boundary. For the closed magnetopause in figure 1, the internal pressure of the magnetosphere deflects the incoming magnetosheath plasma around what is in effect an impervious obstacle. For the open magnetopause in figure 2, this deflection still occurs but the obstacle is no longer impervious. Only about 1% of the plasma crosses the open magnetopause in figure 2. However, this transfer of plasma has a profound effect on the structure and dynamics of the Earth's magnetosphere. Further information on the magnetopause can be obtained from the book entitled *Physics of the Magnetopause* (Song *et al* 1995).

Magnetosphere of Earth: Plasma Sheet

The plasma sheet is a slab of hot plasma in the equatorial region of the geomagnetic tail, and carries the cross-tail (dawn-to-dusk) current that supports the oppositely directed magnetic fields of the tail lobes (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL). The plasma sheet and the embedded current sheet are clearly present to distances of at least 1.5 million km away from the Earth.

The existence of the current sheet was inferred immediately after the discovery of the geomagnetic tail by the IMP-1 satellite in 1964; the magnetic field directions are nearly antiparallel between the northern and southern lobes. It was also inferred that the current sheet must be filled with hot plasmas to sustain the magnetic pressure in the lobe. The lobe field magnitude is typically ~20 nT at a distance of 30 R_E (Earth radii; $1R_E \sim 6378$ km), and the distance dependence is given by $\sim 124x^{-0.54}$, where x is the downtail distance (in units of R_E) from the Earth.

Later observations have revealed that the plasma temperature and number density in the central plasma sheet are typically of order ~keV and $\sim 10^6$ m^{-3}, respectively. The magnetic field inside the plasma sheet is weaker and more variable than in the lobe. However, it is still consistent with being oppositely directed in the northern ($B_x > 0$) and southern ($B_x < 0$) parts and separated by a neutral sheet ($B_x = 0$), where B_x is the magnetic field component in the Sun–Earth direction and positive toward the Sun. Towards the neutral sheet, the field magnitude decreases and plasma pressure increases, and thus the central plasma sheet is characterized by a high-β plasma ($\beta \gg 1$), where β is the ratio of thermal to magnetic pressure. Usually ions make the major contribution to the pressure and to the cross-tail current associated with the pressure gradient.

The half-thickness of plasma sheet is a few R_E near the tail center and becomes thicker towards the dawn and dusk flanks. It can be clearly identified from the adjacent regions by differences in the magnetic field and plasma properties. Across the boundary from the lobe to plasma sheet, the β value jumps from $\ll 1$ to a fraction of unity. Energetic ion beams are often observed to stream along the magnetic field lines in a layer (called the plasma sheet boundary layer) just outside of this transition. Inside the plasma sheet, plasma flow properties are highly variable with speeds ranging from <50 km s^{-1} (stagnant) to >1000 km s^{-1}. However, the flow directions are consistently associated with characteristic magnetic field variations; it is sunward in association with northward B_z, and antisunward with southward B_z. This coherent flow property represents convection in the plasma sheet. On the average, the convection is directed earthward in the near-Earth region, while it is tailward in the distant tail. This feature is well understood in terms of magnetic reconnection occurring in the neutral sheet of the geomagnetic tail.

In the near-Earth region, the plasma sheet is magnetically connected to the Earth at high latitudes, and particles that can penetrate to low altitudes lose energy through interactions with the dense atmosphere, causing auroral emissions. On the other hand, some of the plasma sheet particles are injected into the ring current region during storms and substorms. Therefore the plasma sheet is the source of the auroral particles as well as of the ring current (see also GEOMAGNETIC STORM, MAGNETOSPHERE OF EARTH: RING CURRENT, MAGNETOSPHERE OF EARTH: SUBSTORMS).

Magnetic reconnection in the plasma sheet

The structure and dynamics in the plasma sheet are basically understood in terms of MAGNETIC RECONNECTION, in which an X-line (neutral line) is formed in the dawn–dusk direction. As shown in the upper panel of figure 1, 'Petschek' reconnection leads to the formation of four distinct boundaries (slow shocks). The upper and lower regions represent the northern and southern lobes, respectively, where cold plasmas are convected toward the neutral line, while in two separate regions inside the boundaries hot plasmas flow out earthward on the earthward (left-hand) side and tailward on the tailward (right-hand) side of the neutral line. The earthward and tailward flows are accompanied by northward ($B_z > 0$) and southward ($B_z < 0$) magnetic fields, respectively. Hence the plasma flows carry magnetic flux, and the resultant convection electric field is directed dawn to dusk on both sides of the neutral line. Statistically, the neutral line is formed at distances of $\sim 140R_E$ down the tail, which is called a 'distant' neutral line. The convection electric field is of the order of 0.1 mV m^{-1} on the average. The field lines on the earthward side are closed, with both feet connected to the ionosphere at high latitudes in the northern and southern hemispheres, while on the tailward side both ends are connected to the interplanetary magnetic field (IMF).

In addition to the distant neutral line, magnetic reconnection is initiated explosively at a time close to substorm onset in the near-Earth region (20–30 R_E). The resultant neutral line is called a 'near-Earth' neutral line (NENL). The NENL formation is required to dissipate magnetic energy stored in the tail lobes during the substorm growth phase because the reconnection rate in the distant tail is generally too slow to balance the enhanced reconnection on the dayside under continuously southward IMF. In the growth phase, the magnetic field configuration becomes tail like and the current sheet becomes thinner in a wide region of the geomagnetic tail. Then, magnetic reconnection commences somewhere in an extremely thin sheet near the central axis of the tail. The plasma sheet on the tailward side of the NENL, which was originally convecting earthward with closed field lines, forms a plasmoid with a magnetic island, or flux ropes, which is expelled down the tail. On the earthward side, high-speed earthward flows transport northward magnetic flux towards the Earth, which contributes to 'dipolarization' of the magnetic field near the Earth.

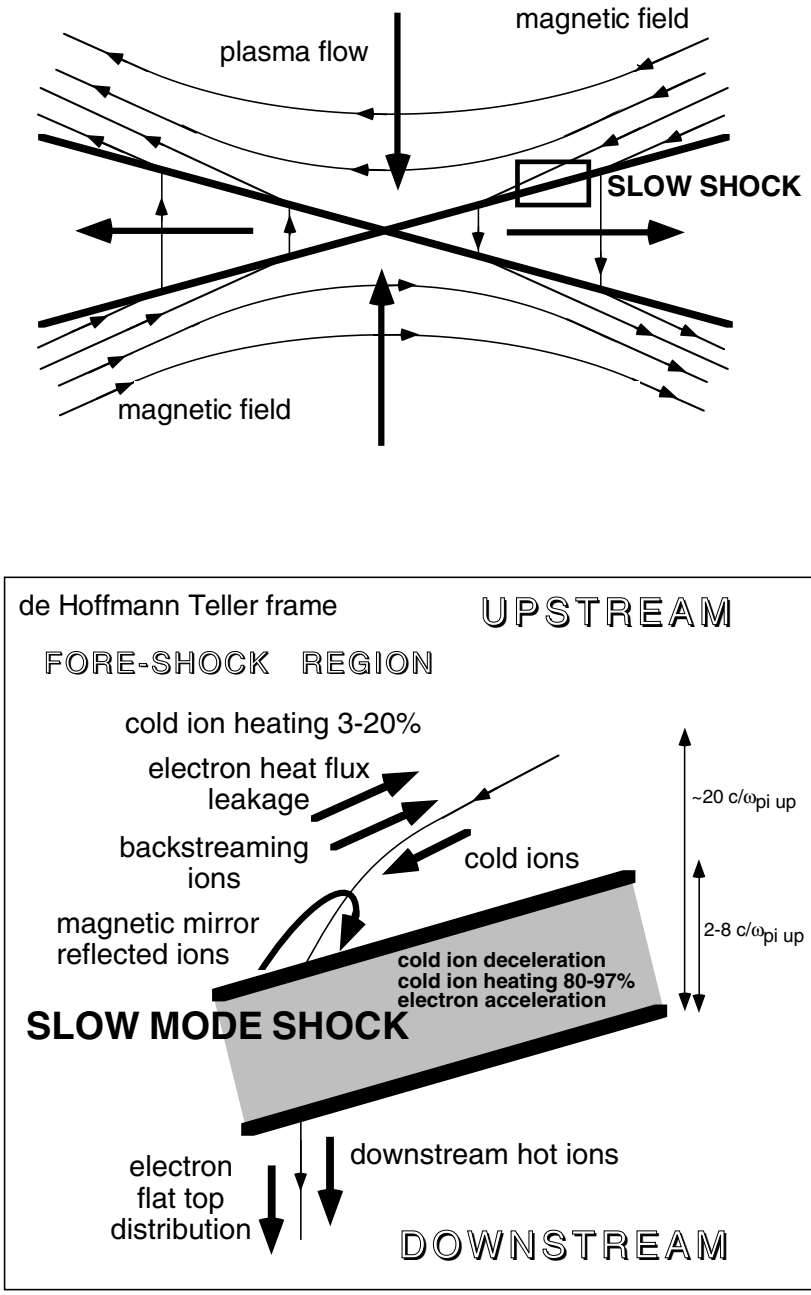

Figure 1. A schematic structure of 'Petschek' reconnection and slow-mode shocks in the Earth's magnetotail.

Recent *in situ* plasma measurements on satellites have revealed characteristic features in the particle distribution functions associated with magnetic reconnection. Comparison of the observed data with results from computer experiments has enabled us to understand them qualitatively and quantitatively. Magnetic reconnection and the associated particle heating processes are topics of current research in space physics.

Plasmoid

A plasmoid is created initially near the center of the geomagnetic tail at distances of 20–30 R_E by magnetic reconnection at a time close to substorm onset, as described above. The magnetic reconnection of open (lobe) field lines leads to a configuration change from originally closed field lines to a magnetic island, or flux ropes, on the tailward side of the neutral line. Since it is no longer connected magnetically to the Earth, the plasmoid can freely propagate down the tail (see also figure 1 in

MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL). The tailward propagation velocity is ∼300 km s^{-1} in the near-Earth region, subsequently accelerating to ∼700 km s^{-1} at ∼100 R_E downtail. Then, it slows down to ∼500 km s^{-1}. It is noted that the initial tailward speed is only a fraction of the lobe Alfvén velocity, but, beyond ∼100R_E, it becomes comparable with, or a little lower than, the Alfvén velocity in the ambient lobe region. The plasmoid is initially confined in a narrow region near the tail axis, but it expands during the tailward propagation, until at ∼100R_E the dawn–dusk extent reaches the magnetopause, while the length (in the Sun–Earth direction) reaches several tens of R_E.

Plasma sheet boundary layer

Energetic ion beams are often observed to stream along the magnetic field direction near the plasma sheet–lobe boundary. This region is called the plasma sheet boundary layer (PSBL). In the near-Earth region, these energetic field-aligned beams are directed earthward and precipitate into the ionosphere near the poleward boundary of the auroral oval on the night side. A part of them are reflected back to the tail by the magnetic mirror force and constitute counterstreaming beams. While it is generally interpreted in terms of current sheet acceleration for the near-Earth observations, their generation mechanism is most likely to be associated with magnetic reconnection. Beyond several tens of R_E down the tail, they are observed just outside of a region in which the β value jumps from $\ll 1$ to a fraction of unity. They often coexist with cold ions of the lobe origin. This is a fore-shock region of the slow shocks formed by magnetic reconnection.

Slow shocks

With the formation of an X-type neutral line, cold plasmas in the lobes are convected toward the plasma sheet with the $\boldsymbol{E} \times \boldsymbol{B}$ drift under the action of the dawn-to-dusk electric field. The velocity of a slow-mode wave approaches zero as the propagation direction becomes perpendicular to the magnetic field. Therefore the plasma flow becomes supersonic with respect to the slow-mode wave in the vicinity of the X-type neutral line, even when the inflow velocity of the plasma is small. As a result, the collision of plasmas flowing from the northern and southern lobes is expected to give rise to slow shocks. The lower panel in figure 1 shows a schematic view of the structure of a slow-mode shock in the Earth's magnetotail. On entering the plasma sheet, cold plasmas are heated and accelerated by the slow shock. In the fore-shock region, backstreaming energetic ions and incident cold ions coexist, and the cold ions are preheated before crossing the slow shock. These features are evidenced in the geomagnetic tail by recent spacecraft observations (although there are a considerable number of other cases in which the slow-shock condition cannot be satisfied).

Current sheet acceleration

Let us consider the motion of a single particle near the neutral sheet under the cross-tail (dawn-to-dusk) electric field in a tail-like magnetic field configuration, in which the magnetic field magnitude decreases toward the neutral sheet. As they approach the neutral sheet owing to the $\boldsymbol{E} \times \boldsymbol{B}$ drift, particles are largely accelerated by the cross-tail electric field and begin to meander in the dawn–dusk direction (duskward for ions and dawnward for electrons) near the neutral sheet. They are further accelerated to higher energies with the meandering cycles. This is called current sheet acceleration.

This process may generally occur everywhere in the neutral sheet with the dawn-to-dusk electric field, but it appears most prominently in a thin current sheet near the diffusion region of magnetic reconnection. Recent *in situ* observations from satellites have revealed the existence of non-gyrotropic ion distribution functions as evidence of the acceleration in the thin current sheet, of which the thickness is estimated as $\sim$ 1000 km ($<$ 500 km in extreme cases), that is comparable with, or smaller than, a typical ion Larmor radius.

Sources of the plasma sheet

Potential sources of the plasma sheet are the solar wind and the Earth's ionosphere. According to the reconnection–convection model, the solar wind (magnetosheath) plasma enters the magnetosphere via dayside reconnection and is transported to the mantle region in the geomagnetic tail. It also continues to enter the mantle at the open-tail magnetopause. Then a portion of the mantle plasma is convected into the plasma sheet. (See also MAGNETOSPHERE OF EARTH: CONVECTION, MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL for the reconnection–convection model.) Plasmas (especially ions) in the topside ionosphere are energized so as to escape both from the polar cap and from the auroral region. Particles escaping from the dayside cusp and the polar cap are transported along magnetic field lines to the mantle and lobe region, and trace similar trajectories to those of solar wind origin. Upflowing ion beams accelerated above the auroral oval are directly injected into the near-Earth plasma sheet. Generally the ionospheric plasma makes a significant contribution to the near-Earth plasma sheet during geomagnetically active times, while the solar wind plasma is usually the major source.

Although the structure and dynamics are reasonably interpreted in terms of the reconnection process, it is still a matter of controversy whether this process is always the most important for plasma supply to the plasma sheet population. In the plasma sheet, there is a general tendency for the density to increase and the temperature to decrease as geomagnetic activity drops to a quiescent level. This may suggest that a diffusive process in the flank magnetopause is more effectively transporting cold dense solar wind plasma directly into the plasma sheet during quiet times, in which case the reconnection process may be considered to be less effective.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

It should be noted that the ion temperature in the plasma sheet is several times higher than the solar wind kinetic energy (∼1 keV) and several orders of magnitude higher than the temperature of the ionospheric plasma. The temperature of the lobe plasma just outside the plasma sheet is as low as several tens of eV, while the ion temperature in the central plasma sheet is typically around several keV, and the electron temperature is 1/4–1/7 of the ion temperature. Efficient heating processes must take place across the plasma sheet–lobe boundary and inside the plasma sheet. Possible candidates are the slow shocks at the plasma sheet boundary, the current sheet acceleration and the resistive dissipation in the magnetic diffusion region, but their quantitative assessment is yet to be done in future work.

Magnetosphere of Earth: Plasmasphere

The plasmasphere is a torus of cold, dense plasma encircling the Earth that usually exhibits a very sharp edge at a distance ranging between 2 and about 6 Earth radii in the equatorial plane. Figure 1 is a simplified diagram of the plasmasphere as viewed from the Sun, showing some of its main features: the plasmapause, the main body of the plasmasphere, the dusk-bulge region and a detached plasma region outside the main body of the plasmasphere. The plasmasphere is essentially an upward extension of the medium-to-low-latitude ionosphere, formed as ionospheric ions flow upwards from their creation points at low altitudes to fill the relative vacuum of space surrounding the Earth. The sharp edge called the plasmapause was entirely unexpected. Here densities drop by a factor of 10–100 in a relatively short distance. The plasmapause was discovered in 1963 nearly simultaneously by Konstantin Gringauz in the Soviet Union, using lunar rocket observations of the thermal plasma, and by Donald Carpenter in the United States, observing very low frequency plasma waves called whistlers.

These whistlers, generated by lightning flashes, propagated between northern and southern hemispheres along geomagnetic field lines on both sides of the plasmapause.

The plasma density ranges from 10^4 cm^{-3} just above the topside ionosphere at ~1000 km altitude to 10^2–10^3 cm^{-3} within and 10–10^2 cm^{-3} just outside the plasmapause in the equatorial plane. The average radius of the plasmasphere varies in response to changing SOLAR-WIND conditions. In addition, the plasmasphere extends to larger radial distance in the afternoon–dusk sector in a region termed the dusk bulge. These two characteristic features of the plasmasphere have been very successfully explained by considering the influences of the magnetospheric electric fields on plasma drifts. Erosion of the plasmasphere in the dusk sector appears to produce outlying structures that may be attached plumes or high-density regions completely detached from the main body of the plasmasphere.

Plasmaspheric composition and temperature

The plasmasphere is composed mostly of protons and for this reason was originally called the protonosphere. The base of the plasmasphere is taken as the altitude (~1000 km) at which protons replace oxygen as the dominant species in the ionospheric plasma. Small amounts of helium and oxygen ions (1–5% oxygen and 2–20% helium) as well as trace amounts of singly charged nitrogen and deuterium and doubly charged helium and oxygen ions are also found in the plasmasphere. Satellite observations indicate that, on occasion, an enhanced torus of heavy ions (O^+ and O^{++}) appears in the outer plasmasphere in the region of a newly established plasmapause.

Ion temperatures in the plasmasphere are generally between 0.5 eV and several eV (1 eV = 11 700 K). In the outer plasmasphere, temperatures are, for the most part, anticorrelated with the density changes, rising sharply as the densities decline, moving toward the plasmapause and beyond. It is not clear whether ion and electron temperatures are in equilibrium in the outer plasmasphere. In fact, observations suggest that ion temperatures may exceed electron temperatures in this region. In the outer plasmasphere, the cold plasma temperature varies with magnetic and solar activity, reflecting the corresponding changes in its heat sources. One of the major heat sources is the terrestrial ring current, which is also found in this region of space (see MAGNETOSPHERE OF EARTH: RING CURRENT). The energetic plasma of the ring current overlaps the outer regions of the plasmasphere and dusk bulge, transferring energy to the thermal plasma through Coulomb collisions, and the damping of plasma waves. The time dependence of this energy transfer, its variation with solar and magnetic activity and its relationship to the changing composition and energy characteristics of the ring current are key areas of research at the present time.

The structure of the plasmasphere

Cold plasmas, such as those that form the plasmasphere, are strongly influenced by the large-scale electric field in the magnetosphere. This electric field drives a circulation of magnetic field lines and cold plasmas along trajectories that approximately coincide with electric field equipotentials. The large scale electric field in the inner magnetosphere originates from the superposition of two major sources: (1) the corotation electric field, resulting from the Earth's rotation, which points radial inward at all local times, and (2) the convection electric field, generated by the solar-wind–magnetosphere interaction, assumed to be constant and directed from dawn to dusk throughout the entire region. Figure 2 shows electric potential patterns (and thus cold plasma drift trajectories) from each of these sources along with the combined potential from their superposition. The electric potential patterns are drawn in the magnetospheric equatorial plane with the Sun to the bottom of the figure. In steady state, the plasmapause corresponds to the boundary between the closed drift paths encircling the Earth and the open drift paths moving plasma from the magnetotail to the dayside magnetopause (see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE). Within the plasmasphere, magnetic field lines, that confine the plasma, approximately rotate with the Earth allowing high densities to build up. Outside the plasmasphere, the circulation of magnetic field lines is influenced strongly by the convection electric field. The resultant trajectories of these external field lines no longer enclose the Earth. Magnetic field lines external to the plasmasphere convect to the magnetopause boundary on the dayside of the Earth, sweeping their burden of upflowing ionospheric plasma out of the magnetosphere. On these field lines, a buildup of upflowing plasma from the ionosphere, comparable to that achieved within the plasmasphere,

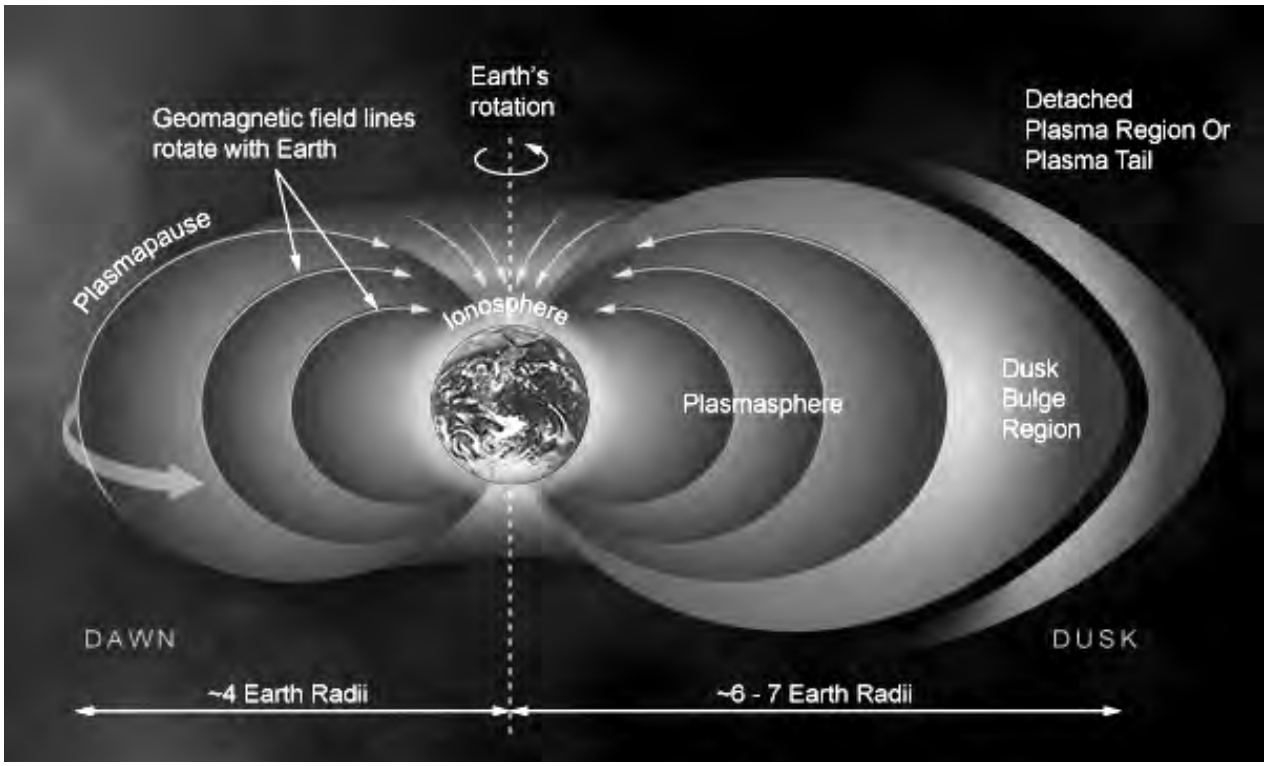

Figure 1. View from the Sun of the Earth's plasmasphere. The plasmasphere is a torus-shaped region of cold, dense plasma surrounding the Earth in the near-space environment that has a very sharp edge called the plasmapause at equatorial distances of 4–6 Earth radii. It is essentially an extension of the ionosphere to high altitudes. The plasmasphere bulges out to greater radial distances on the dusk side of the Earth due to the nature of the plasma drift paths. However the dusk bulge region appears to be a separate region from the main body of the plasmasphere. Within the dusk bulge region, the plasma contains many structures, which may by blobs of plasma detached from the main body of the plasmasphere or plumes of plasma still attached by thin tails in another local time sector.

cannot occur. This difference in field-line circulation patterns accounts for the significant density difference between the plasmasphere and the so-called plasma trough region beyond. Solar-wind-generated electric fields vary continuously in strength while the corotation electric field remains constant to a first approximation. Since the size and shape of the plasmasphere depend upon the interplay of these electric fields, the mean radius of the plasmapause tends to diminish as the strength of the convection field increases.

In steady state, the dawn–dusk asymmetry in the drift paths produces an observed extension of the plasmasphere to larger radial distances on the dusk side, called the dusk-bulge region. However steady state is rarely achieved in practice. Erosion of the outer plasmasphere occurs with timescales of the order of a day and refilling takes several to 10 d. The solar wind, the source of the convection electric field, does not remain constant for such long periods. Although large-scale plasmaspheric features are explained to some extent by the potential patterns given in figure 2, inner magnetospheric electric fields are seldom this simple and plasmaspheric features exhibit interesting smaller-scale structures. The key process that complicates this picture is the tendency for energetic ions drifting at the inner edge of the plasma sheet to create electric fields through charge separation that shield the convection electric field from regions inwards of their location (see MAGNETOSPHERE OF EARTH: PLASMA SHEET). Recent satellite observations indicate that the inner magnetosphere electric fields have quite complicated spatial distributions as a consequence of shielding. Models indicate that shielding is time-dependent (being noticeable after 10 min but taking several hours to complete) and not always effective. Because of these properties, the electric field penetrates very close to Earth at times, and complicated electric field patterns are created in the region of the outer plasmasphere and plasmapause.

The dusk bulge region is also rather more complicated than the steady-state picture implies. Observations indicate that the main plasmasphere is nearly circular, with only a slight bulge near dusk. During periods of enhanced convection activity, erosion of the plasmasphere in the dusk sector appears to produce outlying structures. It is not clear from satellite data whether these structures are plumes, which extend from the dusk region, or are completely detached from the main plasmasphere. Meanwhile, a new plasmasphere boundary is formed

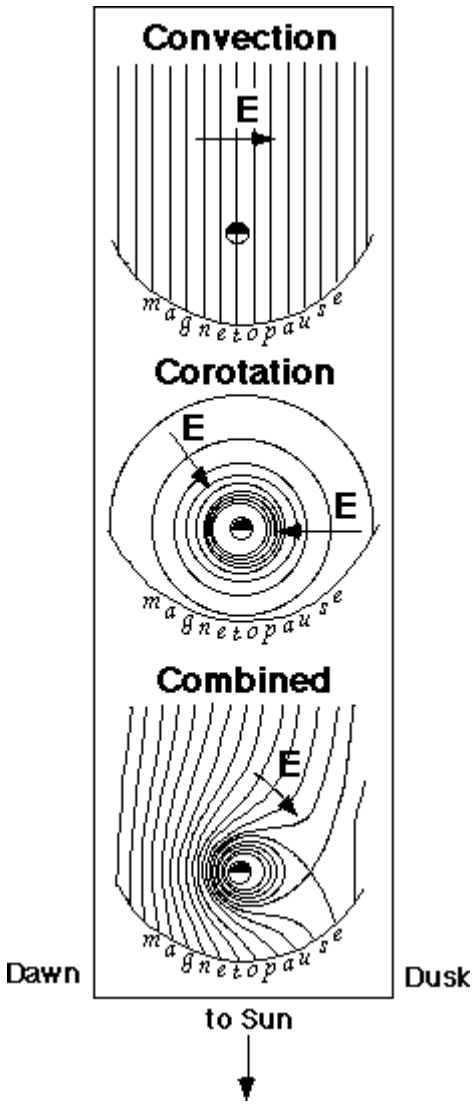

Figure 2. Lines of constant electric potential are shown looking down on the Earth in the equatorial plane with the Sun at the bottom. Since cold plasma moves along constant equipotentials in the magnetosphere, these lines also represent plasma drift paths. In this simplified representation (which nonetheless captures the most important elements of plasmaspheric structure), the pattern of the drift paths is determined by the superposition of two key large scale electric fields: the convection and corotation electric fields. The convection electric field is directed from dawn to dusk (left to right above) and has constant amplitude throughout the inner magnetosphere in this simplified model. It is produced by the solar-wind–magnetosphere interaction and drives plasma from the night side to the dayside magnetopause boundary. The corotation electric field points radially inward toward the Earth at all local times and forces cold plasma to approximately move with the Earth as it rotates. The superposition of the potentials from these two fields produces the combined pattern. In steady state, the boundary between open and closed drift paths is the plasmapause. A pronounced dawn–dusk asymmetry, seen in the drift paths, is responsible for the dusk bulge region of the plasmasphere.

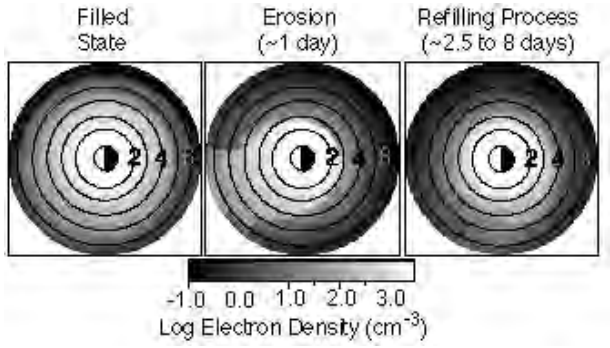

Figure 3. Model view of the plasmasphere during erosion and recovery, looking down on the Earth in the equatorial plane, with the Sun to the left. The plasmasphere is initially completely filled and in equilibrium with the underlying ionosphere (left panel). During erosion the convection electric field is enhanced which causes the boundary between closed drift paths, that encircle the Earth, and open drift paths, that move plasma to the dayside magnetopause boundary, to move inward. Plasma that was initially on closed drift paths now finds itself on open drift paths. This plasma is stripped off the plasmasphere and swept to the magnetopause boundary layers (center panel). As magnetic activity quietens, the convection electric field weakens and the open/closed drift path boundary moves outward. Newly corotating but empty plasma regions begin to refill immediately as plasma moves upward along field lines from the ionosphere (right panel). The circles mark the radial distance every 0.5 Earth radii moving outward from the center of the Earth.

closer to the Earth on the nightside under the influence of the enhanced convection electric field (by mechanisms yet to be observed). In a fashion similar to that of a lathe, the new nightside boundary radius appears to be communicated to the dayside and eventually to the dusk sector through approximate rotation of the affected nightside regions with the Earth, leading (statistically) to a roughly circular condition of the main plasmasphere. Finally, the difference in field-line circulation patterns, which accounts for the significant density difference between the plasmasphere and the so-called plasma trough region beyond, does not necessarily explain the abruptness of the density change at the plasmapause that is often observed. The mechanisms at work in plasmasphere boundary formation remain a topic of research.

Erosion and recovery of the plasmasphere

The plasmasphere goes through continuous cycles of erosion and recovery. Figure 3 is a simulation of one such cycle. When the convection electric field strengthens, the region of closed trajectories encircling the Earth decreases in size. The plasmapause, which roughly marks the outermost boundary of this region of closed trajectories, moves inward. Thermal plasma, formerly trapped on closed trajectories, now finds itself on open drift paths. It is peeled off the plasmasphere and moved along open drift paths, to be lost at the magnetopause boundary. The number of ions lost from outside a newly formed plasmapause boundary, that has moved inward from a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

distance of 5 to 3.5 Earth radii, is of the order of 1×10^{31}. When the convection electric field weakens, the plasmapause moves outward again trapping a relatively empty plasma region on corotating drift paths. Refilling of this region from the ionosphere, through magnetic-field-aligned plasma flows, begins immediately. The time required to build up high plasma densities in the outer plasmasphere through this refilling process, increases with radial distance because of the accompanying increase in the volume enclosed by the magnetic field lines. Refilling times range from ∼1 d at 2.5 Earth radii to ∼8 d at 4 Earth radii. As a result of this radial increase in refilling times, the plasmasphere tends to behave as if it were separated into two distinct regions: an inner region which is completely refilled on short timescales, and an outer region which is almost always in the process of refilling but never quite reaches equilibrium before the next erosion episode begins. Time-varying electric fields further complicate this process by producing plumes of plasma still attached to the main body of the plasmasphere that extend from the dusk plasmasphere to the dayside magnetopause boundary. In addition, numerous small-scale regions of enhanced density are observed between the plasmasphere and the magnetopause in the dusk region during times of enhanced activity. There is evidence to suggest that these cold plasma structures remain trapped for extended periods, presumably on open drift paths, implying that the processes by which plasma is swept out of the dayside magnetopause are not fully understood. There is also new evidence from whistler wave observations to suggest that plasmapause formation may partly involve a process that dumps plasma (∼50% of the amount lost at the magnetopause) from the corotating outer portions of the eroded plasmasphere into the underlying ionosphere. The roles of instabilities in enhancing losses of plasma at the plasmapause boundary and in creating irregular plasma structures have not yet been resolved.

Recent interest has focused on the response of the plasmasphere to induction electric fields that occur during magnetic substorms (see MAGNETOSPHERE OF EARTH: SUBSTORMS). These induction fields can sometimes be even stronger than convection electric fields generated by the interaction between the solar wind and the Earth's magnetosphere. They are produced by reconfigurations of the Earth's magnetotail. During the growth phase of substorms, magnetic field lines become more stretched producing induction fields that are directed eastward opposite in direction to the westward convection electric field. When substorm onset occurs, the Earth's magnetotail field lines snap back into a more dipolar configuration producing induction fields that point westward and add to the convection electric field (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL). These fluctuations in the large-scale electric field play a role in the production of detached plasma regions and turbulence in the outer plasmasphere.

There is still one additional source of electric fields in the inner magnetosphere that has a strong influence on the dynamics and structure of the plasmasphere. Neutral-atmospheric winds, through collisions, drive ions across magnetic field lines, creating electric fields. These electric fields which are generated in the ionosphere map out along magnetic field lines to high altitudes and alter the potential pattern in the magnetosphere and with it the cold plasma drift paths. There are three major sources of neutral winds that are important in altering magnetospheric electric fields, including (1) solar heating which maximizes on the dayside at the subsolar point and drives winds antisunward from the dayside to the nightside, (2) weather disturbances and topology at the Earth's surface which drive gravity waves that propagate upward to the ionosphere, and (3) auroral heating which drives gravity waves towards the equator from the polar regions. Electric fields from each of these neutral-wind systems impact the large-scale electric field in the vicinity of the outer plasmasphere and plasmapause region. The interplay between plasmaspheric erosion and refilling during disturbed periods and the neutral-wind system is not yet fully understood. Progress in realistic modeling of the plasmasphere requires a complete description of the inner magnetosphere and its coupling to the ionosphere–neutral-atmosphere system as well as to the geomagnetic tail.

Magnetosphere of Earth: Radiation Belts

The Van Allen radiation belts, first discovered by the EXPLORER I satellite in 1958, consist of charged particles in orbits determined by the Earth's magnetic field (see VAN ALLEN BELTS). The Earth's magnetic field is approximately a dipole, see figure 1. Both electrons and ions which make up the radiation belts have typical energies of one million electron volts (1 MeV), and execute three different types of periodic (oscillatory) motion about the magnetic field. They gyrate about magnetic field lines at the electron cyclotron frequency, $\omega = qB/m$, which depends on the local magnetic field strength, decreasing like $1/r^3$ for a dipole. Those with finite velocity parallel to the Earth's magnetic field bounce between hemispheres with a frequency which is proportional to their parallel velocity, and inversely proportional to the length of magnetic field lines. Lastly, they drift around the Earth with a frequency which is proportional to their perpendicular energy, and inversely proportional to the length of magnetic field line about which they gyrate.

Source and loss processes

There are two separate zones of electrons, called the *inner* and *outer zone*, while radiation belt protons have only an inner zone on average. Heavier ions of atmospheric and SOLAR WIND origin, notably oxygen and helium, contribute to the radiation belts; however their percentage of composition is small. Another recently discovered component comes from the trapping of COSMIC RAYS which enter the magnetosphere singly charged, become stripped of outer electrons as they interact with the neutral atmosphere, and trapped by the Earth's magnetic field. This so-called ANOMALOUS COSMIC RAY belt contains helium, nitrogen, oxygen and neon nuclei. The primary source of inner zone protons comes from the decay of neutrons produced by cosmic rays scattered off the atmosphere. This process is called *cosmic ray albedo neutron decay* (CRAND), and produces electrons as well as protons as a neutron decays with a 10.5 min half-life. Neutrons produced by scattering of energetic cosmic rays off the atmosphere are themselves energetic (MeV range), and most of their energy goes into the proton in the decay process, while the electron is emitted in a random direction with a few hundred keV energy. These electrons can, like the protons, be trapped by the Earth's magnetic field, but they are inadequate as a source of MeV electrons in either inner or outer zones. A loss process due to the interaction of electrons with electromagnetic waves, described below, is responsible for the existence of two separate zones for electrons. This loss mechanism becomes comparable to the rate at which electrons are supplied to the region around 3 R_E geocentric distance in the magnetic equatorial plane, producing a *slot region* between inner and outer zones (see review by Walt (1996)).

The source of electrons for both inner and outer zones is primarily at larger radial distances, outside the orbit of geosynchronous spacecraft which orbit the Earth at a radial distance of 6.6 R_E with a period of 24 h. A major storage region for plasma or ionized gas consisting primarily of electrons and protons in the magnetosphere is the *plasma sheet* in the geomagnetic tail (see MAGNETOSPHERE OF EARTH: PLASMA SHEET; GEOMAGNETIC TAIL). The Earth's magnetic field is stretched into a long windsock in the anti-sunward direction by momentum coupling of solar wind flow past the magnetosphere, with a reversal of the magnetic field from outward in the southern hemispheric tail lobe to inward or earthward in the northern. There is a balance of magnetic and kinetic particle pressure, described by the equations of MAGNETOHYDRODYNAMICS (MHD), which leads to confinement of plasma sheet electrons and ions in the region of magnetic field reversal where the magnetic pressure is weakest. Some of this plasma originates in the solar wind, making its way into the magnetosphere in the tail region where the magnetic field is weak, where plasma of solar wind origin is identifiable by different ion mass and charge states from protons. Another source of plasma is the Earth's ionosphere. Plasmasheet electrons have an average energy ~600 eV, with ion energies typically greater by a factor of seven. Both solar wind flow and MHD flows in the magnetosphere impart greater energy to ions because of their greater mass (scaling as $\frac{1}{2}mv^2$), with electrons and ions drifting together transverse to the magnetic field B in most regions of the magnetosphere. Both charge species are energized as they are transported earthward by the two-cell *convection* that provides return flow towards Earth in the central tail region, driven by anti-sunward flow at the boundary (see MAGNETOSPHERE OF EARTH, figure 1). In detail, processes such as *reconnection* of oppositely directed magnetic field lines in the tail impart magnetic field-aligned flow and thermal kinetic energy to the plasma, and play a role in large-scale reconfiguration of the magnetotail, from a stretched–stressed shape to a more dipolar shape, called *substorms* (see MAGNETOSPHERE OF EARTH: SUBSTORMS). Impulsive electron and ion injection at geosynchronous orbit due to substorms is well documented, and provides a major outer boundary source for energetic particles in the inner magnetosphere, along with steady, sunward convection. This is the main source for radiation belt electrons, as well as the low energy ion population in the 100 keV energy range which makes up the Earth's *ring current* (see MAGNETOSPHERE OF EARTH: RING CURRENT). The latter is well distinguished from the proton radiation belts by energy, radial location with maximum flux around 4 R_E geocentric, and an outer versus inner boundary origin.

There is an approximate constant of motion associated with each type of periodic particle motion: gyro, bounce and longitudinal drift. These are called *adiabatic invariants*, and the first conserves the magnetic moment of a particle, which is the product of the equivalent current carried by a particle gyrating about a magnetic field line times the area enclosed by the orbit. The second invariant is proportional to the parallel momentum, mass times parallel velocity,

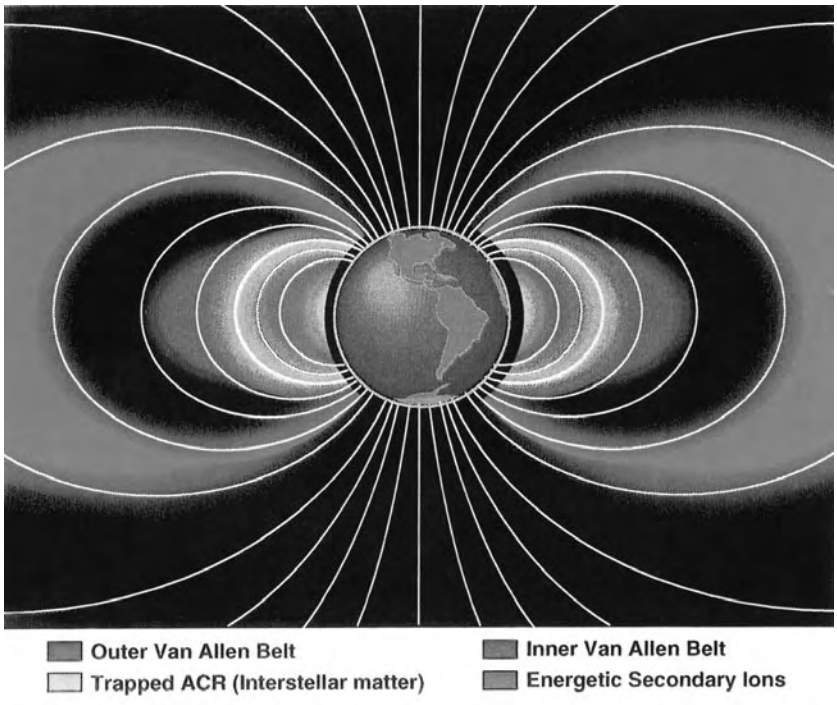

Figure 1. Dipole representation of the Earth's magnetic field showing proton inner zone, inner and outer zone electron radiation belts, and the anomalous cosmic ray component. **This figure is reproduced as Color Plate 34.**

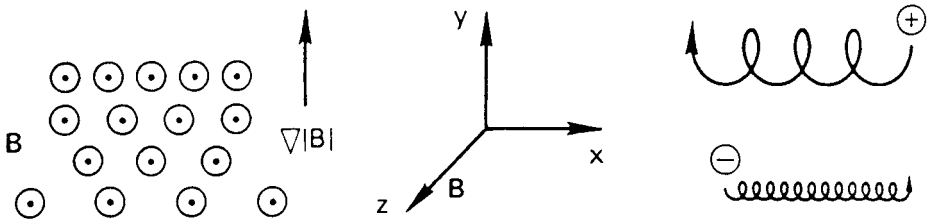

Figure 2. Drift of a gyrating particle in a non-uniform magnetic field directed out of the page. Radial (earthward) gradient points up, ions drift westward and electrons eastward due to changing magnetic field strength across their gyro orbits.

and the length of the magnetic field line along which bounce motion is executed. The third invariant is the magnetic flux enclosed by a complete longitudinal drift path, which is the integral of the magnetic field times the area enclosed, $\int B\,\mathrm{d}a$. The principal mechanism for energizing radiation belt electrons as they are transported radially inward involves conservation of the first and second adiabatic invariants. Thus, as an electron gyrating about a magnetic field line moves earthward in the convection flow indicated in figure 1, into a region of increasing magnetic field strength, its perpendicular energy must increase in order to conserve the *first adiabatic invariant*. A charged particle's longitudinal drift in the radial magnetic field gradient of a dipole field depends on the sign of the charge, as shown in figure 2, providing the source of the ring current as well as radiation belt particle longitudinal drifts, with ions drifting westward and electrons eastward. Fluctuations in electric and magnetic fields, e.g. due to low frequency MHD waves, give rise to radial diffusion of charged particles represented by their distribution f in velocity and position, which on average transports particles from their source to loss region. This process can be described by a diffusion equation of the form

$$\frac{\partial f}{\partial t} = L^2 \frac{\partial}{\partial L}\left(\frac{1}{L^2} D_{LL} \frac{\partial f}{\partial L}\right)$$

when the radial motion is so small, while the particle is interacting with a fluctuating electric or magnetic field, that one can neglect the change in its longitudinal drift velocity. Particles are assumed to be uniformly distributed in longitude, and remain so during the diffusion process. Neither of these assumptions is valid during a substorm injection, nor during the compression of the outer boundary of the magnetosphere by an interplanetary shock wave which originates from the Sun. A third implicit assumption is that, while particle distributions

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

can be expressed as functions of the six dimensions of velocity and position coordinates, diffusion in velocity and position are decoupled processes. The latter is often a good assumption, because *radial diffusion* occurs on the timescale of the drift period, while velocity diffusion occurs on the timescale of particle bounce and gyromotion. Under these assumptions, the following two radial diffusion coefficients have been calculated for fluctuations in the magnetic and electric field, respectively:

$$D_{LL}^{M} = \frac{\pi^2}{2}\left(\frac{5}{7}\right)^2 \frac{R_E^2 L^{10}}{B_0^2} \nu_{\text{drift}}^2 P_A(\nu_{\text{drift}}) \quad (1)$$

$$D_{LL}^{E}(L, \nu_{\text{drift}}) = \frac{L^6}{8R_E^2 B_0^2} \sum_{n=1}^{n} P_n(L, n\nu)_{\nu=\nu_{\text{drift}}}. \quad (2)$$

These coefficients are written as functions of the surface magnetic field strength at the Earth's equator, $B_0 = 0.3$ G, the geocentric radial distance at the equator L in units of earth radius R_E, the power spectrum P_A of the asymmetric part of the magnetic perturbation at the particle longitudinal *drift frequency* ν_{drift}, and the nth Fourier component of the global electric field perturbation P_n, for magnetic and electric field-driven radial diffusion, respectively. While the *magnetic diffusion coefficient* is written for equatorially confined particles, and is substantially reduced for those in bounce motion off the equator, the *electric diffusion coefficient* is independent of the equatorial *pitch angle* of a particle, which is the angle between the velocity vector and the magnetic field at the equator. Electric field-driven diffusion tends to predominate in transporting particles to the low L values of the radiation belt flux peaks inside geosynchronous orbit. Diffusion coefficients which include both theoretical calculations of the power spectral functions P, and calculations based on local measurements of P, all decrease rapidly with decreasing L because of the strong L dependence in (1) and (2). There is substantial spread, but all have the behavior that diffusion times are greater than a day into $L = 4$.

The primary loss processes for radiation belt particles are collisions with the neutral atmosphere and interaction with right (left) hand circularly polarized electromagnetic waves which propagate along the magnetic field such that an electron (ion) sees the rotating electric field vector of the wave remain constant at its gyrofrequency. This electric field can then cause particle diffusion in velocity which changes either the particle's energy, pitch angle, or both. Particles which diffuse toward more parallel motion will strike the atmosphere and be collisionally lost, e.g. via *charge exchange* with a neutral. Thus diffusion in velocity space acts to move particles away from more perpendicular pitch angles, which result from increasing their perpendicular velocity as they diffuse radially inward in the Earth's magnetic field, toward pitch angles with increased collisional interaction with the neutral atmosphere. This type of wave–particle interaction sets a theoretical limit on the flux of radiation belt particles called the *stable trapping limit*, since the velocity space diffusion coefficient is proportional to wave power near the electron and ion gyrofrequencies and harmonics, which in turn is proportional to the density of particles and gradients in velocity space away from the peak at 90° to the magnetic field. This mechanism has been generalized to nonparallel propagation, and was highly successful in explaining the electron slot region which separates the inner and outer radiation belt zones.

Non-diffusive processes

The preceding, steady-state view of radiation belt processes has been accepted for three decades, and shown to be successful in predicting particle flux levels during geomagnetically quiet periods. However, it was learned during the 1989–91 maximum in solar SUNSPOT activity that there are significant deviations from this quiescent picture. For example, on 24 March 1991, an interplanetary shock initiated by a *coronal mass ejection* (CME) at the Sun, a global scale detachment of plasma from the outer atmosphere or corona of the Sun (see SOLAR CORONAL MASS EJECTION), impacted the Earth's magnetosphere at a velocity estimated to be as high as 1400 km s^{-1} and compressed the outer boundary of the magnetosphere inside the orbit of geosynchronous spacecraft for several hours. This impact launched an MHD pulse called a *magnetosonic wave*, which spread around the flanks of the magnetosphere at a speed comparable to the drift velocity of outer zone electrons between geosynchronous orbit and $L = 9$–10. Electrons drifting eastward synchronously with the wave pulse saw an approximately constant azimuthal electric field, which follows from Faraday's law and the time-dependent compression of the Earth's dayside magnetic field. This electric field transported electrons resonant with the pulse radially inward in the direction of $E \times B$, forming a flux peak at $L = 2.5$, normally the slot region, with an energy peak at 13 MeV. Electron fluxes increased in this region by several orders of magnitude, and remained elevated for well over a year. Simultaneously, solar energetic protons which originate both at the Sun during the coronal mass ejection, and are accelerated by interaction with the *interplanetary shock* as it propagates toward the magnetosphere, formed a new, trapped proton radiation belt, when they were accelerated inward by the same azimuthal electric field which formed the new electron belt. While the March 1991 event produced the largest radiation belt perturbation of the Sunspot Cycle 22 solar maximum (1989–91), others were seen which require a similar explanation that violates the steady-state radial diffusion assumptions.

Another important type of variability in outer zone electron fluxes is associated with *high speed solar wind stream* interactions with the magnetosphere. As far back as 1965, during the first minimum in sunspot activity following the solar maximum of the International Geophysical Year, the Explorer 26 satellite observed regular monthly injections and decay in outer zone electron fluxes which were later confirmed to be correlated

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

with high speed solar wind flows. A correlation was also noted with southward orientation of the interplanetary magnetic field (IMF), which in figure 1 (MAGNETOSPHERE OF EARTH) is seen to favor enhanced reconnection of the solar wind magnetic field with the Earth's northward field at low latitudes on the dayside. Southward IMF enhances the coupling of solar wind flow energy which drives convection and substorm activity internally to the magnetosphere. The regularity of outer zone electron flux variation seen at *sunspot minimum* is due to the orderly structure of the *solar current sheet*, associated with solar wind outflow from the heliomagnetic equator which may cross the Earth's orbit once or twice per solar rotation. Superimposed upon such recurrent behavior are CMEs, which become more prevalent approaching *sunspot maximum* when solar activity in general increases. CMEs can produce a detached plasma region with large-scale organized helical magnetic field structure called a *magnetic cloud*, carried radially outward by the ambient solar wind flow. Magnetic clouds impacting the magnetosphere can provide an extended period of southward IMF favorable to enhanced convection and substorm injection of plasma sheet particles into the inner magnetosphere. Such a sequence of events was evident for the 6–11 January 1997 magnetic cloud interaction with the magnetosphere, which produced prolonged substorm activity, increase in the ring current which identifies a *geomagnetic storm*, and significant enhancement of outer zone electron fluxes (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS). An increase in relativistic electron fluxes by several orders of magnitude around $L = 4$ was observed on the timescale of a few hours, which cannot be explained by radial diffusion. Observations of *ultra low frequency* (*ULF*) oscillations in the mHz frequency range, which corresponds to the longitudinal drift frequency of hundred keV electrons at geosynchronous orbit and MeV electrons at $L = 4$, suggest that *drift-resonant acceleration* by the electric field associated with these ULF oscillations may play an important role in transporting the electrons radially inward on the timescale of a few electron drift periods.

A dynamic view of the radiation belts is necessary to explain the variations in particle fluxes by orders of magnitude which can occur on a timescale of minutes to hours, modifying integrated fluxes to which spacecraft are exposed over much longer periods. New multipoint spacecraft and ground-based diagnostics and computer modelling are expected to greatly alter the static view of the radiation belts shown in figure 1, and provide radiation belt environment forecasting capability (*space weather* prediction) of importance to satellite systems and manned presence in space.

Magnetosphere of Earth: Ring Current

The ring current consists of energetic positive ions that drift westward through the Earth's inner magnetosphere. That ring of westward current causes a southward perturbation in the magnetic field on the Earth's surface. The ring current is always present, but it intensifies during a magnetic storm.

The discovery of the ring current

In the nineteenth century, scientists noticed that the horizontal magnetic field strength occasionally decreases over most of the Earth, often after times when strong activity has been observed on the solar surface. It seemed as if the Earth sat within a great ring of westward current that strengthened during times of intense solar activity. Thus the idea of an Earth-centered ring current arose long before the space age and long before the development of modern plasma physics. However, in those early days, there was no sure way to determine how electrical current could flow through the space beyond the Earth's atmosphere.

A 'magnetic storm' is defined by a worldwide decrease in the horizontal magnetic field strength on the Earth. Nowadays, the effect is quantified in terms of the *Dst* (storm disturbance) magnetic index, which is an average of the northward magnetic perturbation observed at several low-latitude ground stations, with effects of quiet-time neutral winds carefully subtracted. In a typical magnetic storm, the *Dst* index decreases sharply over a period of a few hours, indicating a strengthening of the ring current. This period of decrease is called the 'main phase' of the storm. In a very large storm, the total decrease in *Dst* can be as much as 600 nT (nanoteslas), about 2% of the Earth's total field strength at low latitudes. In the 'recovery phase' of the storm, which typically lasts a day (or several days for very large storms), the index returns to its normal level (near zero).

In the first half of the twentieth century, theoretical calculations and laboratory experiments clarified how charged particles should be expected to move in the dipolar field of the Earth. The early pioneers in the field were Kristian Birkeland and Carl Størmer and later Hannes Alfvén and Sydney Chapman. They demonstrated that particles with energies below about 100 million electron volts (MeV) could easily be trapped in the Earth's nearly dipolar magnetic field. A charged particle executes a spiral motion about a field line, as shown in figure 1. As a charged particle moves toward the Earth along a dipole field line, its motion parallel to the field gradually slows as it encounters stronger and stronger fields. The field-aligned velocity eventually reverses, as if the particle were reflected from a mirror. Then the particle heads back out into the magnetosphere and towards the other pole of the Earth, where it is similarly reflected. The particle thus executes a nearly periodic motion along the field line, between 'mirror points' in the northern and southern hemispheres. It also drifts very slowly from one field line to another, with negative particles (electrons) drifting east around the Earth and positive ions drifting west. The eastward drift of negative particles and westward drift of positives leads to a net westward electrical current around the Earth. Theorists naturally identified this westward current as the ring current that had been inferred from ground measurements.

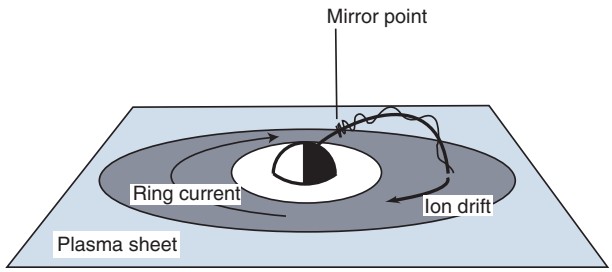

Figure 1. The geometry of the ring current. The shaded regions are in the equatorial plane. The southern hemisphere is not shown.

Early in the space age, Alexander Dessler, Eugene Parker and Norbert Sckopke demonstrated that the magnetic perturbation near the Earth caused by a charged particle moving in a dipole magnetic field is a constant times the particle energy, independent of how far the particle is from the Earth. Thus the *Dst* index provides an estimate of the total energy of all of the charged particles trapped in the magnetic field. A typical magnetic storm with $Dst = -100$ nT corresponds to a ring-current energy of 4×10^{15} J.

Spacecraft observation of the particles that carry the bulk of the ring current proved to be non-trivial, and comprehensive measurement of their properties even more so. Neither of the first two major particle populations discovered in the inner magnetosphere had enough total energy to explain the ring current. The first population to be discovered was the Van Allen radiation belt particles with energies above 1 MeV (see VAN ALLEN BELTS), but those were insufficiently numerous. The second was the plasmasphere, which includes a huge number of particles; but with less than an electron volt of energy per particle it also proved insufficient to explain the ring current (see MAGNETOSPHERE OF EARTH: PLASMASPHERE). By the late 1960s, however, spacecraft measurements made by Louis A Frank and collaborators at the University of Iowa began to detect a particle population that had sufficient energy density to explain the observed magnetic perturbations. Their observations and those of succeeding spacecraft flown in the early 1970s showed that the ring current was carried primarily by ions in the energy range from a few keV to a few hundred keV. The ions occupy field lines that cross the equatorial plane between about 2.5 and 7 Earth radii from the Earth's center. Of course, these ring current ions are accompanied by a nearly equal number of electrons, to maintain charge neutrality, but most of those neutralizing

electrons are less energetic and produce a current that is proportionately weaker.

The chemical composition of the ring current also held a surprise. The instruments that first discovered the ring current particles could not distinguish between different ion species, but most scientists assumed that the particles were hydrogen ions (i.e. protons), the dominant component of the solar wind (see SOLAR WIND COMPOSITION). However, when the composition of the ring current was actually measured, the truth turned out to be different. The lower-energy part of the ring current turned out to be predominantly O^+ ions, while the high-energy part was mostly H^+. The solar wind contains virtually no O^+, which, however, is a major component of the ionosphere. Thus it became clear that a large fraction of the ring current ions come from the Earth and not from the solar wind.

The source of the ring current

The most obvious source of ring current particles is the plasma sheet, the hot (kilovolt) plasma that occupies the equatorial region of the magnetosphere beyond the ring current (see MAGNETOSPHERE OF EARTH: PLASMA SHEET). The plasma sheet is the source of the AURORA. Like the ring current, the plasma sheet contains both H^+ and O^+ ions, but the ratio of O^+ to H^+ decreases with distance from the Earth. Convection causes plasma sheet particles to drift Sun-ward from the magnetotail and divert around the Earth (see figure 2.) In the near-Earth region, westward gradient drift dominates the motion of most ions above about 10 keV, and the particles are trapped in Earth-circling orbits. The separatrix between the two types of trajectories is called the 'Alfvén layer'. The particles that lie inside the separatrix and are trapped around the Earth are generally identified as ring current particles, while those on open trajectories are identified as plasma sheet particles.

The Alfvén layer, which separates convection-dominated trajectories from gradient-drift-dominated trajectories, is not stationary in time. It moves toward the Earth in times of strong convection and away from the Earth in quiet times, as indicated in the right half of figure 2. A brief period of strong convection brings plasma sheet ions close to the Earth on the night side. If the convection weakens again by the time the particles drift to the day side, they remain on trapped orbits about the Earth. This kind of event, in which fresh plasma sheet particles are added to the trapped ring current, is called an 'injection'.

A second source of the ring current is the underlying ionosphere. Ions are observed flowing up along field lines from the ionosphere to the magnetosphere. Some of these upflowing ions have energies not much greater than the thermal energy of particles in the underlying ionosphere, i.e. less than an ELECTRON VOLT. However, intense electrical currents that flow along auroral-zone field lines generate plasma waves that heat the ions. Electric fields that accelerate electrons downward to produce bright auroral forms also accelerate ionospheric ions upward. Consequently, some ionospheric ions are accelerated to kilovolt energies on their way to the magnetosphere, and some of them become part of the ring current.

Ring current loss mechanisms

Overall, the most important loss mechanism for ring-current ions is charge exchange with neutral atoms in the Earth's exosphere, sometimes called the hydrogen geocorona, the outermost part of the neutral atmosphere. The crucial reactions are

$$H^+ + H \rightarrow H + H^+$$

$$O^+ + H \rightarrow O + H^+.$$

A kilovolt H^+ or O^+ ion captures an electron from a hydrogen atom of the Earth's exosphere, which typically has an energy much less than 1 eV, producing a kilovolt neutral atom and an ion of very low energy. The energetic neutral travels off in a straight line and, in most cases, leaves the Earth's environment entirely. The low-energy ion remains trapped in the inner magnetosphere but, because of its low energy, makes a negligible contribution to the ring current.

Charge exchange lifetimes increase rapidly with distance from the Earth, because the density of the exosphere decreases rapidly with distance from the planet. Charge-exchange lifetimes in the ring current region range from hours near the Earth to weeks in the outer region. The recovery phase of a storm, in which the *Dst* index recovers back to its pre-storm level over period of 1–3 days, is usually attributed to charge-exchange loss of ring current ions.

There are several other loss mechanisms:

(a) Convection to the dayside magnetopause. Periods of enhanced convection can sweep ring current particles Sun-ward to the magnetopause, even as they bring fresh particles in.
(b) Coulomb scattering. Ring current ions gradually lose energy by collisions with low-energy electrons, particularly within the plasmasphere where the electron density is high. This loss process is particularly important for the lowest-energy ring current ions.
(c) Pitch-angle scattering. Interactions with high-frequency waves can scatter a ring current ion. If the scattering results in a velocity that is very nearly parallel to the magnetic field, it may move the particle's mirror point to such low altitude that the ion is lost by collisions in the dense part of the atmosphere. Whether or not this loss mechanism is strong enough to have a major effect on the total loss rate for ring current ions is a matter of current debate and study.

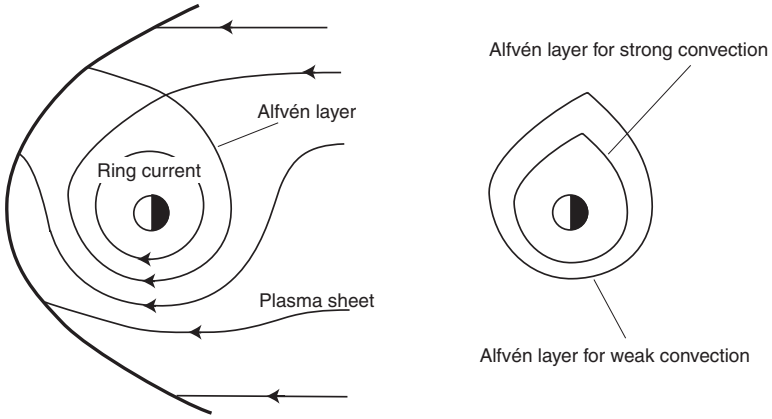

Figure 2. Drift trajectories of energetic ions in the equatorial plane of the Earth's magnetosphere. The Sun is to the left, the tail to the right. The left diagram shows drift paths. The drift motion is a combination of Sun-ward convection, which dominates far from the Earth, and westward (clockwise) gradient drift, which dominates near Earth. The right diagram shows how the regime of closed drift paths shrinks in times of strong convection.

Relationship of the ring current to the rest of the magnetosphere

The overall magnetic configuration of the magnetosphere can be substantially affected by the ring current. In a magnetic storm, the particle pressure in the ring current region becomes comparable to the magnetic pressure, and the magnetic field is substantially inflated. The magnetic connection between the ionosphere and the magnetosphere is thus altered: a field line from a given latitude in the ionosphere extends further from Earth when the ring current is strong. This change in the magnetic field allows the aurora, which normally lies on field lines connected to the plasma sheet, to be seen at lower latitudes.

The ring current also affects the distribution of the convection electric field. Particularly during times of strong convection, and thus particularly in the main phase of a magnetic storm, the ring current does not flow entirely on closed loops in the magnetosphere. There is often a partial ring centered in the pre-midnight sector, with its ends connected to the conducting ionosphere through magnetic-field-aligned currents. A current down into a region of the ionosphere causes it to charge positively, whereas a region of upward current charges negatively. Thus partial rings of current in the magnetosphere affect ionospheric currents and electric fields.

A matter of current debate is the relationship between magnetic storms and magnetospheric substorms (see MAGNETOSPHERE OF EARTH: SUBSTORMS). The substorm is a brief but intense disturbance in the magnetosphere–ionosphere system. It is centered on the night side of the Earth, in the plasma sheet and auroral ionosphere. Typically, a few large substorms occur during the main phase of any large magnetic storm.

The geosynchronous orbit, where a spacecraft orbital velocity is the same as the rotation rate of the Earth, lies at 6.6 Earth radii from the center of the Earth. It is home to many operating spacecraft, some of which carry particle detectors. That orbit typically lies close to the Alfvén layer and affords a good view of particle injections. Nearly every magnetospheric substorm injects some fresh particles into the geosynchronous orbit region. However, most substorms do not occur within magnetic storms. In other words, every substorm injects fresh particles into the inner magnetosphere, but most do not cause a lasting enhancement of the ring current. It is not clear whether the substorm is essential to the injection of the storm-time ring current.

Magnetosphere of Earth: Substorms

The term *magnetospheric substorm* is used to describe a host of phenomena which occur as a result of the transfer of momentum and energy from the SOLAR WIND into the MAGNETOSPHERE OF EARTH and subsequently into the ionosphere and upper atmosphere. The word 'substorm' was initially used in the early part of the 1960s to portray rapid and repeatable variations of the polar magnetic field during magnetic storms. In order to characterize the overall phenomenology of auroral disturbances, the term was modified to *auroral substorm*, before becoming more widely incorporated as the magnetospheric substorm in the 1970s. The study of magnetospheric substorms has tended to attract controversy and this remains the case currently. At the moment there are a number of aspects of magnetospheric substorms on which there is general consensus within the scientific community and this article deals with those aspects before moving to the more controversial aspects.

The AURORA is caused by the precipitation into the ionosphere of particles, with energies up to 10 keV or more, and is extremely dynamic during auroral substorms. The original description of an auroral substorm derived from the development of auroral activity based on the analysis of data from arrays of all-sky cameras deployed around the auroral oval during the International Geophysical Year (IGY) of 1957. A schematic representation of the development of an auroral substorm as portrayed in 1964 is given in figure 1. The quiet state (figure 1, panel A) consists of multiple arcs on the nightside drifting equatorward. A sudden brightening of the equatorward-most arc (figure 1, panel B) represents the onset of the *expansion phase* of the auroral substorm. Thereafter, the auroral activity moves westward, poleward and eastward (figure 1, panel C) forming a broad region of bright and dynamic auroral activity in the midnight sector, often known as the *auroral bulge*. As the auroral activity within the bulge continues to move westward, the westward edge of the bulge becomes deformed with a sharp kink developing, which is called the *westward travelling surge*, WTS (figure 1, panel D). Auroral activity continues throughout 60 min or so after the onset (figure 1, panels D and E), including the formation of auroral forms called *omega bands* at the eastern edge of the bright aurora (figure 1, panel D). Eventually, when the auroral activity has reached its most poleward extent, it starts to decline and the luminosity decreases, representing the start of the *recovery phase* (figure 1, panel F). During this time quiet auroral arcs reappear near the equatorward part of the active region, while the luminosity in the poleward part of the active region disappears. Also the high latitude edge of the substorm-disturbed region moves equatorward and recovery is then complete when the polar cap, the region within the auroral oval, has shrunk in size and auroral activity has moved to high latitudes. Figure 2 represents a series of six images taken by the VIS Earth Camera from the POLAR spacecraft on 12 January 1997. This series of images illustrates the global auroral activity associated with a magnetospheric substorm starting from the quiet auroral oval at 0658 UT to the maximum extent of the auroral emission at 0833 UT. Research, partly based upon global images of the aurora from space such as those in figure 2, has led to refinements to the picture of auroral activity described above which will be discussed later.

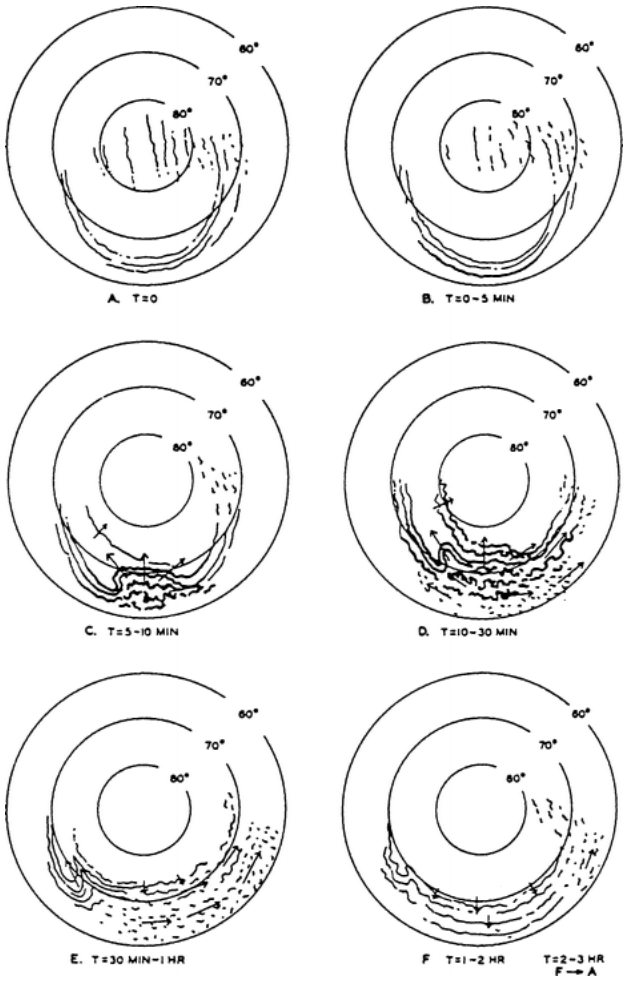

Figure 1. Schematic representation of six stages in the development of an auroral substorm as determined from all-sky camera data (from Akasofu 1964).

It is now generally accepted that a magnetospheric substorm comprises three separate phases: the growth, expansion and recovery phases. The *growth phase* is generally an interval of energy transfer from the solar wind and subsequent storage in the tail of the magnetosphere together with a small amount of dissipation in the ionosphere. This phase was not

considered part of the original auroral substorm, and is the interval prior to panel B in figure 1. The expansion phase is an interval when energy stored in the tail is explosively released, with some energy appearing in the ionosphere, some in the ring current and some being lost to the solar wind. The onset of the expansion phase occurs at the time of panel B in figure 1 and continues through to panel F. Finally, the recovery phase is an interval when the magnetosphere–ionosphere system relaxes back to a quiescent state. By describing the associated phenomena, we now consider each of these phases in turn.

Substorm phases

The interplanetary magnetic field (IMF) is convected away from the Sun with the solar wind, varying in magnitude and direction as it is transported. The growth phase of the magnetospheric substorm is considered to begin with the onset of southward interplanetary magnetic field (IMF) at the dayside magnetopause. This leads to MAGNETIC RECONNECTION between the IMF and the geomagnetic field, thereby creating open magnetic flux which is connected at one end to the Earth and at the other to the solar-wind plasma. This newly opened magnetic flux is transported by the motion of the solar wind into the *magnetotail* where it is added to the lobes (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL). In this way, magnetic energy, $B^2/2\mu_0$ per volume, is stored in the tail as the lobe magnetic field intensity increases. The region of the ionosphere, which is threaded by open flux, is termed the *polar cap*. Ionospheric flow is stimulated by the transport of open flux from the dayside into the tail and the polar cap also expands. If the IMF remains southward for an extended period of time, for example several tens of minutes, then ionospheric flows continue to be stimulated and the polar cap continues to expand, thereby also moving the auroral oval to lower latitudes. This global convection process is the *directly driven* part of the magnetospheric substorm and some energy is dissipated in the ionosphere, mainly via *Joule heating* of the ionospheric plasma. In the nightside ionosphere the auroral forms tend to be quiescent and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

relatively stable. There is one dynamic auroral feature which takes the form of equatorward moving arcs. These arcs begin their equatorward drift close to the border between the auroral oval and the polar cap, and several can be seen during the interval of the growth phase.

A further consequence of the addition of magnetic flux in the tail is the re-orientation of the magnetic field in the near-Earth tail, for example at geostationary orbit, where the field becomes less dipolar-like and more like the stretched mid and far tail field. This re-orientation results from the formation and subsequent intensification of a thin current sheet in the inner magnetosphere, the *cross-tail current*. Another signature at geostationary orbit is the reduction of particle fluxes, especially in the energy range 30–300 keV. This reduction in particle fluxes is caused by the 90°pitch angle particles, which drift through the nightside during this time, moving closer to the Earth. Small pitch angle particles are less affected and the resultant pitch angle distribution becomes elongated, and is often referred to as 'cigar-like'. This particular signature normally occurs in the late growth phase, some 10 min or so prior to the expansion phase onset. Further down the tail the stretching of the field caused by the addition of magnetic flux into the tail lobes results in *plasma sheet thinning* (see MAGNETOSPHERE OF EARTH: PLASMA SHEET). The growth phase, as defined by the interval from the southward turning of the IMF to the expansion phase onset, normally lasts between 30–60 min.

The expansion phase of the magnetospheric substorm is normally accepted as starting with the brightening of the equatorward-most auroral arc in the nightside ionosphere. This brightening begins in a localized region near midnight and propagates along the length of the arc both westwards and eastwards at phase velocities of up to 10 km s^{-1}. This is then followed by a poleward expansion of the auroral luminosity at speeds of typically a few hundred m s^{-1}. This is known as the *auroral break-up* because of the rapid deformation of the original quiet arc. The poleward expansion forms the auroral feature known as the auroral bulge and the westward motion of the western edge of the bulge develops the WTS, as discussed earlier, which has a westward phase velocity of ~1 km s^{-1} and may ultimately reach the dusk meridian. This original concept of the WTS, however, seems not to apply when considered carefully. Based upon high time resolution auroral images taken by the UV imager on the Viking spacecraft, it seems that the WTS is not a single surge form which propagates but is more likely a series of new surge forms which appear to the west of previously formed regions. In fact, each individual surge form does not appear to propagate far from the meridian on which it was initiated. Eastern motion of the auroral activity at the eastern part of the substorm active region can also occur but is in general less distinctive.

Also at the expansion phase onset a wave, called a *Pi 2 pulsation*, occurs. This wave has a frequency between 5–25 mHz, equivalent to a period range of 200–40 s, and is normally of order 10 mHz, a period of 100 s, and lasts for a few cycles whilst decaying in amplitude. The Pi 2 pulsation is primarily a nightside feature which can be seen over a wide range of local times, sometimes around to noon, and at latitudes from the auroral zone to the equator although it is most well defined at mid latitudes. The 'global' nature of the wave allows it to be considered as an ideal timing indicator for substorm onset in the event of no auroral observations, at least to times of order 1 min. These waves result from an impulsive change in the geomagnetic tail which causes a fast magnetohydrodynamic (MHD) wave to propagate throughout the tail (see MAGNETOHYDRODYNAMIC WAVES). This wave couples to a cavity mode inside the plasmasphere causing the well-defined mid-latitude signature.

At the same time as the development of the enhanced luminosity associated with the auroral break-up, ground magnetic perturbations are also observed which occur as a result of enhanced currents flowing in the ionosphere, termed *auroral electrojets*. These magnetic deflections are typically several hundred nT but during particularly intense intervals of current flow, can reach up to 2000 nT. Note the magnitude of the field at Earth's surface is typically 50 000 nT. With increasing time, there may be subsequent intensifications of the auroral activity, usually to the west of the original break-up, resulting in further enhancements of the current, and a poleward motion of the luminosity and current, often apparently in a stepwise manner rather than a smoothly varying way. At the time the poleward motion of the luminosity stops and the auroral region is at its widest, the expansion phase is said to have ended and the recovery phase begins. The enhanced auroral luminosity and the enhanced electrojets are a consequence of a change in the flux and energy spectrum of the precipitating electrons into the ionosphere. There are more particles with a harder spectrum resulting not only in increased luminosity but also in enhancements in electron density at lower altitudes, sometimes down to less than 100 km. A further characteristic signature caused by this change in *particle precipitation* is the absorption of radio waves in the MHz frequency band.

Most spacecraft observations in the magnetosphere during the expansion phase have been made at geosynchronous orbit. Here there are two typical signatures of onset, one being the dispersionless, in energy, injection of electrons and ions in the energy range 30–300 keV, the other the *dipolarization* of the magnetic field. *Dispersionless injections* of particles tend to occur in a limited local time sector near midnight. All energies appear at the spacecraft at the same time. Subsequently electrons and ions are subject to forces due

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to the gradient and curvature of the near-dipolar magnetic field in the inner magnetosphere which cause the particles to drift around the Earth, electrons to the east and ions to the west. Thus a spacecraft at geosynchronous orbit located several hours or more away from midnight will observe enhancements in the particle fluxes which are dispersed in energy, with higher energy particles reaching the spacecraft before lower energy particles. The magnetic field re-orientation, called the dipolarization, is also a characteristic signature of the early expansion phase. Again this feature is initially limited in local time extent in the tail, although there is evidence for expansion to west and east during the expansion phase in a stepwise manner. A further reproducible signature of the expansion phase onset in space is the onset of a burst of AURORAL KILOMETRIC RADIATION (AKR). This radiation, which typically occurs in the frequency band 200–500 kHz, is generated on the field lines of discrete aurora typically 1.5–3R_E above the auroral ionosphere and results from the electron cyclotron maser instability which is induced by energetic electrons.

The recovery phase is perhaps the hardest to characterize of the three phases. During this interval the system returns to a quiescent state. However, there are still optical features such as omega bands which are present and moving, in general eastwards. A double oval is also seen to form when the luminosity in the centre of the oval decreases, creating two bands of enhanced luminosity at the equatorward and poleward edges of the oval. The optical luminosity is reducing along with the electrojet currents, but decay times can be relatively long, of the order of 30–60 min, since particles are still present and drifting in the magnetosphere and consequently precipitating into the ionosphere. Ultimately, however, the system returns to a state which is similar to that prior to the onset of the growth phase. The timescales for the three phases are typically 30–60 min (growth), 1–2 h (expansion) and 30–60 min (recovery). The situation may become more complex if the IMF varies on timescales which are longer than those described above.

The phenomena that are observed during each of the three phases have been described above. Typically these observations have been made on the ground or at geosynchronous orbit. There have been other space observations as well but these will be mainly discussed below as we describe various models for the expansion phase of the substorm. It is this part of the substorm process that attracts most of the current debate.

Substorm current wedge

Apart from the auroral activity described earlier which occurs during the substorm, there are also characteristic magnetic signatures which appear during the expansion phase in particular. The auroral electrojets have already been mentioned, but the westward electrojet forms part of one of the universally accepted features of substorms, the *substorm current wedge* (figure 3). At expansion phase onset the cross tail current is diverted along magnetic field lines into the ionosphere where the enhanced current flows as the westward electrojet before flowing out of the ionosphere back into the tail. The diversion of the cross tail current changes the stretched tail field configuration observed at geostationary orbit near midnight during the growth phase and results in the dipolarization of the field. The current wedge consists then of two *field aligned currents* (FAC), downward to the Earth in the east and upward from the Earth in the west. The upward current is generally believed to be colocated with the western edge of the auroral activity and is intimately related to the WTS. Each surge form which is part of the WTS as it evolves has an upward FAC at its core with a circulating Hall current in the region surrounding the core. While there is a downward FAC in the volume surrounding the surge, there is generally a preference for downward current in the east to connect to the upward FAC by the westward electrojet. This wedge of current has characteristic magnetic signatures at mid-latitudes which are termed *magnetic bays* because of the similarity of the time varying magnetic field to coastal bays on a map. The north–south component of the field has perturbations which are positive, i.e. has a northward direction, at longitudes within the current wedge, since the direction of the magnetic field perturbation due to the currents is in the northward direction. The east–west component has a positive bay, i.e. in an eastward direction, on the western half and a negative bay at the eastern half. The east–west component bays are maximum at longitudes which coincide with the field-aligned currents. The SCW is closely related to the Pi 2 pulsations which occur at expansion phase onset and the waves are seen as a high-frequency response on the lower frequency bay variation. This current system is occasionally referred to as the *DP-1 current* (disturbance polar type 1) and is an expansion

phase signature alone. The *DP-2 current* is the current system which develops during the growth phase and is equivalent to the ionospheric flow which is stimulated by reconnection processes at the dayside magnetopause.

Substorm models

The first model proposed to explain many of the observations of magnetospheric substorms is the *near-earth neutral line* (NENL) model. Here the cause of the expansion phase onset is magnetic reconnection of closed magnetic field lines in the tail which originally thread the plasma sheet forming a *neutral line* in the near-Earth tail. Consequently the process which powers the substorm expansion is reconnection. Figure 4 illustrates the original version of the NENL which demonstrates schematically the changes in the magnetotail occurring during substorms. The panels in figure 4 are cuts along the midnight meridian plane of the magnetotail. The onset of reconnection in the tail at a new neutral line, N' (figure 4, panel 2) follows from the growth phase thinning of the plasma sheet. Initially, the NENL is of limited azimuthal extent and, as reconnection continues, newly reconnected magnetic field lines form an island of plasma tailward of the neutral line which is disconnected from the Earth (figure 4, panels 3 and 4). Plasma flows into the neutral line from above and below and out from the neutral line in both earthward and tailward directions. Ultimately, open magnetic flux of the tail lobes begins to reconnect (figure 4, panels 5–8) and the island of plasma forms a *plasmoid* which then, free from restraining forces, travels down the geomagnetic tail and is ejected into the solar wind. The timescale for reconnection to 'eat' through the plasma sheet is believed to be of the order of 5–15 min. The formation of the NENL interrupts the cross-tail current, which had intensified during the growth phase, causing the near-Earth magnetic field to adopt a more dipolar-like orientation, the dipolarization. The current system that results is the substorm current wedge. The radial position of the onset of reconnection in the geomagnetic tail has been debated often. The key signatures that are used to identify the existence of a NENL are southward-directed magnetic field and tailward flow. The evidence from a number of studies, involving data from several different spacecraft, suggests that these signatures are not seen in the tail at radial distances less than $19R_E$ from the Earth. Recent work with the GEOTAIL spacecraft indicates that tailward flows

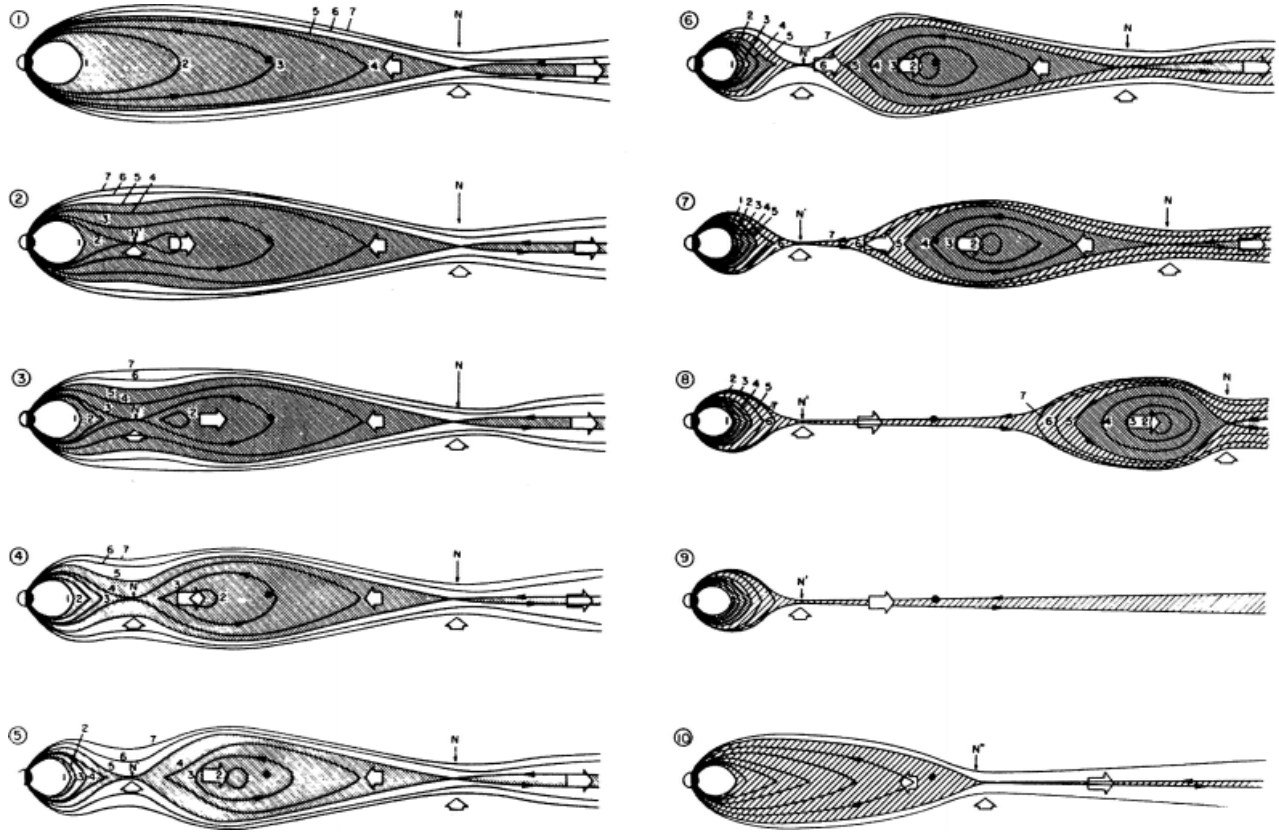

Figure 4. A schematic representation of the changes in the tail configuration during the substorm. This is the near-Earth neutral line model (see Hones 1979).

are seen predominantly between 20–30 R_E down tail and, interestingly, mainly pre-midnight. Furthermore, these flows occur within ±5 min of a Pi 2 pulsation observed on the ground and last on average between 7–9 min.

The location of the onset of reconnection at expansion phase onset some 20–30 R_E downtail does not appear to be consistent with a number of ground observations, which indicate that the auroral break-up maps to between 6–10 R_E downtail. These observations include the location of the initial disruption in the auroral forms at the equatorward-most auroral arc. Also, equatorward-drifting arcs are seen to continue to drift after the onset of the expansion phase, as identified either by Pi 2 pulsations or by auroral break-ups. Then the auroral arc which breaks up is seen to occur close to the location of latitudes where long period ULF waves are observed which imply both closed field lines and ones which will allow the formation of standing waves on them. This latter point implies that the magnetic field which maps from the auroral break-up into the tail is not as stretched as suggested in the NENL model. Thus, reconnection may not be the only process involved in the substorm expansion phase onset.

One proposal to overcome these difficulties is that the reconnection region in the tail does not connect magnetically with the auroral arc which brightens at expansion phase onset. If the onset of reconnection in the tail at some 20–30 R_E downtail is the start of expansion phase onset, earthward flows of plasma would result. This earthward flow would be reduced as it enters the near-Earth tail as a result of the increase in the magnetic field. *Convection breaking*, as this process is termed, leads to magnetic flux pile up, dipolarization, the formation of the substorm current wedge and energetic particle precipitation (see MAGNETOSPHERE OF EARTH: CONVECTION). These signatures then propagate tailward down the tail. This proposal leads to the conclusion that the auroral break-up, or expansion phase onset in the ionosphere, does not occur at the same time as the onset of the expansion phase in the tail.

The *current sheet disruption* (CSD) model is an alternative to the NENL model which is proposed to explain the expansion phase onset. In this model, the thin current sheet still develops in the inner magnetosphere during the growth phase. A combination of lower hybrid waves, produced by streaming non-adiabatic ions interacting with adiabatic electrons, and the lower hybrid drift instability at the density gradient on the boundary of the plasma sheet produces anomalous resistivity which disrupts the cross-tail current, thereby resulting in the substorm current wedge. A further key difference from the NENL model is that disruption of the tail current begins close to geostationary orbit and then expands radially earthward and tailward. In fact it has been proposed that a rarefaction wave is launched downtail reducing the B_z component in the magnetotail and inducing plasma sheet thinning. Ultimately these effects induce reconnection in the tail which leads to the subsequent formation of the plasmoid. Thus closure of open magnetic flux is not necessary for expansion phase onset in the CSD model, although it does occur at some time later.

Another class of model considers the effects of the ionosphere on the magnetotail, through the action of field aligned currents, and such models have been termed *magnetosphere–ionosphere coupling* (MIC) models. In such models, changes in the ionospheric conductivity influence the tail through positive feedback processes, leading to expansion phase onset. By including reconnection in the tail, a *globally integrated substorm* (GIS) model has been developed.

In summary, although there is good agreement on the signatures of the expansion phase, there is no such agreement on the cause of the expansion phase onset. There are a number of models for this element of the substorm process, each of which predicts certain expansion phase signatures. A general consensus, or unified theory, still eludes us however and is a major challenge over the next few years.

Multiple onsets and pseudo break-ups

The discussion above is based upon many observations, but in general relates to what are termed isolated substorms. There are two aspects of such events which have not been covered. During most substorms the expansion phase does not continue in a smooth manner which would imply a continuous release of stored energy. Rather, following the initial auroral break-up, there are a series of intensifications of auroral luminosity, enhancements of the westward electrojet and Pi 2 pulsations which imply that the stored energy is released impulsively. Such *multiple intensifications* have a typical timescale of 10–15 min. The auroral luminosity appears generally to the west and poleward of the initial intensification which is in general separate from the stepwise motion of the WTS. Furthermore, the enhanced ionospheric currents also appear poleward of the initial location. There is also evidence from mid-latitude magnetograms that the western FAC of the SCW moves westward. These intensifications continue throughout the expansion phase, ceasing only when the aurora and currents reach their poleward-most location. A second feature of substorms which has become apparent is the so-called *pseudo break-up*. Such events occur during the growth phase of the substorm. They have most of the characteristics of an auroral expansion phase, for example auroral brightening, Pi 2 pulsations, enhancements of the electrojet current, but the brightened aurora does not appear to expand poleward and westward and after a few minutes simply fades away. It appears therefore that processes which lead to expansion phase onset are in some way quenched. How this happens

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

remains uncertain, although the various paradigms discussed above require different physical mechanisms for such quenching to take place.

A typical substorm will include a growth phase, an expansion phase and a recovery phase and such a description is adequate under conditions where the IMF B_z does not remain south for longer than the typical length of those three phases, of the order of 3 h. However, it is possible that the IMF will in fact remain southwards for longer than this interval. In such a case it is entirely possible that substorms will occur when there does not appear to be a separate growth phase, i.e. the expansion phase of the second substorm will occur at some time during the recovery phase of the first substorm. Also, the auroral oval can continue to expand equatorward in a global sense during the expansion phase. Of course the main physics of the growth phase, i.e. energy storage, is continuing to take place if the IMF remains southward.

Modular approach to auroral activity

Auroral activity is central to the substorm process. The original definition of the auroral substorm was based upon records from a network of all-sky cameras based around the auroral zone. Subsequent developments in spacecraft instrumentation provided images of part of, or the whole, auroral oval at good temporal and spatial resolution. Based on data from one such satellite, Viking, certain researchers have put forward an alternative approach to considering the auroral substorm. This approach stems from the considerable variety which can be identified in auroral activity during the various phases of the substorm, such that no two substorms are exactly alike. The proposal is that certain cycles of auroral activity, modules, couple together to provide the global auroral substorm. The cycles of activity represent the response in the ionosphere to different magnetospheric processes coupling in a repeatable manner.

The approach proposed divides the auroral activity into primary and secondary auroral modules. The primary auroral modules represent the fundamental characteristics necessary for a complete description of the global auroral activity within a substorm. Such modules are also important as they represent timing indicators for other observations. Separate auroral forms occur but these secondary auroral modules do not exist independently of the primary modules. There is uncertainty in the time and location at which these secondary auroral modules appear such that they are not easily included in the framework of a magnetospheric substorm. Here we consider only the primary modules.

The first primary module is auroral growth and dayside patterns and effectively represents the auroral activity during the growth phase. This is something of a departure from the original auroral substorm which did not include any growth phase signatures. Such auroral activations are most probably directly driven by the solar wind. The next time marker or module is auroral onset. In this modular approach there is no difference accorded to break-up and pseudo break-up since the event may or may not develop into a major disturbance. Whether it does or not depends upon its coupling to other modules. However, if the third module, the auroral bulge, develops, then the onset is considered to be an expansion phase onset. The fourth module is the double oval and its variations. During the expansion phase the auroral activity moves poleward. A double oval occurs when the auroral luminosity in the centre of the broad substorm oval decays, when both the equatorward-most activity and poleward-most activity are seen to behave independently, the implication being that different parts of the magnetosphere are responding independently. The final module consists of polar arcs which were originally thought to be independent of the substorm process, since it was thought that they disappeared at expansion phase onset. However, it has been demonstrated that they can occur throughout the substorm phases, and often are seen to intensify during the expansion phase onset. Furthermore, it seems that there is evidence that such arcs can occur on both open and closed magnetic field lines.

Some of the key features of the original auroral substorm, such as the westward travelling surge and omega bands, do not appear as primary auroral modules. They are, however, secondary modules, and therefore represent refinements to the basic model.

External triggering of substorms

The models proposed above for expansion phase onset all advocate an internal instability as being responsible for the explosive release of energy. There is an alternative suggestion, however, that this need not be the case and that substorm expansion phase onset may in fact be triggered by changes in the IMF. This proposal is based upon the empirical evidence of both case studies and statistical analyses that a significant positive turning of the IMF occurs at the time of expansion phase onset. Reductions in the IMF B_y component may also apparently trigger substorms. The proposed mechanism for this triggering is a reduction in the electric field imposed on the magnetosphere by the solar wind, although the physical link is, at the moment, controversial. The delay between the northward turning and the expansions phase onset is very short—a few minutes.

Magnetic indices

The study of substorms has been aided by the use of magnetic indices. Such indices are used to provide a summary of the magnetic variations over a period of time. They can also be used to investigate physical

processes and in terms of substorm behaviour the auroral electrojet indices are perhaps the most widely used. The AE indices are determined from the north–south component of 12 stations which are approximately equally spaced in longitude around the auroral regions. The AU and AL indices represent the upper and lower envelopes of the north–south components of these 12 stations, i.e. the maximum and minimum deflections at any given time. Since the magnetic variations are caused by the ionospheric currents, they should represent the behaviour of these currents during the various phases of the substorm. An example of the AU and AL indices for one particular event is given in figure 5. In this example, an isolated substorm comprising of the three phases is described. The growth phase appears to be mainly observed by the AU index, while the largest deflection in the AL index takes place in the expansion phase, during which there are intensifications of the electrojet currents. The recovery phase is represented by the return of the AL index to lower values, but there are still significant enhancements which may occur during this phase in the AU index.

Magnetosphere of Earth: Waves

Waves are oscillations with respect to an equilibrium position of a given quantity, ω being the angular frequency of the oscillation. Here we are concerned with magnetic and electric field oscillations, the electromagnetic and electrostatic waves. Two main reasons lead us to study such waves in the magnetosphere, their role in the dynamics of the particles with which they interact and the remote diagnosis of magnetospheric plasma parameters.

One important characteristic of the magnetospheric plasma is that it is collisionless. In such a medium the waves that are mostly generated by the free energy of the particle distribution functions are the means to relax this free energy. Waves, once amplified, can heat particles, permit exchange of energy between different populations of particles and precipitate magnetospheric particles into the atmosphere.

Two regions are particularly favorable for the generation of waves, the equatorial region of the magnetosphere where most of the energetic particles are concentrated owing to the convection electric field and the auroral field lines, where particles originating from the ionosphere, outer magnetosphere and the solar wind are accelerated (see MAGNETOSPHERE OF EARTH: CONVECTION, SOLAR–TERRESTRIAL CONNECTION: COUPLING BETWEEN SOLAR WIND, MAGNETOSPHERE, IONOSPHERE, AND NEUTRAL ATMOSPHERE).

Magnetospheric waves were first observed on the ground. *In situ* measurements by spacecraft have helped in understanding the origin of these waves and permitted new observations of waves that cannot propagate to the ground, in particular electrostatic waves.

The different kinds of magnetospheric waves can be organized by their frequency range, ultralow frequency (ULF, up to 5 Hz), extremely low frequency (ELF, 5 Hz–3 kHz), very low frequency (VLF, 3–30 kHz) and low frequency (LF, 30–300 kHz). We are not concerned with frequencies above this range. An overview of the location in the various regions of the magnetosphere of the different types of waves is given in figure 1.

Before describing and interpreting the different observations, a summary of the main wave modes and a short description of some wave–particle interaction processes are needed to understand how these modes can be amplified and interact with particles.

Principal wave modes in the magnetospheric plasma

The different wave modes must satisfy the Maxwell equations, the equations of motion of the particles and conservation laws. The solutions for monochromatic propagating plane waves can be written as $E = E_0 \exp[\mathrm{i}(\boldsymbol{k}\cdot \boldsymbol{r} - \omega t)]$, E_0 being the wave amplitude, ω the angular frequency, and $\boldsymbol{k}$ the wavevector in which direction the wave propagates. All linear fluctuations, or small-amplitude fluctuations with respect to the equilibrium, can be represented as superpositions of these eigenmodes. In plasmas, there can be both transverse electromagnetic and longitudinal electrostatic waves, the wave components being either mainly perpendicular or parallel to the wave propagation vector $\boldsymbol{k}$, respectively. Contrary to vacuum where a continuum of electromagnetic waves can propagate, in plasmas only some frequency windows are possible, which are represented on figure 2, in the $(\omega, \boldsymbol{k})$ plane.

MHD approach

MAGNETOHYDRODYNAMIC (MHD) theory allows the investigation of wave propagation modes in the limit $\omega \ll \Omega_\mathrm{i}$, where Ω_i is the proton gyrofrequency—typically 1 Hz, for an infinite homogeneous medium. The linearization of the plasma equations in such conditions leads to a dispersion relation that has three solutions. These three modes have different polarizations, the perturbation being either in a plane perpendicular to the geomagnetic field $\boldsymbol{B}_0$ or with a magnetic component parallel to $\boldsymbol{B}_0$ (compressional). In what follows, parallel ($\parallel$) and perpendicular ($\perp$) refer to $\boldsymbol{B}_0$.

The shear Alfvén mode or Alfvén mode (also known as the toroidal mode) has the simplest dispersion relation:

$$\omega = k_\parallel V_\mathrm{A} \tag{1}$$

where $k_\parallel$ is the parallel component of $\boldsymbol{k}$, V_A is the Alfvén velocity ($V_\mathrm{A} = B/(\mu_0\rho)^{1/2}$), μ_0 is the magnetic permittivity of free space and ρ is the mass density of the plasma.

The two other modes are the fast magnetosonic mode (the compressional or poloidal mode) and the slow magnetosonic mode (which has also a compressional component). Their dispersion relations do not have simple expressions; they depend on both the Alfvén and the sound velocities, and on their direction of propagation.

The slow mode cannot propagate in cold plasma and is rapidly damped for high temperature, and thus most often only the two other modes are considered (figure 2(*a*)). The ULF fluctuations whose frequency satisfies $\omega \ll \Omega_\mathrm{i}$ are identified with these modes.

Electromagnetic modes at higher frequencies

When considering higher frequencies, it is necessary to modify the equations. A first step is to add new terms to the Ohm's law equation which take into account the movement of both electrons and ions (i.e. a bi-fluid model), the new system of equations then being called the Hall MHD equations. The kinetic approach is more general, taking into account the velocity distribution function of particles. This is used to calculate possible wave amplification or damping and/or consider the effect of a hot plasma population. The principal wave modes thus obtained for different conditions are represented in figures 2(*b*)–2(*e*). The different modes depend on both the direction of propagation $\boldsymbol{k}$ and the corresponding values of the characteristic frequencies: the gyrofrequencies $\Omega_\mathrm{i,e}$ (linked to the magnetic field amplitude) and the plasma frequencies $\omega_\mathrm{pi,e}$ (linked to the plasma density).

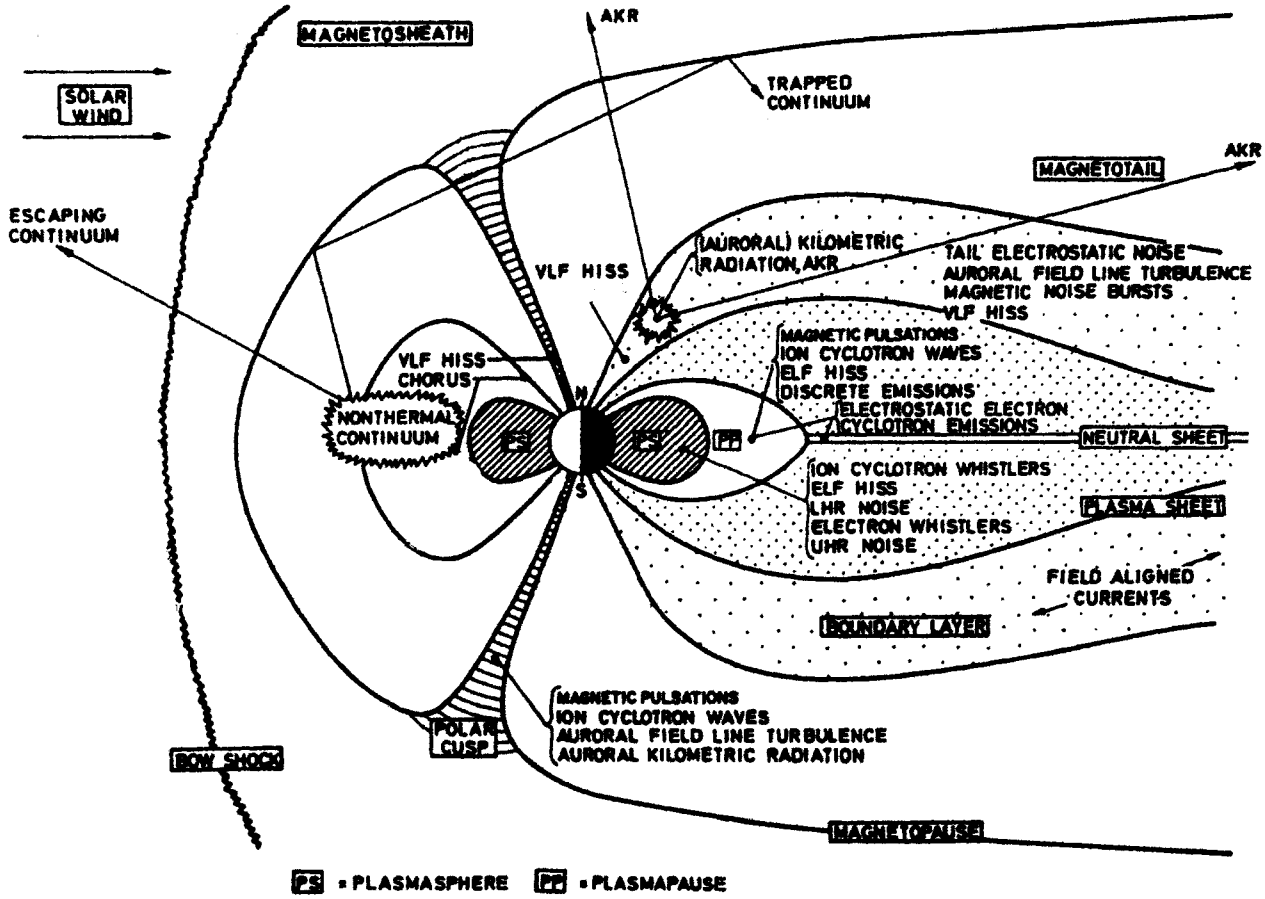

Figure 1. Types of magnetospheric plasma waves and regions of occurrence in a noon–midnight meridian plane cross section of the Earth's magnetosphere.

The most frequent situation encountered in the magnetosphere is the so-called dense plasma or weak magnetic field approximation, where $\Omega_e < \omega_{pe}$ (figures 2(*b*) and 2(*c*) for parallel and perpendicular propagation). For $\omega < \Omega_i$ there is a left-hand-polarized mode and up to Ω_e a right-handed-polarized mode (called the whistler mode), whose low-frequency limits are the shear Alfvén and magnetosonic modes respectively. At higher frequencies there are two modes ω_L and ω_R, on each side of the plasma frequency for small $k_\parallel$; at the limit $k_\parallel = 0$, it is a kind of ZEEMAN EFFECT, $\omega_{L,R} = \omega_p \pm \Omega_e/2$. The plasma frequency ω_{pe} is an electrostatic mode. Figure 2(*c*) gives the modes in the perpendicular propagation. The polarization modes in this case are either ordinary or extraordinary, meaning that the electric component of the wave is either parallel to $\boldsymbol{B}_0$ or rotating in a plane perpendicular to $\boldsymbol{B}_0$. Note in this case the presence of new characteristic frequencies or resonances, the lower hybrid and the upper hybrid resonances ($\omega_{LH} \approx (\Omega_e\Omega_i)^{1/2}$ and $\omega_{UH} = \omega_{pe}^2 + \Omega_e^2$). The forbidden frequency ranges for the different modes are indicated by dark vertical lines on the left of each plot.

In the auroral zones there are regions of very low density. The possible modes in this case are given in figures 2(*d*) and 2(*e*). The modes are the same as in the previous case, but the possible frequency windows are different.

Electrostatic modes above the electron gyrofrequency

Electrostatic waves have their electric component parallel to $\boldsymbol{k}$, being longitudinal. Among them, the plasma frequency propagates at $k_\parallel$ (parallel to $\boldsymbol{B}_0$). Using the kinetic theory and modeling the plasma by a Maxwellian distribution function it is possible to find electrostatic modes with $k_\perp$. These Bernstein modes only exist at frequencies above the electron gyrofrequency (figure 2(*f*)). The behavior of the dispersion relations (one curve between each electron gyroharmonics) is different below and above ω_{UH}. Above ω_{UH} the dispersion relations present maxima corresponding to a null group velocity ($V_g = \partial\omega/\partial k$), at frequencies denoted by F_q.

Some wave–particle interaction mechanisms

The modes described before, except the Bernstein modes, are possible propagation modes in a cold magnetoplasma.

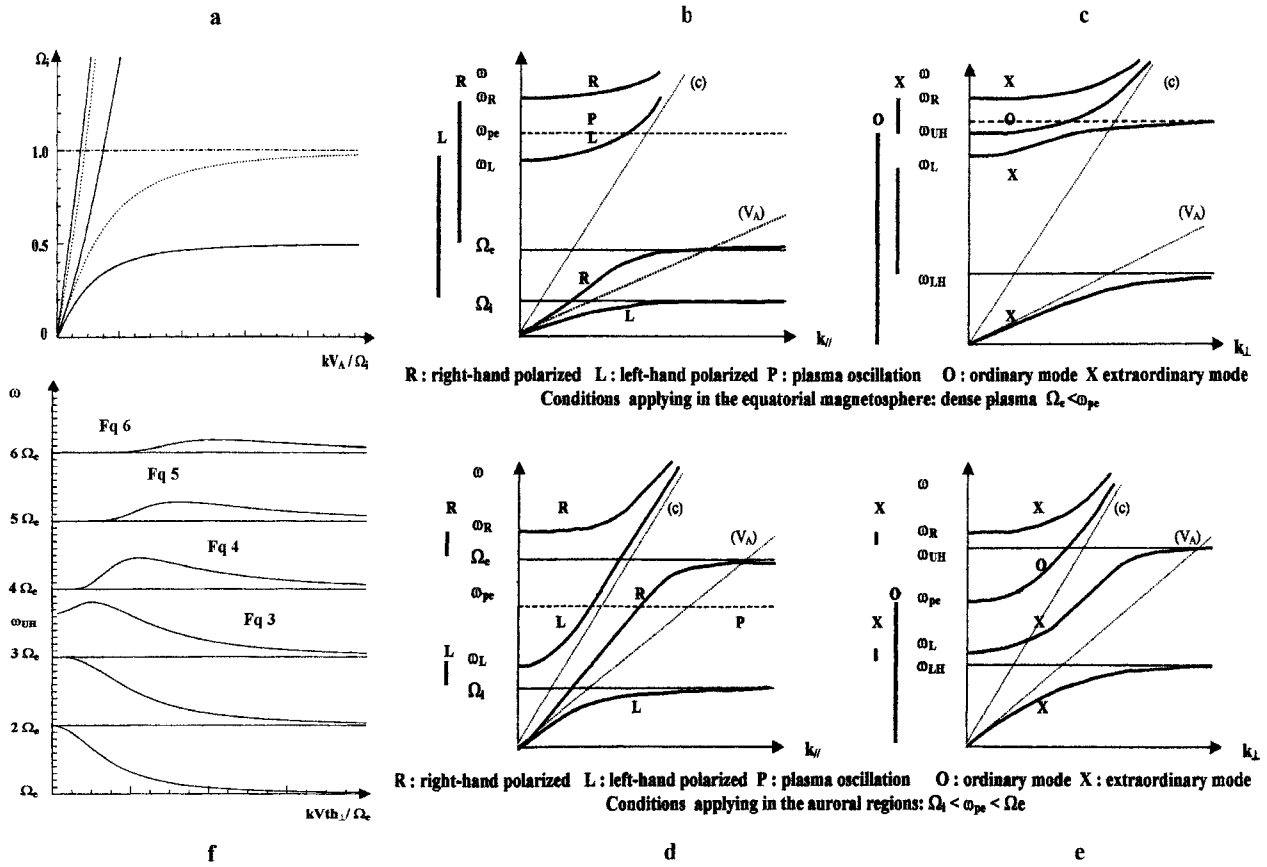

Figure 2. The different wave modes relevant to the magnetosphere in the ω, k plane (dispersion relations). (*a*) MHD modes: there are two modes for cold plasma conditions (dotted curves), fast magnetosonic and shear Alfvén modes from left to right, and three for warm plasma, fast magnetosonic, shear Alfvén and slow magnetosonic modes from left to right. The dispersion relations are given for a propagation angle between $\boldsymbol{k}$ and $\boldsymbol{B}_0$ of 60°.(*b*)–(*e*): Electromagnetic modes in cold plasma, for a single ion species. Black vertical lines correspond to forbidden propagation. (*b*), (*c*) correspond to dense plasma or weak magnetic field ($\Omega_e < (\omega_p)$, which applies in the equatorial magnetosphere, for (*b*) parallel and (*c*) perpendicular propagation. (*d*), (*e*) correspond to $\Omega_i < \omega_p < \Omega_e$ which applies in most parts of the auroral zones, for (*d*) parallel and (*e*) perpendicular propagation. (*f*) The electrostatic Bernstein modes: the frequencies of the dispersion relations' maxima above ω_{uh} are called F_q.

In practice, the cold plasma approximation is often valid, considering that the hot particles are far less numerous than the cold plasma particles, the latter sustaining the propagation of the waves. Nevertheless, in order to be amplified waves need some source of energy: that is mostly provided—at least in a linear phase—by the free energy of the particles, the 'hot' particles. To calculate the amplification of the waves it is necessary to take into account the particle distribution function, in a kinetic treatment, starting from the Vlasov equation.

The exchange of energy between given waves and particles will depend on the possible matching between characteristic particles and wave velocities. This matching is called resonance; some resonances are described below.

Landau resonance—introduction to particle trapping

The Landau resonance is a collisionless interaction between a longitudinal plasma wave and particles whose velocity is nearly equal to the wave phase velocity. The resonance condition is

$$V_{res} = \omega/k. \tag{2}$$

This was first studied by Landau for electrostatic waves propagating in a homogeneous plasma without a magnetic field. By neglecting the temperature of the plasma and considering the ions at rest, one finds the dispersion relation $\omega \approx \omega_{pe}$.

The wave growth rate γ is obtained from the linearized Vlasov equation, where the wave amplitude E is $E = E_0 \exp(\gamma t)$ and f is the particle distribution function, for $V_{res} = \omega/k > 0$:

$$\gamma = (\pi/2)(\omega_{pe}^2/k^2)\partial f/\partial v|_{v=\omega/k}.$$

The important point is that the sign of the growth rate depends of the slope of the distribution function: if there

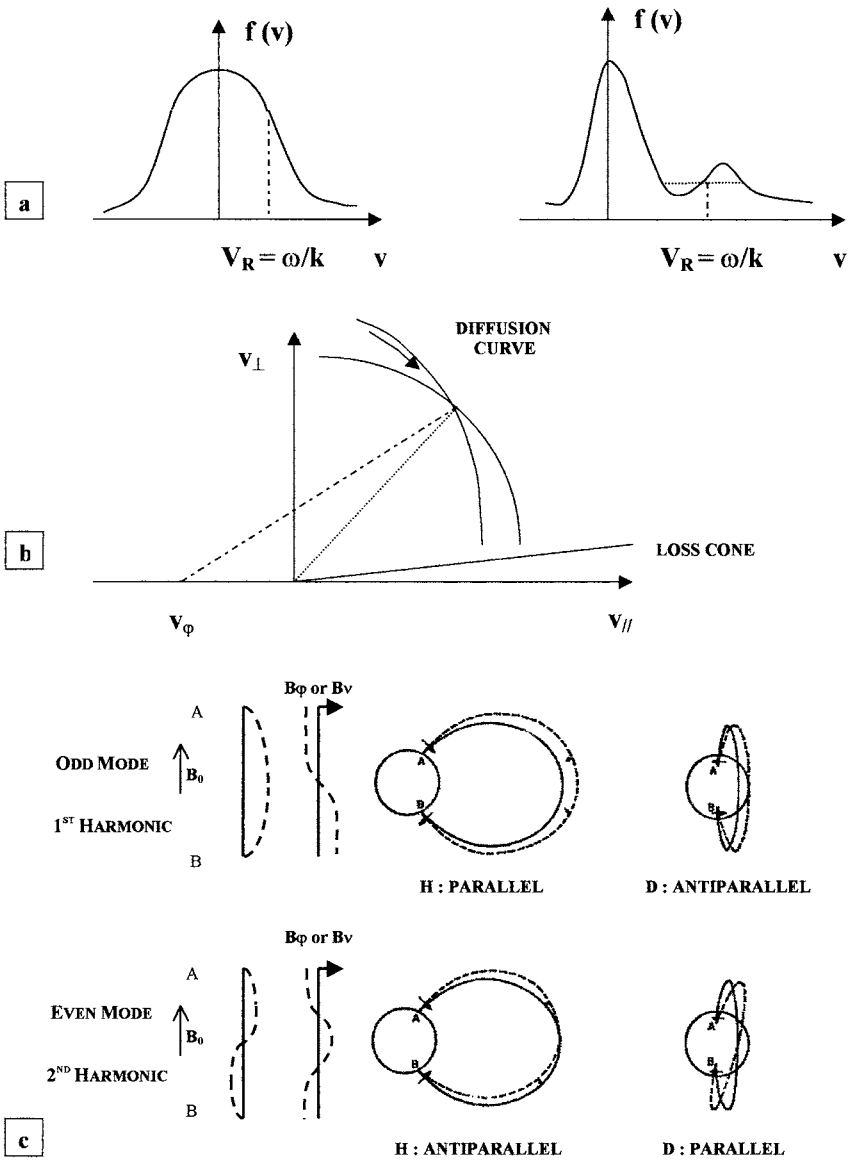

Figure 3. Schematic of wave–particle interaction processes. (*a*) Landau resonance. Landau damping at left, Landau amplification and formation of a plateau at right. V_R is the wave phase velocity. (*b*) Gyroresonance interaction. Particle diffuses along the diffusion curve where the particle energy is constant in the reference frame of the wave V_φ (see text). (*c*) Schematic of the fundamental (top part) and second harmonic (bottom part) oscillations of geomagnetic field lines. Shown from left to right are the oscillation along the field line, the amplitude along the field line of the poloidal (B_v) and toroidal (B_φ) components in a meridian plane, the projection in the meridian plane and a three-dimensional view of the azimuthal component. A and B are the ionospheric footprints of the field lines. The full curves represent the equilibrium state and the broken curves the oscillations.

are more particles at velocity $v = V_{\rm res} + \Delta v$ than particles at $v = V_{\rm res} - \Delta v$, then on average particles can give energy to the waves, the slope of the distribution function being positive (for the case of positive velocities).

In a Maxwellian plasma, $\partial f/\partial v < 0$, and the particles take energy from the wave, damping them. This is called Landau damping (figure 3(*a*), left-hand side). In the opposite case, the wave can take energy from the particles and is amplified. This is what happens when the distribution function has some warm component (e.g. a beam) superimposed on the thermal or Maxwellian distribution. The amplification can continue until the evolution of the distribution function forms a plateau, the slope then being equal to zero (figure 3(*a*), right-hand side). This effect is called quasi-linear diffusion.

The particles that are resonating, or in phase, with the wave are first accelerated and then decelerated as they move through the wave structure. In the frame of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

reference of the wave they oscillate in the wave potential well. If the particles suffer many oscillations, they are trapped. The higher the wave amplitude, the stronger is the trapping effect. The trapping frequency is $\omega_T = (qkE/m)^{1/2}$; the trapping time for one oscillation is $\tau_T = 1/\omega_T$.

The Landau effect, damping or amplification, dominates as long as $\tau_L = 1/\gamma < \tau_T$. Trapping, a non-linear phenomenon, can stop the energy exchange; on average, therefore, it cancels out the Landau effect.

Similar interactions can apply in a magnetized plasma. Trapping may exist for electromagnetic monochromatic waves with a frequency $\omega_T = (kv_\perp qb_1/m)^{1/2}$, where b_1 is the magnetic wave amplitude and $v_\perp$ the perpendicular particle velocity.

Gyroresonant interactions—an example of quasi-linear diffusion

For a plasma in a uniform magnetic field the wave–particle interaction can take place through gyroresonance. This means that, in the frame of reference linked to the parallel velocity of the particle, the particle rotates around the magnetic field at the same angular velocity as the wave, or a multiple of it. The resonance condition is

$$\omega - k_\parallel v_\parallel = N\Omega \tag{3}$$

where N is an integer. The most important cases is $N = \pm 1$; $N = 0$ is the Landau resonance.

We consider the gyroresonance condition (3) with $N = -1$, for which the particle and the wave propagate in opposite directions:

$$V_R = v_\parallel = (\omega - \Omega_{i,e})/k_\parallel. \tag{4}$$

Electrons resonate with right-hand-polarized waves and protons with left-hand-polarized waves.

Because of its resonance with the warm particles, the wave amplitude b can grow, $b = b_0 e^{\gamma t}$, where b_0 is the initial wave amplitude, γ the growth rate and t the time. To calculate the growth rate, the distribution function of the warm population susceptible to resonance with the waves has to be taken into account in the dispersion relation. The solution of the dispersion relation for the angular frequency is complex, $\omega = \omega_r + i\gamma$, where

$$\gamma \propto \eta(V_R)[A(V_R) - A_C] \tag{5}$$

$$A(V_R) \propto \int (\partial f/\partial\alpha)\, d\alpha|_{v_\parallel = V_R}$$

and

$$A_C = \omega/(\Omega_{i,e} - \omega).$$

In these expressions $\eta(V_R)$ is the relative number of resonating particles, A and A_C the particle anisotropy and the critical anisotropy respectively and α is the pitch angle (angle between the direction of the particle velocity and the magnetic field). The wave will grow if γ is positive, which implies that A has to exceed the critical anisotropy A_C. In general the anisotropy depends on V_R, so γ varies with the frequency through equation (4). A is positive if $\partial f/\partial\alpha$ is positive, i.e. if the perpendicular temperature $T_\perp$ exceeds the parallel temperature $T_\parallel$. In the special case of a bi-Maxwellian distribution function, $A = T_\perp/T_\parallel - 1$. As for Landau resonance, the slope of the distribution function is important, A representing the free energy to amplify the waves.

The above expression for the growth rate corresponds to the linear phase: the waves cannot grow indefinitely; some non-linear process will stop their amplification. One process that applies to wide-band wave spectra is quasi-linear diffusion. The waves can diffuse the particles both in pitch angle and in energy, i.e. reducing the pitch angle in order to diminish the anisotropy and diminishing the particle energy respectively, the diffusion in pitch angle being the most important effect. This is schematically shown in figure 3(*b*), where the particle constant-energy curve and the diffusion curve are drawn, the particle energy being constant in the reference frame of the wave on the diffusion curve. One can see that the pitch angle diffusion is faster than the energy diffusion. The diffusion coefficient is proportional to the wave power b^2. The quasi-linear pitch angle diffusion limits the anisotropy and precipitates the particles into the atmosphere (particles that enter the loss cone).

Bounce resonance

Until now we have considered a homogeneous magnetic field. For a slightly inhomogeneous magnetic field on the gyroradius scale, as is the case for the dipolar geomagnetic field, there are other periodicities (or characteristic frequencies) in the particle movement, τ_b (ω_b) the bounce period (frequency) and τ_d (ω_d) the drift period (frequency). The bounce period is the time for the particle to oscillate back and forth along a field line from one hemisphere to the other between magnetic mirror points, and the drift period is the time for particles to drift in azimuth around the Earth. The bounce resonance condition is

$$\omega - N\omega_d = \pm\omega_b \tag{6}$$

where N is an integer and ω/N the east–west angular phase velocity of the wave. Poloidal waves are amplified by taking energy from energetic protons. The resonance will correspond to a breakdown of one or more of the particle's adiabatic invariants, the magnetic moment invariant and the longitudinal invariant. The exchange of energy is

$$dW/dL = q\omega/N B_0 R_E^2/L^2.$$

The resonant particles will diffuse in W, L space, where W is the energy and L the McIlwain parameter.

ULF waves

Ultralow-frequency waves (from 600 to 0.2 s periods) have been studied for many years by means of ground-based magnetometers. ULF waves are separated into

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Table 1. Classification of ULF pulsations.

	Period (s)
Pc1	0.2–5
Pc2	5–10
Pc3	10–45
Pc4	45–150
Pc5	150–600
Pi1	1–40
Pi2	40–150

continuous (Pc) and irregular (Pi) pulsations, classified in each category, according to their period (table 1).

ULF waves comprise propagating waves and standing oscillations. The latter, in the Pc3–5 range, are mainly resonances of the Earth's geomagnetic field lines.

Pc3–5: field line resonances; fundamental and harmonics
Pulsations in the 10–600 s period range have been observed on the ground for many decades and more recently by spacecraft. Much work has been devoted to both observations and theoretical interpretations. Because of the large spatial scale of the phenomenon, it is not easy to put together all the observations needed. While Pc3–5 waves cover the 1.5–100 mHz range, a given event has a quasi-sinusoidal behavior, with a narrow frequency bandwidth.

From combined results of many statistical and case studies of spacecraft data and ground measurements, these observations can be organized into four main classes: fundamental-mode toroidal resonances, harmonic toroidal resonances, radially polarized pulsations and compressional low-frequency pulsations.

A field line resonance can be understood as an excitation of the magnetic field line by some mechanism, the field line being considered as a string whose two ends are anchored in the ionosphere. As for strings, the oscillation can be either the fundamental or a higher harmonic. The possible resonance frequencies are

$$\omega = \pi N \langle V_A \rangle / \ell \tag{7}$$

where N is an integer, $\langle V_A \rangle$ is the average Alfvén velocity over the field line and ℓ is the length of the field line. The field line resonances are usually interpreted in terms of standing Alfvén waves. These waves generally have toroidal and poloidal components. The poloidal component is in the direction of the principal normal of the magnetic field B_ν and the toroidal component is in the azimuthal direction B_φ. In figure 3(*c*) the first harmonic (top part) and the second harmonic (bottom part) of a field line oscillation are drawn. At left, the modulus of the field oscillation is plotted; the second panel gives the amplitude along the field line of the poloidal and toroidal components. The third column gives the projection in the meridian plane and the last one a three-dimensional view of the azimuthal component. A and B are the ionospheric footprints of the field lines.

The azimuthally polarized (toroidal) Pc5 pulsations are observed predominantly at dawn and at dusk for a large range of L values. The amplitude of the azimuthal component is weak at the geomagnetic equator and increases with the latitude. The period of the oscillation increases with L value (or radial distance from the Earth). These observations are consistent with the hypothesis that they are the fundamental of the field line oscillations: the magnetic component of the odd mode is null at the equator, the amplitude of its oscillation increasing along the field line and reaching a maximum at the ionosphere, the period of the oscillation increasing as the length of the field line increases (larger L value). It is identified as a shear Alfvén mode. The facts that the maximum occurrence is on the flank of the magnetosphere and that the maximum amplitude and occurrence rate are observed for the larger L values ($L > 8$) indicate that these Alfvén waves are excited by surface waves at the magnetopause owing to the Kelvin–Helmholtz instability (see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE). The latter waves propagate from noon toward both dawn and dusk.

Higher-frequency regular pulsations (Pc3), also azimuthally polarized and observed both on the ground and in space, are the most common Pc activity on the day side, from 06:00 to 16:00 magnetic local time (MLT), with an abrupt cutoff at those MLTs. Spectrogram displays of such waves show equally spaced monochromatic frequencies. They are interpreted as harmonics of the field line resonances, the even modes showing a maximum amplitude in the vicinity of the geomagnetic equator. The uniformity of occurrence and amplitude of the harmonics with radial distance needs to be explained, with respect to the source of excitation. Different external sources have been invoked, linked to interplanetary activity, waves coming from the magnetosheath and global magnetospheric compressions.

Second-harmonic radially polarized oscillations of the field lines are observed in the dusk and night sides of the magnetosphere. They are believed to be amplified by the bounce resonance interaction with ions of some keV.

Storm-time Pc5 waves
The so-called storm-time Pc5 waves seem to be substorm-associated pulsations, detected mainly in the dusk sector near the equatorial region and associated with energetic particle injections (see MAGNETOSPHERE OF EARTH: SUBSTORMS). The drifting energetic ions, among other possibilities, may be responsible for their amplification.

Pc1 or pearl: a way to transfer energy from magnetospheric protons to ionospheric particles
Ground-based study of Pc1 waves intensified when magnetometer chains multiplied and geomagnetically conjugated stations started to operate. The name 'pearls' comes from their waveform time displays, looking like a succession of pearls. Pc1 waves are mostly observed during quiet to moderately active periods, at $3.5 < L < 7$, at about 1 Hz.

The spectral analysis of pearls reveals an important characteristic: after a rather monochromatic start, a pearl's frequency spectrum broadens into a succession of dispersive rising tones, separated by a period T of the order of 2 min (figure 4(*a*)). The occurrence at geomagnetically conjugate stations (i.e. located at the two footprints of the same field line) is shifted in time by $T/2$. The observations are consistent with generation by gyroresonance between left-handed waves and ring current energetic protons in the equatorial magnetosphere, the waves propagating back and forth along closed magnetic field lines. T is the wave propagation time between two hemispheres. From the dispersion observed on the ground and the repetition period, the L value and cold plasma density in the generation region at the equator can be inferred. From the initial frequency of the events and the variation with time of the dispersion, combined with theoretical results on wave amplification (equation (5)), characteristics of the resonating particles have been inferred. The frequency spread is interpreted as being due to new waves generated by the trapping of protons in the potential well of the initial wave, giving rise to side bands.

In situ measurements performed in the equatorial region, around $L = 6.6$, were surprising. The expected structure separated by a well-defined repetition period was not observed. In those magnetospheric regions there is an abundance of some 1–2% of cold helium ions. This induces new characteristic frequencies at one of which the mode of propagation of Pc1 changes: the waves are focused in a restricted region of the magnetosphere and the time resolution could not resolve the fine structure, if present, for waves above the helium gyrofrequency. Waves below this frequency can propagate to the ground, and in simultaneous ground–spacecraft data the presence of fine structure has been observed at both locations.

These observations have confirmed the amplification of Pc1 waves by energetic protons and their diffusion into the atmosphere. They have also shown that, in the presence of ionospheric helium ions, the waves transfer via non-linear processes some of the proton free energy to electrons and helium ions of ionospheric origin. The waves in this collisionless plasma thermalize particles. A diagram of the different processes involved is given in figure 5.

Irregular pulsations of decreasing period: a signature of drifting protons?

IPDPs, Pi1 pulsations, are observed on the ground in the evening sector for about 1 h, after substorm onset. They consist of a rather wide band of noise whose central frequency increases with time. A schematic of their dynamic spectra is given in figure 4(*b*). The variation of the frequency has been related to the displacement of the inner boundary of the radiation belts during substorm. The association of IPDPs with proton auroras and their westward drift at a velocity compatible with the proton drift at medium energies (<100 keV) are in favor of the generation of IPDPs by protons. The combined radial and westward drifts of energetic protons under the combined action of the convection electric field, which is reinforced during substorms, and magnetic field gradient drift explain the displacement of the interaction region. One of the effects of the convection on particles is to increase their anisotropy, favoring wave generation, which in turn precipitates protons into the atmosphere. Correlated wave measurements in space only show monochromatic waves: at a given L value, only one limited frequency range is emitted, whereas waves observed on the ground come from different L shells.

From the IPDPs frequency increase, an estimate of the intensity of the convection electric field can be inferred, leading to some tens of mV m^{-1}, a value compatible with other E field measurements.

Short irregular pulsations: a field-aligned current signature

Short-time Pi1 pulsations, called SIPs, cover a rather wide frequency range (figure 4(*c*)). They are mainly observed on the ground during active periods, their intensity being at a maximum in the auroral zone. Spacecraft observations have shown that SIPs observed in the night sector were signatures of field-aligned currents moving quickly in the vicinity of the spacecraft during a substorm. The most intense are correlated with the change of configuration of the geomagnetic field, the dipolarization, signature of a substorm onset. These observations and deduced quantities (a drift velocity of $\cong$ 70 km s^{-1} in the east–west direction, and a current intensity $\cong$ a few 10^{-8} A m^{-2}) are in good agreement with the so-called current disruption model of substorm onset. The signature of the currents is sometimes accompanied by some higher-frequency turbulence.

On the ground, SIPs are also observed on the day side. Are they a signature of field-aligned current there too?

Pi2: signature of substorm onset

Pi2 magnetic pulsations, of longer period than Pi1 (40–150 s), mostly appear at substorm onset. They are interpreted as the signature of disruption of cross tail current at substorm onset, diverted down along the magnetic field lines. Current then flows in the ionosphere and returns to the tail along magnetic field lines, transported along the field lines by shear Alfvén waves. The Pi2s are more clearly seen at ground mid-latitude stations. The analysis of Pi2s simultaneously recorded at different stations permits remote determination of substorm onset local time.

Whistler mode waves in the equatorial magnetosphere

Whistler waves, described below, propagate in the right-hand mode, in the frequency range of some hundred Hz to some kHz, at sonic frequencies, below the electron gyrofrequency. Those propagating parallel to the geomagnetic field lines have been observed on the ground, over many decades, since 1930.

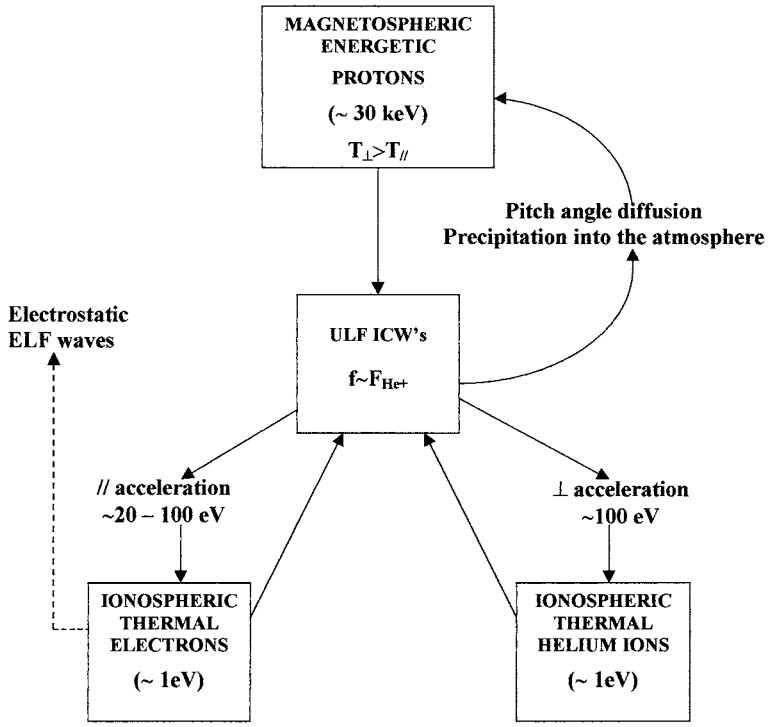

Figure 5. Schematic of the series of wave–particle interaction processes implied in relation to Pc1 waves in a multi-ion plasma: an example of the role of waves in the dynamics of magnetospheric particles. In the equatorial magnetosphere, the anisotropic energetic magnetospheric protons (some 10 keV) amplify ion cyclotron waves that precipitate those protons into the atmosphere by quasi-linear diffusion. In the presence of thermal helium ions originating from the ionosphere, new characteristic frequencies appear. This allows, by non-linear effects, heating of these thermal helium ions and thermal electrons, also of ionospheric origin. The accelerated electrons amplify new electrostatic waves.

Whistlers: a diagnostic tool for equatorial magnetosphere parameters

Lightning discharges are short impulses that excite a wide frequency range of electromagnetic waves. The induced electromagnetic waves propagate from the atmosphere into the ionosphere along a field line and then into the magnetosphere on slightly overdense ducts, in the right-hand mode (figures 4(*d*)–4(*g*); figure 4(*d*) shows their trajectory in a meridian plane). Their group velocity V_g, or propagation velocity, depends on the frequency; the frequency corresponding to the minimum group velocity is called the nose frequency, F_N (see figures 4(*e*)–4(*g*)). They can be observed on the ground in the opposite hemisphere using a radio receiver (figures 4(*e*) and 4(*g*)). The sound thus obtained, generally a falling tone, gave their name to such waves, whistlers. They can also be observed on board spacecraft (figure 4(*f*)). A given emission can propagate back and forth along a field line, as can be seen on the schematic spectrograms (figures 4(*e*)–4(*g*)). Similarly to what is done with pearls, from these dispersion characteristics and from the time delay between the successive hops information on the plasma traversed can be inferred. With some reasonable hypothesis for waves propagating inside the plasmasphere (dipolar magnetic field, cold and dense plasma), it can be shown that the nose frequency $F_N \cong 0.4F_{ce,eq}$, $F_{ce,eq}$ being the equatorial electron gyrofrequency, allowing one to determine L. The density at the equator is determined by the propagation time $t_g \propto (n_{e,eq})^{1/2}$. For frequencies above F_N the cold plasma hypothesis is no longer valid, and, from the observed deviation from this, the electron temperature can be inferred. When the dawn–dusk electric field varies, inducing a change in the plasmapause position, the electric field can be deduced from the variation of L with time.

Hiss: a way to regulate the radiation belt electron flux

Hiss is a very common phenomenon in the near-Earth magnetosphere, outside and inside the plasmasphere, predominantly inside the plasmasphere (plasmaspheric hiss). It is a rather broad-band stationary electromagnetic emission, some hundred Hz wide, in the frequency range from 100 Hz to some kHz. *In situ* observations have confirmed that hiss is the result of a gyroresonant interaction with electrons in the energy range from some keV to some tens of keV. The low-frequency part of figure 4(*h*) is an example of hiss.

Spacecraft measurements have allowed a comparison of wave spectra with the experimental growth rate γ calculated by means of the electron distribution functions. The growth rate γ (relation (5)) maximizes at the wave

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

spectrum peak. Calculation of the anisotropy has confirmed that the quasi-linear diffusion of particles by the amplified waves was efficient: $A > A_C$ when hiss is present, and A is very close to A_C when the amplitude, and thus the diffusion, is strong. The role of hiss in diffusing the particles into the atmosphere, thus limiting the flux of electrons in the radiation belts, has been confirmed.

Chorus: an example of non-linear effects

The peculiarity of chorus is its spectral shape, a succession of quasi-monochromatic rising tones (or sometimes falling tones), spaced in time by some hundred of ms. Their frequency range lies from some 100 Hz to some kHz, at higher frequencies than hiss. Figure 4(*h*) gives an example of simultaneous observation of hiss and chorus; the gap between the two series of chorus elements is at about half the local gyrofrequency. They are preferentially generated after substorms, when new energetic electrons are injected and drift eastward around Earth, and are observed outside the plasmasphere at dawn and on the dayside. Chorus generation in its initial phase is due to gyroresonant interaction between whistler mode waves and electrons (some keV). Their spectral shapes are due to non-linear effects, whose starting point may be the monochromatic structures, evidenced in the concomitant hiss, observed just below the frequency of chorus elements. Interpretation of chorus fine structure is a topic of research. Trapping of the electrons by the monochromatic waves and detrapping by the inhomogeneity in the geomagnetic field are being considered. One difficulty is in measuring the electron distribution function with time resolution as chorus elements. Globally, chorus participates in the precipitation of electrons into the atmosphere.

Waves observed above the electron gyrofrequency in the equatorial magnetosphere

Above the electron gyrofrequency F_{ce}, numbers of wave types are observed in the equatorial magnetosphere (figure 4(*j*)). The full set of Bernstein mode waves is observed: electrostatic electron cyclotron harmonic (ECH) waves between the electron gyroharmonics below F_{UH}, F_{UH} waves and waves at the F_q frequencies (figure 2(*f*)). As can be seen from figures 2(*b*) and 2(*c*), there is a wide forbidden frequency range for the electromagnetic mode between F_{ce} and F_{pe}; it is not surprising that observed waves in this range are electrostatic, electromagnetic waves being at and above F_{UH}.

Electrostatic electron cyclotron harmonic waves at $(n+1/2)\,F_{ce}$: a source for the diffuse auroras?

Electrostatic ECH waves are a common feature of the equatorial magnetosphere, just outside the plasmasphere, in an L value range of field lines having their footprint in the auroral zone (∼6–7). They are confined in the equatorial region, amplified by 100 eV to some keV electrons whose distribution function is of the loss cone type, containing regions where $\partial f/\partial v_\perp > 0$, created by the convection of the plasma from the tail toward the Earth. The lowest harmonic ($(3/2)F_{ce}$) is the strongest and the most often present. From the first case studies ECH waves were thought to be responsible for the diffuse auroras as a result of pitch angle diffusion into the loss cone. Statistical studies have shown that the required amplitude to provoke strong diffusion of 1 keV electrons ($\simeq 2$ mV m^{-1}) was only reached 2% of the time, while diffuse auroras are a permanent feature. $(3/2)F_{ce}$ waves cannot be the only cause of diffuse auroras. A complementary mechanism has to be found. The higher harmonics ($n > 1$) being inefficient in diffusion, other candidates are proposed to precipitate these electrons, such as an acceleration by field-aligned currents or a diffusion by chorus. Figure 4(*j*) gives an example of multiple $(n + 1/2)F_{ce}$ waves observed in the equatorial magnetosphere.

F_{UH} and F_q

The natural lines at the upper hybrid frequency F_{UH} and at F_q frequencies are weak, the most intense being in the close vicinity of F_{UH} (or F_{pe}, as it is very difficult to experimentally differentiate F_{UH} and F_{pe} for large F_{pe}/F_{ce} values). A very weak line at F_{pe} should always be present, reflecting the fluctuation of the electrons due to their thermal agitation, which maximizes very close to F_{pe} but is often hidden either by the lack of sensitivity of the instruments or by stronger emissions. When observable it is a tool to determine the plasma properties: the spectrum peak gives the plasma frequency (and thus the density) and its width gives the thermal temperature of electrons. Sometimes the F_{UH} emission becomes very intense and broadens, amplified by a loss cone distribution function of some 100 eV electrons. Figure 4(*j*) gives an example of weak F_q's and of F_{pe} emission, first rather intense and then of weak amplitude.

Non-thermal continuum radiation

The electromagnetic non-thermal 'continuum' radiation is observed in the 5–100 kHz frequency range, above the local plasma frequency. It is observed in two forms, a series of discrete lines and a smooth continuum (figure 4(*i*)), hence its name. If emitted above the solar wind electron plasma frequency (∼ 20 kHz), it can escape out of the magnetosphere, the escaping continuum. It is highly structured in frequency, composed of narrow-band lines. If generated below the solar wind plasma frequency, it is trapped in the magnetosphere. The different emissions are mixed and superimposed after multiple reflections, forming a broad-band continuum. Sources at the plasmapause have been deduced from multispacecraft measurements. Observations in the tail suggest that the plasma sheet boundary layer and/or the magnetopause can also be source regions.

The exact generation mechanism of the non-thermal 'continuum' is still under debate. Whereas it is generally admitted that the starting point is an electrostatic emission around F_{UH} originating in density gradients, different processes are proposed to convert the electrostatic

emission into an electromagnetic one. Linear conversion, possible in density gradients, is probably inefficient (∼1%). Non-linear coupling is more efficient, such as the coalescence of F_{UH} waves with low-frequency electrostatic waves to form the electromagnetic emission or the decay of the F_{UH} wave into the electromagnetic wave and a low-frequency wave.

Auroral emissions

Among the wave–particle interactions in the auroral zone, the most striking effects are related to the processes which accelerate ionospheric ions toward the magnetosphere, the generation of radio emissions and the possible role of auroral waves in the acceleration of electrons which cause visible auroras.

AKR: a radio source

The Earth is a strong radio source that has been discovered by high-altitude Earth-orbiting spacecraft. The emission is generated in the auroral night side region, in the 50–700 kHz frequency range, at altitudes varying between 5000 and 10 000 km. The emission is powerful (10^7–10^8 W) and is called auroral (or terrestrial) kilometric radiation (AKR or TKR). The plasma frequency of the dense ionospheric layers below this altitude is much higher than the AKR frequency and acts as a cutoff frequency for the radio emission; thus it is not observed on the ground. The occurrence of AKR is correlated with auroras and accelerated electrons, thought to be the source of AKR, by the cyclotron maser instability (see AURORAL KILOMETRIC RADIATION).

Other auroral emissions: a way to accelerate electrons and ionospheric ions

As well as AKR, many kinds of waves are observed in the auroral zone. To account for the acceleration of various particle species, a combination of different wave–particle interaction mechanisms has to be considered. The complete picture of the roles of the different waves has not yet been obtained.

From ground observations, very little was known about auroral waves as compared with subsequent progress made as a result of rockets and polar orbiting spacecraft. The auroral acceleration region of particles is located between 65° and 75° geomagnetic latitude at an altitude between 1000 and 25 000 km. The parallel electric field in this region corresponds to a potential drop of 1–10 kV. How the waves participate in the build up of the parallel electric field is one of the main questions. A field-aligned electric field can be produced by the separation between electrons and ions due to the difference in their mirroring point along a field line but also by waves, since parallel electric field are associated with kinetic Alfvén waves. Small-scale localized solitary structures can add up to produce a significant potential drop. Oxygen electromagnetic ion cyclotron waves can also accelerate electrons. All these phenomena can contribute to down-going electron acceleration. Up-going observed electron acceleration can be achieved by fluctuating parallel electric fields at about 1 Hz or by an interaction with lower hybrid resonance (LHR) waves.

The positive parallel slope in the distribution function of accelerated electrons can generate different kinds of observed waves: auroral hiss, LHR waves, plasma waves or upper hybrid resonance (UHR) waves (see figure 2(*d*) and (*e*)).

An important source of magnetospheric particles is the outflow of ionospheric ions. Before escaping, the ions are accelerated perpendicularly to the field line and then they move upward under the action of the mirror force, or conservation of the first adiabatic invariant: when the ion reaches higher altitudes its parallel energy increases at the expense of its perpendicular energy, as the field strength decreases. The heating can be significant from a few eV to about 100 eV. However, how are the ions accelerated perpendicularly to the magnetic field? Different observed waves are candidates; electrostatic ion cyclotron waves (EICWs) or LHR waves, amplified by electrons, when very intense can collapse into small-scale structures that could accelerate ions. It is also proposed that down-going Alfvén waves suffer a mode conversion to ion cyclotron waves when the Alfvén wave frequency matches the ion gyrofrequency (for either H^+ or O^+) leading to a resonant absorption that heats the ions. This conversion mode can occur in a multi-ion component plasma, which is the case in the auroral region. As these heated ions move along the field line they interact with waves at different frequencies, the local ion frequency varying as the geomagnetic field does, causing broad-band electromagnetic waves. A statistical study correlating wave and ion measurements has shown that most of the oxygen outflow is correlated with broad-band electromagnetic ULF–ELF waves for all local time sectors.

Conclusion and perspectives

Not all magnetospheric waves have been described, in particular those occurring at the magnetopause, in the cusp region or in the tail. The near-equatorial region has been rather well explored and the global role of the waves and wave–particle interactions has been pretty well understood, although some non-linear processes remain to be elucidated. The corresponding importance of different processes occurring in the auroral regions is still to be established. Furthermore, it remains for us to understand the physical processes by which solar wind particles enter into the magnetosphere and the role of waves in such processes. This is one of the aims of the CLUSTER project to be launched in 2000. Its four identical spacecraft will successively fly through the key regions that are the polar cusp, the magnetopause and the tail. Its three-dimensional configuration will allow us to separate temporal and spatial effects, derive differential quantities such as div and curl, and in particular locate wave source regions, determine $\boldsymbol{k}$ vector distribution functions and establish wave polarization.

Definitions

Alfvén velocity. $V_A = B/(\mu_0\rho)^{1/2}$; μ_0 is the magnetic permittivity of free space and ρ is the mass density of the plasma; V_A can also be written $V_A = c\Omega/\omega_p$.

Frequency. $F = \omega/2\pi$, ω being the wave pulsation or angular frequency. ω is commonly used for various relations, dispersion relations and velocities. For observed waves, in Hz, F is more often used.

Gyrofrequency. This is the angular velocity of the charged particles in the presence of a magnetic field, in the plane perpendicular to the magnetic field: $\Omega_{i,e} = q_{i,e}B/m_{i,e} - (F_{ci}, F_{ce})$, where q, m are the charge, mass of the considered species and B is the intensity of the magnetic field ; a useful relation is F_{ce} (in Hz) $= 28B$ (B in nT).

Gyroradius. Radius of gyration of the charged particle: $r_g = v_\perp/|\Omega_{i,e}| = mv_\perp/|q|B$.

Group velocity. $V_g = \partial\omega/\partial k$, gives the direction of the wave energy flow.

L-value or McIlwain parameter. L characterizes a magnetic field line $L = R/R_E$ at the equator, R being the geocentric distance and R_E the Earth radius.

Loss cone—first adiabatic invariant. $\mu = mv_\perp^2/2B$ is the magnetic moment of the particle (ratio between the perpendicular energy of the particle and the magnetic field). This quantity can often be considered as constant and is called the first adiabatic invariant. Combined with the conservation of the particle energy along its trajectory, one obtains $\sin^2\alpha_1/\sin^2\alpha_2 = B_1/B_2$. A particle mirror on the field line at the point where its pitch angle $\alpha = 90^\circ$, being then trapped on this field line. If the point is too low (in the atmosphere), the particle is lost by collision. The corresponding equatorial angle range for which the particles are lost is called the loss cone.

Lower hybrid resonance (LHR). $\omega_{LH} \approx (\Omega_e\Omega_i)^{1/2}$ for one ion species.

Phase velocity. $V_\varphi = \omega\boldsymbol{k}/k^2$, direction of propagation and speed of the wave front, parallel to $\boldsymbol{k}$

Pitch angle. Angle between the particle velocity and the direction of the geomagnetic field $\boldsymbol{B}_0$, usually called α.

Plasma frequency. $\omega_{pi,e} = (n_{i,e}q_{i,e}^2/m_{i,e}\varepsilon_0)^{1/2} - F_{pe}$, F_{pi}, i or e referring to ions or electrons and ε_0 being the vacuum dielectric constant; a useful relation is F_{pe} (in kHz) $=9n_e^{1/2}$ (n_e in particles cm^{-3}).

Spectrogram. This is a visualization in three dimensions of the time evolution of the waves in a frequency–time plane. The time is the abscissa, the ordinate is the frequency and the amplitude is given by the intensity of the signal, either in a gray scale or in color. At each time, it is the result of a Fourier transform of the waveform signal.

Upper hybrid resonance (UHR). $\omega_{UH} = (\omega_{pe}^2 + \Omega_e^2)^{1/2}$.

Magnetospheres: Jupiter, Radio Emissions

The magnetosphere of Jupiter (see JUPITER: MAGNETOSPHERE) is an immense particle accelerator, allowing free electrons in it to reach kilo- to mega-electron-volt energies (keV to MeV). These energetic electrons, moving along and circling around Jovian magnetic field lines, produce intense electromagnetic emissions all over the radio range, with wavelengths ranging from millimeters to tens of kilometers.

Among the dozen or so Jovian radio components, we emphasize here the *synchrotron radiation* from energetic (MeV) particle belts in the decimeter range, and the *cyclotron radiation* from keV electrons in high magnetic latitude regions (auroral field lines, and those linked to the Io–Jupiter electrodynamic circuit (see MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS)).

Discovery and observations of Jovian radio emissions

Between 1955 and 1958, radio emissions from Jupiter were discovered using ground-based radiotelescopes, at frequencies between 10 and 5000 MHz (wavelengths between 30 m and 6 cm). These emissions are extremely intense: if they had a thermal origin, the source temperatures should be ~10^4–10^5 K at 6 cm, and 10^{18} K at 30 m! The latter are so unphysically high that these radio emissions were attributed to non-thermal mechanisms, involving the motion of free electrons in a magnetic field. This was the first inference of a magnetic field, and hence a magnetosphere, for a planet other than Earth. These interpretations were confirmed by high-frequency radio maps like that of figure 1, and by *in situ* measurements of the magnetic field and charged particles around Jupiter by the Pioneer 10 and 11 and Voyager 1 and 2 spacecraft in the 1970s. At the same time, the Earth's magnetosphere and auroral radio emissions were discovered (see MAGNETOSPHERE OF EARTH, MAGNETOSPHERE OF EARTH: WAVES and MAGNETOSPHERE: AURORAL KILOMETRIC RADIATION), and in the 1980s Voyager 1 and 2 revealed the magnetic fields, magnetospheres and radio emissions of Saturn, Uranus and Neptune (see SATURN: MAGNETOSPHERE, URANUS AND NEPTUNE: ATMOSPHERES, IONOSPHERES AND MAGNETOSPHERES).

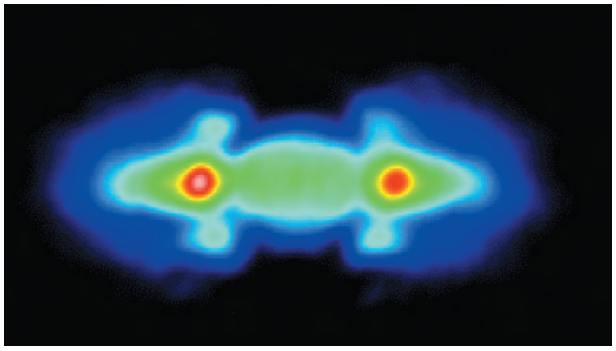

Figure 1. Map of decimeter radio emission (DIM) around Jupiter at a wavelength of 22 cm. The synchrotron emission originates from electron populations near the equator and at high latitudes, and dominates the thermal emission from the planetary disk. The brightness asymmetry between the two ansas comes from the non-dipolar character of the Jovian magnetic field. (From Leblanc Y *et al* 1997 *Astron. Astrophys.* **319** 274–81.)

Jovian radio emissions have been studied from the ground since 1955, at frequencies ≧10 MHz, with various centimeter/decimeter wavelength antennas, as well as decameter arrays (table 1). At lower frequencies, the Earth's ionosphere reflects radio waves, and observations have been performed from space with experiments on board near-Earth spacecraft (RAE 1 and 2 in low Earth orbit, and Wind at the L1 Lagrange point), space probes which flew by Jupiter (Voyager 1 and 2 in 1979 and Ulysses in 1992), and a Jupiter orbiter (Galileo, in orbit since 1995). These various instruments measured the radio emission intensity and polarization, and their variations versus time and frequency.

At frequencies below a few hundred MHz, the angular resolution (λ/D, with λ the radio wavelength, and D the antenna dimension, typically <100–1000 m) becomes very poor, and no direct information can be obtained on the radio source locations. Those must then be

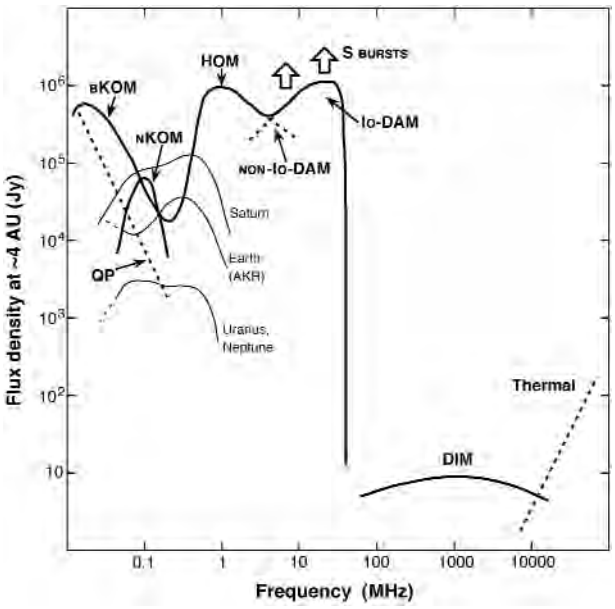

Figure 2. Spectra of Jovian radio components (bold lines) and auroral kilometric radiations from the other giant planets and the Earth (light lines). Average emission levels are sketched as they would be detected from the minimum Earth–Jupiter distance (~4.2 AU). Peak flux densities may exceed the displayed one by up to one order of magnitude, and Jovian S burst fluxes may reach 10^7 Jy (1 Jy = 1 jansky = 10^{-26} W m^{-2} Hz^{-1}). The low-frequency limit of DAM control by Io is somewhere between 1 and 3 MHz. (Adapted from Zarka 1998.)

Table 1. Some key properties of Jovian radio magnetospheric components.

Component	*Frequency range*	*Source location*	*Beaming*	*Power*	*Emission process*	*Discovered/observed by*
Thermal	≧10 GHz	Atmosphere	Isotropic	$<10^9$ W below 10 GHz	Thermal	GB/HF
DIM	≦100 MHz →~10 GHz	Radiation belts (Van Allen)	Mostly $\perp \boldsymbol{B}$	≧10^9–10^{10} W	Synchrotron	GB/HF
Non-Io DAM	A few MHz → 40 MHz	Along auroral field lines ($\lambda_B \approx 67°$–$75°$)	Hollow beam at large angle/$\boldsymbol{B}$	10^{10}–10^{11} W	Cyclotron-maser	GB/LF Voyagers
Io DAM (L bursts/ S bursts)	A few MHz → 40 MHz	Along Io and Io's torus field lines ($\lambda\alpha_B \approx 65°$)	Hollow beam at large angle/$\boldsymbol{B}$ (70°–80°)	Up to 10^{11} W	Cyclotron-maser (?)	GB/LF Voyagers, Wind
HOM	200 kHz → a few MHz	Along auroral field lines ($\lambda_B \approx 68°$–$72°$)	Hollow beam at 30°–90°/$\boldsymbol{B}$	10^9–10^{10} W	Cyclotron-maser	Voyagers, Ulysses, Galileo
bKOM	~10 kHz →>300 kHz (up to 1 MHz)	Along auroral field lines ($\lambda_B \approx 70°$–$75°$)	Hollow beam at 30°–80°/$\boldsymbol{B}$	10^8–10^9 W	Cyclotron-maser	Voyagers, Ulysses, Galileo
nKOM	~50 kHz →200 kHz	Plasma	Broad filled inhomogeneities in Io's plasma torus pattern, around radial direction	~10^8 W	Upper hybrid or plasma frequency?	Voyagers, Ulysses, Galileo
QP bursts/ non-thermal continuum	A few kHz → 50/700 kHz	Auroral? Magnetopause?	? ?	10^7–10^8 W	Cyclotron-maser? Conversion?	Voyagers Ulysses

GB/HF = ground-based high-frequency (centimeter/decimeter wavelength) antennas, including the Very Large Array in New Mexico, the Arecibo radiotelescope in Puerto Rico, etc.

GB/LF = ground-based low-frequency (decameter) arrays in Nançay (France), Kharkov (Ukraine) or Gainesville (Florida).

λ_B = magnetic latitude (the Jovian dipole field makes a tilt of 9.6° relative to the rotation axis).

DIM = decimeter; DAM = decameter; HOM = hectometer; bKOM = broadband kilometer; nKOM = narrowband kilometer; QP = quasi-periodic.

determined indirectly. The only exception is Ulysses, whose radio experiment was able to measure the direction of arrival of incoming radio waves, although only below 1 MHz.

However, while the spectrum of thermal and decimeter emissions (figure 2 and table 1) is very stable in time, it becomes very sporadic and structured in the frequency–time plane at lower frequencies, and gains several orders of magnitude in intensity below 40 MHz. It is thus possible to build frequency-time images of intensity or polarization variations, with high signal-to-noise ratio. These 'dynamic spectra' permit us to follow the rapid variations of emission characteristics (down to a few milliseconds) with a good spectral resolution (down to a few kHz or less) over a broad spectral domain, and these constitute the main tool compensating for the dramatic lack of angular resolution at long wavelengths. Figure 3(*a*) displays a typical dynamic spectrum of low-frequency Jovian radio emissions recorded by Voyager 2 in the kilometer-to-decameter wavelength range, during one complete rotation of the planet (9 h 55.5 min). Figure 3(*b*) is a dynamic spectrum recorded from the ground (in Nançay), displaying the fine temporal structure of decameter emissions named 'S' bursts ('S' stands for 'short').

Characteristics of Jovian radio components

Almost a dozen Jovian magnetospheric radio components have been identified in some 40 years of ground-based and spacecraft observations (see Carr *et al* 1983, Zarka 1998 and references therein). This number is larger than for any other magnetized planet, and Jovian emissions also reach higher intensities. This is mainly due to the intense, quasi-dipolar Jovian magnetic field, together with the fact that most planetary radio emissions are cyclotron emissions: the larger amplitude $|\boldsymbol{B}|$ of the near-surface magnetic field at Jupiter ((4.3–14) –10^{-4} T, compared with <1–10^{-4} T for the other planets) corresponds to higher electron cyclotron frequencies ($f_{ce} = e|\boldsymbol{B}|/2\pi m_e$, with e the charge of the electron and m_e its mass). The large Jovian magnetic dipole moment also creates a huge magnetospheric cavity in the solar wind,

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

with a radius varying between 60 and 120 Jovian radii. The solar wind ram pressure (or kinetic energy flux) thus provides a large input power on this magnetospheric obstacle (~10^{15} W), a fraction of which feeds electron acceleration. Jupiter's rapid rotation is also an effective energy source. Finally, large numbers of accelerated electrons converge towards the magnetic poles along auroral field lines or are trapped within Van Allen 'radiation' (actually energetic particle) belts (see MAGNETOSPHERE OF EARTH: RADIATION BELTS), where they produce intense radio waves.

In addition, the plasma populating every other PLANETARY ATMOSPHERE comes from the solar wind or the planet's ionosphere, whereas a third important source exists at Jupiter: the satellite Io, whose volcanism produces a dense plasma torus around its orbit (see IO: PLASMA TORUS). An electrodynamic circuit forms from the interaction of Io with the Jovian magnetic field, driving strong currents and leading to electron precipitation towards Jupiter and intense radio emissions in the decameter wavelength range.

The exact number of radio components of truly distinct origin is not known because some of them may be different manifestations of the same source and/or phenomenon, for example over different frequency ranges. Table 1 is an up-to-date list of some key properties of these radio components. Their average spectra, as they would be detected from the minimum Earth–Jupiter distance (~4.2 AU), are plotted on figure 2, while figure 3(*c*) sketches how these various emissions appear in the frequency–time plane. Figure 4 sketches the corresponding radio source locations in the Jovian magnetosphere. Detailed information can be found in Rucker *et al* (1997) and Zarka (1998).

Auroral radio components

Part of the decameter emission (DAM) is strongly related to the satellite Io (the Io DAM component), i.e. it is observed only for specific configurations of Io–Jupiter–observer, and the rest is independent of Io (non-Io DAM). Both Io and non-Io DAM emissions are structured in 'arcs' in the frequency–time plane (figure 3(*a*)), and various modulations and fringes may affect them, due to diffraction by plasma inhomogeneities near Jupiter or in the interplanetary medium. Arc shapes have been explained in terms of the complex topology of the near-surface Jovian magnetic field (non-dipolar terms) and of the non-isotropic directivity of the emission. The

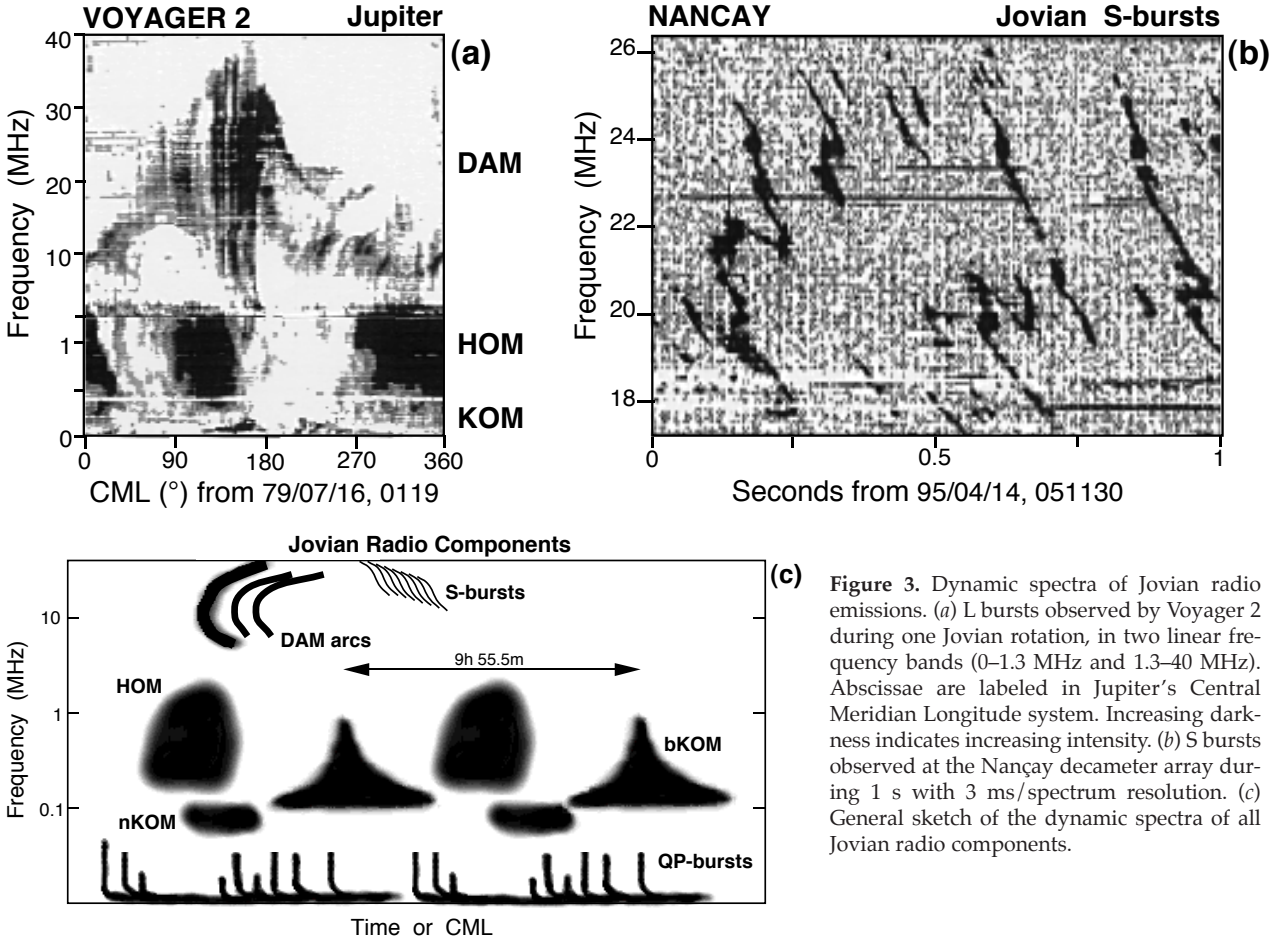

Figure 3. Dynamic spectra of Jovian radio emissions. (*a*) L bursts observed by Voyager 2 during one Jovian rotation, in two linear frequency bands (0–1.3 MHz and 1.3–40 MHz). Abscissae are labeled in Jupiter's Central Meridian Longitude system. Increasing darkness indicates increasing intensity. (*b*) S bursts observed at the Nançay decameter array during 1 s with 3 ms/spectrum resolution. (*c*) General sketch of the dynamic spectra of all Jovian radio components.

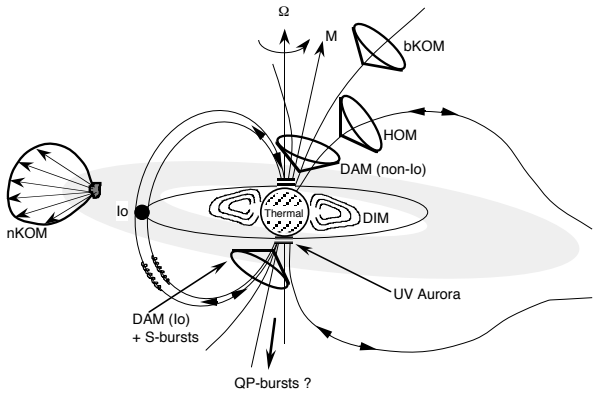

Figure 4. Radio source locations in Jupiter's internal magnetosphere and Io plasma torus. The nKOM is emitted in ~70° wide beams from quasi-point sources in the torus, while the auroral emissions (bKOM, HOM, DAM and possibly QP bursts) are produced near the local gyrofrequency and beamed in hollow cones with axes aligned with the high latitude magnetic field lines. Arrows indicate field lines along which energetic electron precipitation is known to occur.

hectometer component (HOM), independent of Io, is thought to be the low-frequency extent of non-Io DAM. Its source and that of bKOM have been directly located by Ulysses. The broadband kilometer (bKOM) source overlaps with that of HOM, but these components appear distinct on dynamic spectra (figures 3(*a*), (*c*)). They may have the same generation mechanism, driven by different sources of energetic electrons.

DAM, HOM and bKOM constitute the Jovian auroral (high magnetic latitude) emissions, in many respects similar to Earth's auroral kilometric radiation. They are generated between the Jovian surface and a few planetary radii above it, along field lines at the footprints of which the precipitated electrons generate UV, visible and IR auroras. Io DAM is linked to the Io–Jupiter current system, and can be considered as a secondary 'auroral' source, at a slightly lower latitude than non-Io DAM.

The low-frequency part of the Jovian radio spectrum, between a few kHz and a few tens of kHz, had been attributed after Voyager flybys to non-thermal continuum radiation generated at the dayside magnetopause. Ulysses observations attributed at least part of it to the merging of the low-frequency part of ubiquitous bursts recurring with quasi-periods (QP) of 15 to 40 min. Their origin is unclear, but they may be auroral too.

Time variations

DIM to bKOM components are strongly modulated by the planetary rotation (9 h 55 min 23.7 s), due to their non-isotropic directivity. Actually, magnetospheric radio emissions are the only means to determine the rotation rate of the giant planet's interior, where the magnetic field originates, through the thick cloud layers.

The narrowband kilometer component (nKOM) lags the planetary rotation by a few per cent, due to its origin in Io's torus, whose plasma is not in perfect co-rotation with the planet.

Fluctuations of the solar wind parameters (ram pressure, density, velocity and magnetic field) induce modulations of the bKOM, HOM, non-Io DAM, and possibly QP bursts, but do not affect Io DAM. This is expected because the radio sources of all these components are in 'external' regions of the magnetosphere, while that of Io DAM is along field lines connected to Io's torus, in the inner magnetosphere. But solar wind variations also modulate the occurrence of nKOM, although it originates from the torus itself. The penetration of the solar wind influence there remains to be explained.

Finally, Io DAM is observed with two strikingly different morphologies: it may consist, like non-Io DAM, of slowly varying emissions ('L' bursts on timescales of minutes; 'L' stands for 'long'; figure 3(*a*)), or consist of a series of S bursts (each lasting a few tens of milliseconds; figure 3(*b*)). These two morphologies correspond to different regimes of energy release, and possibly to different generation mechanisms.

Ganymede's radio emissions

In addition to the above Jovian components, Galileo observations revealed the existence of the magnetosphere and radio emissions of the satellite GANYMEDE (Gurnett *et al* 1996), thus providing evidence of a hierarchical organization of embedded magnetospheres in the solar system. Ganymede radio emissions are not auroral, but appear similar to the continuum radiation from planetary magnetospheres. The observed energetic particle environment of Ganymede, and the periodic reconnection of its magnetic field with that of Jupiter, suggests that it might control some Jovian radio emissions in a similar but probably less prominent way than Io.

Generation mechanisms and acceleration processes

The generation of all magnetospheric radio emissions (except nKOM) requires energetic electrons moving in a magnetic field. The intensity and polarization of the radio components are the main constraints permitting us to identify the generation mechanism (Goldstein and Goertz 1983).

The moderate intensity and linear polarization of DIM indicate a synchrotron emission process, non-thermal but incoherent (where the intensity produced by each electron adds up to form the total emission). Detailed maps as in figure 1 have been successfully modeled using an isotropic and an equatorial, trapped electron distribution. The decimeter (DIM) emission is much weaker or non-existent at the other giant planets because of energetic particle absorption by the rings. The Jovian

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

DIM was enhanced for several weeks after the collision of Comet Shoemaker–Levy 9 with Jupiter in 1994.

The circular or elliptical polarization of DAM, HOM and bKOM, and their extremely high intensities, rather require a coherent, maser-like emission mechanism. Ulysses measurements definitely proved that these radio emissions are produced close to the local electron cyclotron frequency, f_{ce}, at each point along auroral magnetic field lines, on the so-called extraordinary propagation mode. This confirmed the cyclotron-maser mechanism as the best candidate for their generation. This mechanism consists of coherent generation at the cyclotron frequency by unstable electron populations containing free energy susceptible to amplify waves, in the form of an excess of electrons with high velocity perpendicular to the local magnetic field. The elliptical polarization of DAM implies that the plasma density within the radio sources is extremely low (possibly <5 cm^{-3}), which is a favourable condition for the cyclotron-maser mechanism.

Electron acceleration processes are not yet firmly identified. Magnetospheric compressions, observed by Ulysses, may lead to the so-called 'Fermi' and 'betatron' acceleration of electrons trapped on magnetic field lines. After several Jovian rotations, electrons may thus reach the MeV energies required by the synchrotron generation of DIM. Auroral emissions require rapid acceleration processes, which include magnetic reconnection in the magnetotail, parallel electric fields (observed in Earth's auroral regions and near Io's magnetic flux tube), and heating by low-frequency plasma waves (observed by Ulysses near Io's torus, or possibly originating from the current disk in the case of QP bursts). Parallel electric fields may be electrostatic or non-stationary (so-called Alfvén waves). The latter are thought to be generated by the interaction between Io and the Jovian magnetic field (Io–Jupiter electrodynamic circuit).

Multispectral (UV/IR/radio) studies of the 'Io' auroral source permit estimates of the energy of precipitated particles and allow us to compute an energy budget: $\sim 10^{12}$ W are dissipated in each hemisphere by the Io–Jupiter circuit, mostly in the form of Alfvén waves converting into electron acceleration (keV to tens of keV); the latter precipitate into an area of $\sim 10^5$ km^2 in the Jovian ionosphere, producing (2–3)–10^{10} W in the IR and UV ranges, and up to 10^9 W above the ionosphere in the DAM radio range. The S bursts are so intense that the cyclotron-maser mechanism might be not efficient enough.

Finally, nKOM was shown by Ulysses to be generated by discrete sources in Io's torus at the local electron plasma frequency (proportional to the square root of the electron density) or upper hybrid frequency (the square root of the sum of the squares of the electron plasma and cyclotron frequencies). These sources might be density inhomogeneities, waxing and waning with time (in relation to solar wind fluctuations). The specific radio generation mechanism has not yet been identified.

Interest of the study of Jovian radio emissions and perspectives

Although representing a small fraction ($\sim 10^{-5}$) of the input solar wind power on the magnetospheric cross section, radio emissions (together with auroral UV and IR emissions) are essential for remote sensing studies. Their intensity, polarization and frequency–time structure are directly linked to the topology of the Jovian magnetic field and energetic electron distributions at the radio sources, which can thus be remotely monitored. The knowledge gained in understanding the generation of Jovian radio emissions will be applied to other distant radio sources (solar, stellar), that no spacecraft can reach. Extrapolating the fact that Jovian DAM is the most intense radio emission in the solar system, it appears interesting to search for exoplanets through their possible magnetospheric radio emissions.

Web Update (31 July 2002)

New observations of Jupiter, its satellites and environs have been made by Cassini, Galileo, the Hubble Space Telescope, the Chandra X–ray Observatory and Earth–based radio and optical telescopes during the CASSINI spacecraft's flyby . The Galileo spacecraft has been in orbit around Jupiter since December 1995 while Cassini observed Jupiter from October 1, 2000 to March 31, 2001. Cassini made its closest approach on December 30, 2000, at a distance of about 9.7 million kilometers (6 million miles).

Radio emissions from Jupiter are believed to be generated along the high–latitude magnetic field lines by the same electrons that produce the aurorae, and both the radio emission in the hectometric frequency range and the aurorae vary considerably. Simultaneous observations using the Cassini and Galileo spacecraft of hectometric radio emissions and extreme ultraviolet auroral emissions from Jupiter show that both of these emissions are triggered by interplanetary shocks propagating outward from the Sun. When such a shock arrives at Jupiter, it seems to cause a major compression and reconfiguration of the magnetosphere, which produces strong electric fields and therefore electron acceleration along the auroral field lines, similar to the processes that occur during geomagnetic storms at the Earth.

Ground–based observations have shown that Jupiter is a two–component source of microwave radio emission: thermal atmospheric emission and synchrotron emission from energetic electrons spiraling in Jupiter's magnetic field. Observations of 13.8 GHz synchrotron emission collected during the Cassini fly–by confirm the presence of electrons with energies up to 50

MeV. These energetic electrons may be repeatedly accelerated through an interaction with plasma waves, which can transfer energy into the electrons. Preliminary comparison of the data with model results suggests that electrons with energies of less than 20 MeV are more numerous than previously believed. The most widely accepted theory postulates that the relativistic electrons originate in the solar wind or in the outer Jovian magnetosphere and diffuse inward, gaining energy through conservation of the first and second adiabatic invariants. This can account for electrons with energies around 10 MeV near the peak of the synchrotron zone. However, additional acceleration mechanisms are required to explain higher energies.

Magnetospheres: Jupiter, Satellite Interactions

Most of the satellites of Jupiter, notably the large Galilean satellites Io, Europa, Ganymede and Callisto (see JUPITER: SATELLITES), orbit deep inside the magnetosphere of Jupiter (see JUPITER: MAGNETOSPHERE) and are therefore immersed in the flow of magnetospheric plasma (made of a mixture of electrons and ions) and subjected to an interaction with the strong Jovian magnetic field. These interactions have dramatic consequences for the Jovian magnetosphere, the satellites of Jupiter and even the ionosphere of Jupiter, particularly in the case of the innermost large satellite Io.

Since during the first three decades of research in this area, observations of this interaction were available only for Io, ideas were initially developed for this case. The early history of this case began with the discovery of the control of radio emissions from Jupiter by Io (see MAGNETOSPHERES: JUPITER, RADIO EMISSIONS). It was followed by first attempts to physically explain these observations. The next important step was the discovery of an ionosphere of Io by the PIONEER 10 spacecraft. A more advanced understanding was developed in response to ground-based observations and the many significant results of the VOYAGER MISSION. The GALILEO MISSION has revealed that all four of the Galilean satellites show interactions with significantly different features and a challenging diversity of physical processes.

The Io effect and the unipolar inductor model

In 1964 the so-called Io effect was discovered by using data on the radio emissions from Jupiter in the decametric range of wavelengths (several tens of meters). It was found that the radio emissions are strongly controlled by the orbital position of the satellite Io with respect to the observer. It was generally concluded that an electrodynamic interaction of Io with the Jovian magnetic field was responsible for the Io effect. The simple idea of the unipolar inductor model of this interaction is shown in figure 1, where Io is shown much larger than in reality for clarity. The unipolar inductor model starts from the idea that the plasma and magnetic field are rotating rigidly with Jupiter with a velocity at the orbit of Io which exceeds the orbital velocity by about 57 km s^{-1}. An observer at rest with respect to Io then observes a motional electric field directed outward from Jupiter. Across the diameter of Io this electric field corresponds to a voltage of about 500 000 V applied to Io. This voltage arises much in the same way as in an electric generator, where electric wires are moved across a magnetic field. This voltage then drives a current system first through Io, as shown in figure 1. The current circuit is then continued along the magnetic field lines which can be viewed as highly conducting wires. The circuit is finally closed by currents through the Jovian ionosphere perpendicular to the magnetic field. When the currents pass through the Jovian ionosphere a 'hot spot' is expected to form as a consequence of the electric heating and precipitation of energetic particles.

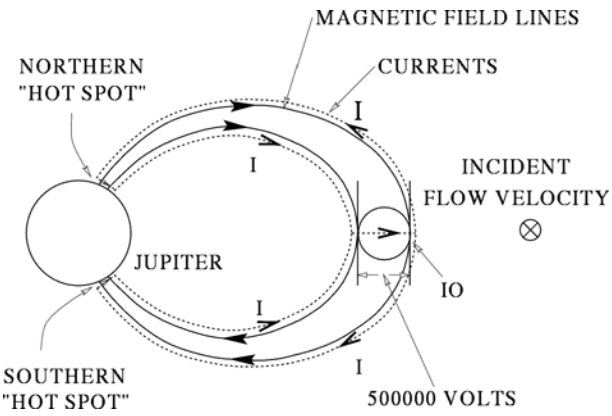

Figure 1. Principle of the unipolar inductor model (not to scale). The corotating plasma flows towards Io into the plane of the drawing. The voltage drop is based on realistic magnetic fields.

The center of this hot spot is defined by the footpoints of the magnetic field lines passing through Io in this simplified picture. Early estimates yielded currents of 1 MA in each branch of the current system based on a voltage of 700 000 V across Io using a somewhat too high magnetic field of Jupiter at that time. The unipolar inductor model also involved the idea that electrons accelerated along the magnetic field lines provide the energy for the emission of radio waves. The frequency of the radio emissions was associated with the local electron cyclotron (or gyro) frequency (the frequency of the gyro motion of electrons around the magnetic field), an idea which is basically accepted today. In this initial work the current was assumed to be closed through the conducting interior of Io. This unrealistic assumption was later replaced by current closure through a conducting ionosphere of Io, which was discovered by a radio occultation experiment on the first spacecraft that explored Jupiter, i.e. Pioneer 10 in 1973. This discovery of an ionosphere implied the existence of a neutral atmosphere around Io. Another far-reaching discovery was the ground-based observation of clouds of neutral gas like sodium atoms with Io as the source.

The Voyager encounters and the Alfvén wing model

The Voyager flybys at Jupiter in 1979 yielded a number of important new observational results, which better defined the problem, but also sparked a number of new theoretical ideas, which led to a much more mature picture of Io's electrodynamic interaction. An SO_2 atmosphere was discovered in the infrared which provided an initial definition of the neutral atmosphere as the basis of the ionosphere discovered by Pioneer 10 and confirmed much later by the Galileo spacecraft. This highly dynamic neutral atmosphere which was later investigated by the Ultraviolet Explorer and the Hubble Space Telescope (HST) is basically due to volcanic activity on Io driven by tidal friction in its interior. Another discovery by Voyager was the Io plasma torus (see IO: PLASMA TORUS),

a population of plasma mostly composed of sulfur and oxygen ions, originating from Io and forming a torus at the radial distance of Io from Jupiter and trapped in the Jovian magnetic field. The high plasma densities in the torus with electron concentrations of several 1000 cm^{-3} at the center of the torus and the energy balance of the torus requires mass loss rates from Io of about 1 ton s^{-1}. This makes Io comparable to a comet of intermediate gas production at 1 AU. In contrast to the comets in orbit around the Sun (see SOLAR WIND: INTERACTION WITH COMETS) Io is moving through its own ion tail. This is because the torus plasma is moving at the fast rotation rate of Jupiter, thereby overtaking slowly moving Io all the time. Thus plasma leaving Io through its wake is reencountered on the front side approximately a rotation later. Io is thus the major source of plasma mass in Jupiter's magnetosphere.

The huge densities (for the magnetospheres of the outer planets) also imply a large inertia of the plasma flow incident on Io. This requires an improvement of the unipolar inductor model described above. The unipolar inductor model must be replaced by the more general and more accurate Alfvén wing model. This is based on the radiation of Alfvén waves (see MAGNETOHYDRODYNAMIC WAVES) by the satellite. This radiation of Alvén waves is similar to the establishment of a bow shock by a supersonic aircraft. In contrast to the sound waves forming a bow shock, the Alfvén waves are restricted to move parallel or antiparallel to the magnetic field for an observer in the rest frame of the magnetospheric plasma. Figure 2 schematically shows the formation of Alfvén wings in the rest frame of Io. Because of the velocity of the magnetospheric plasma the wings are inclined with respect to the unperturbed magnetic field of Jupiter. The northern and southern Alfvén wings distort the magnetic field due to their currents. During the flyby of Voyager 1 at Io the Alfvén wing signature was identified successfully, indicating currents of about 3 MA in one branch of the wing. Figure 2 also illustrates that the Alfvén wings must be reflected either by the ionosphere of Jupiter or at the torus boundary. The reflected Alfvén wave must pass behind Io on its way to the opposite hemisphere. If it passes far behind Io there is no feedback of the Alfvén wave on Io. If Io has not moved very far before the reflected Alfvén wave returns, there will be an interaction of the reflected Alfvén wave with Io. In the extreme case that the reflected Alfvén waves pass through Io's ionosphere several times, the unipolar inductor model is obtained as an extreme case of very close coupling of the Jovian ionosphere and Io's atmosphere–ionosphere system. Figure 2 also suggests that a large number of reflected wing portions may trail the satellite. These reflected wings have also been proposed as the explanation for another significant discovery by Voyager, i.e. the discovery of multiple arcs in frequency–time diagrams of the decametric radio emissions. The Alfvén wing configuration is expected to vary in response to changes in torus density and the magnetic latitude of Io describing its position in the torus. It varies between the pure Alfvén wing picture without feedback to a configuration with some features of the unipolar inductor model. The plasma flow through Io's atmosphere and its electric conductivity are determined by a number of processes of atomic and molecular physics. These are referred to as ion pick-up, charge exchange and elastic collisons. In the wake region there is an excess of plasma leaving Io's environment (relative to the incoming plasma), thereby forming an ion tail. The flow also drags neutral atoms and molecules away to feed the neutral clouds referred to above. These processes describe the loss of mass from Io to be replaced by volcanism.

Advanced Earth-based observations and the Galileo mission

The description of the interaction between Io and the Jovian magnetosphere includes a 'hot spot'. It has been described above as the footpoint of the disturbance system radiated by Io parallel and antiparallel to the magnetic field toward the Jovian ionosphere. Observations of this footpoint contain important diagnostic information on the nature of this disturbance system and also the Jovian magnetic field. First observations of the footpoint were obtained in the infrared in 1993 and with increasing sensitivity by the HST in recent years. The Io-related disturbance system consists of a 'bright spot' with a wake trailing the spot over a large part of a circle around Jupiter.

A new leap forward in our knowledge on the magnetospheric interaction of the Galilean satellites came through the many encounters of the Galileo orbiter with the satellites which is continuing at the time of writing. On 7 December 1995 the Galileo spacecraft passed through the wake of Io at an altitude of 900 km. The main features of the observations were the detection of a deep dip in magnetic field magnitude, an almost stagnant ionospheric plasma near closest approach, and a system of plasma waves which are at least partly due to the pick-up of ions of Ionian origin. The higher torus density during this encounter compared with conditions observed by Voyager in 1979 suggest a somewhat stronger interaction than at that time. It has been suggested that the observations may require the presence of an internal magnetic field although it is not clear yet whether the disturbances in the magnetoplasma around Io really require such a field. During the Galileo encounter at Io peculiar distributions of electron beams in the energy range from 15 keV to above 140 keV parallel and antiparallel to the magnetic field were observed which can be considered the first direct evidence for acceleration processes due to the magnetospheric interaction of Io. They are also of appreciable interest for the mechanisms generating radio emissions from Jupiter's environment.

Until recently there was no observational evidence for the nature of the interaction between the three Galilean satellites outside Io, i.e. Europa, Ganymede and Callisto, and the Jovian magnetosphere. The situation was changed by the HST observations of an oxygen atmosphere of Europa just before the arrival of Galileo at Jupiter. In the meantime there is also

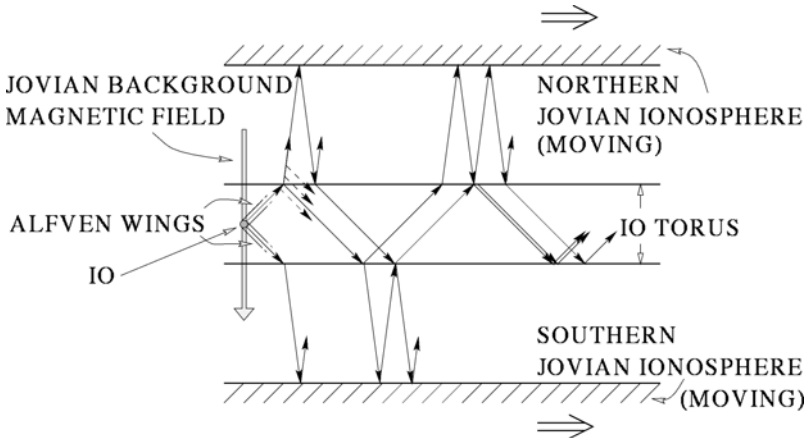

Figure 2. Idealized sketch of the Alfvén wing system generated by Io viewed in the rest frame at Io. In this frame the magnetospheric plasma and the ionosphere of Jupiter are moving toward the right. Reflected wings are shown with reflections at the torus boundary, ionosphere of Jupiter and repetitions thereof.

evidence for an oxygen atmosphere on Ganymede and a CO_2 atmosphere on Callisto. Without any further information this suggests the following scenario for these satellites. Photoionization and collisional ionization by magnetospheric electrons produce ionospheres, which interact with the magnetosphere of Jupiter via the general Alfvén wing model as explained above. A substantial difference with the case of Io exists, however. The neutral atmosphere must be maintained against the loss processes due to the magnetospheric interaction in the absence of the violent volcanism at Io. For Europa the idea has been developed that sputtering by magnetospheric ions generates the observed oxygen atmosphere. A similar idea might be applied to Ganymede and Callisto.

It came as a complete surprise that Ganymede possesses a substantial internal magnetic dipole field, possibly of dynamo (see DYNAMO THEORY) origin. With an equatorial surface field of the dipole of 750 nT roughly antiparallel to the satellite's spin axis, Ganymede is surrounded by its own magnetosphere which itself is embedded in the huge Jovian magnetosphere. Broad Alfvén wings are radiated northward and southward from the polar caps of Ganymede's magnetosphere. An idealized sketch is shown in figure 3. The magnetosphere has closed field regions at low and intermediate latitudes.

The magnetospheric interaction with the remaining satellites Europa and Callisto cannot be explained by the unmodified Alfvén wing model, as the flyby observations show. To explain the observations a magnetic field of internal origin is required again. However, the observations particularly at Callisto show that a dipole moment fixed to the satellite does not explain the observations. The only alternative is an internal field due to electromagnetic induction generating eddy currents. Such an internal field requires an electrically conducting interior of the satellite, which may be provided by subsurface oceans with high electric conductivity due to leaching of salts. The eddy currents are excited because

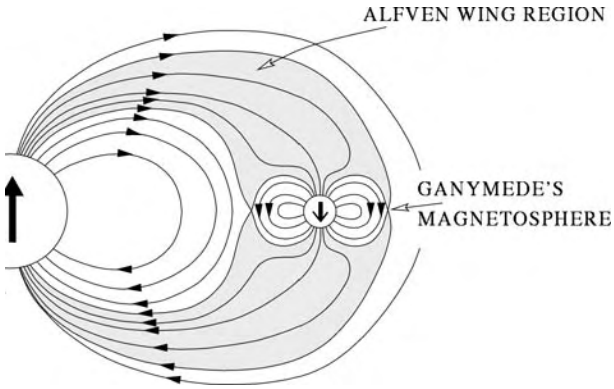

Figure 3. The magnetosphere of Ganymede inside the magnetosphere of Jupiter (not to scale)

the Jovian magnetic field has a time varying component at each satellite, which is due to the tilt of the Jovian dipole moment with respect to the spin axis of Jupiter. The induced fields provide a component of field perturbations which has in principle to be assessed at all satellites.

Magnetospheres: Plasma-Ring/Dust Interactions

Dust particles in space are often immersed in plasmas and UV radiation and, consequently, carry electrostatic charges. The motion of small micron- and submicron-sized charged grains can be influenced or even dominated by electric and magnetic fields in addition to gravity, drag and radiation pressure. Dust particles in plasmas are unusual charge carriers. They are many orders of magnitude heavier than any other plasma particles (electrons and ions) and they can have time-dependent charges many orders of magnitude larger (negative or positive). Small grains act as plasma probes since their charging and dynamics are set by the plasma environment.

Figure 1 shows one of the most unexpected findings of the Voyagers at SATURN, the sporadically appearing, radially expanding dust clouds above the dense B-ring (see also SATURN: RINGS). The 'spokes' consist of charged submicron-sized dust particles that are lofted above the rings due to electromagnetic forces (Mendis *et al* 1984). Meteorites bombarding the rings generate plasma clouds that rapidly drift away from the synchronous orbit (the distance where the rotation rate of the planet matches the Kepler orbital rate) and lift off submicron-sized grains from the ring plane as they move above the rings. Each dust particle follows an approximate Kepler orbit so that grains in the cloud closer to Saturn move faster. As 'spokes' age the Kepler shear results in an increasing tilt and the contrast between the dust cloud and the ring diminishes.

The 'spokes' were the first evidence that, contrary to general belief, gravity alone cannot explain all of the complex dynamics in PLANETARY RINGS. The ring/halo region and the dust streams at Jupiter and the E-ring at Saturn are other examples where the magnetospheric plasma environment shapes the size and spatial distribution of small dust particles.

Electrostatic charging of dust in plasmas

The electrical charge of a dust grain, Q, changes due to the currents reaching its surface

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = \sum_k J_k \tag{1}$$

where J_k represent various electric currents. Electron and ion collection, and secondary and photoelectron emission currents, dominate dust charging in most space plasmas (Whipple 1981). All of these currents are functions of the plasma properties (density, composition, energy distribution) and also the properties of the dust grain (size, velocity, composition, surface roughness). As a dust grain collects charges it changes the electrostatic potential distribution in its environment. A grain that initially collects more electrons than ions develops a negative potential well that enhances the ion flux and lowers the electron flux reaching its surface. The electrostatic surface potential of a grain that balances these fluxes is the equilibrium potential. For an isolated dust grain, with radius a, the surface potential can be easily related to the net charge, $\phi = Q/a$, resulting in

$$Q_\mathrm{e} \simeq 700\phi_\mathrm{v} a_\mu \tag{2}$$

where Q_e is the number of extra/missing electrons, ϕ_v is the surface potential measured in volts and a_μ is the radius of the grain in microns.

In a case where the electron and ion thermal currents are the only charging currents, the equilibrium potential of a grain in a plasma where the electron and ion temperatures ($T_\mathrm{e} = T_\mathrm{i} = T$) are the same is

$$\phi_\mathrm{eq} = -\beta\frac{kT}{e} \tag{3}$$

where, for example, $\beta = 2.5$, 3.6 and 3.9 for H^+, O^+ and S^+ plasma respectively. At this grain potential $J_\mathrm{e}(\phi_\mathrm{eq}) = J_\mathrm{i}(\phi_\mathrm{eq})$. In a $kT = 1$ eV hydrogen plasma $\phi_\mathrm{eq} = -2.5$ V, and a 1 μm radius particle will collect approximately 1800 extra electrons. Because of the statistical nature of the collection currents, charges fluctuate around their equilibrium value and the electron and ion fluxes balance only on average. The electrons and ions bombarding a grain that is in charge equilibrium might recombine on the surface and return to the plasma as neutral particles.

Electrostatic charging can change the physical characteristics of the dust particles. For example, the electrostatic tension might overcome the tensile strength of a grain, resulting in chipping off protruding fingers or even full disruption (Grün *et al* 1984).

The presence of dust can alter the properties of any plasma environment acting as a source or sink for its density, momentum and energy. In a low-density region, for example, photo- and secondary electron production might become an important plasma source. Similarly, energetic plasma particles can sputter off atoms and molecules from dust grains, changing the density as well as the composition of the plasma environment (Johnson 1990).

In fact, if the presence of dust significantly alters the plasma density the charging equations for a single dust particle discussed above are no longer valid. In the case of significant plasma depletion ($Qn_\mathrm{d} \simeq en_\mathrm{p}$, where n_d is the density of the dust grains with a mono-dispersed size distribution for simplicity, Q is the charge calculated for a single grain and n_p is the plasma density) the charge of a dust particle in a cloud of other dust particles is reduced.

Often grains traverse regions where the plasma parameters change rapidly and the grains do not accommodate quickly enough to assume their equilibrium potential. Charged dust grains in PLANETARY MAGNETOSPHERES can rapidly trade energy and angular momentum with the electric and magnetic fields due to their time-dependent electrostatic charges. Hence, the evolution of the spatial distribution of small dust particles is often shaped by the plasma environment.

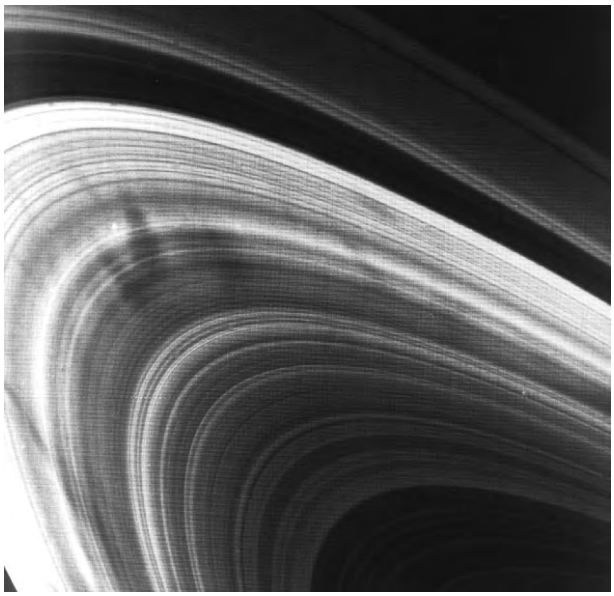

Figure 1. Image of Saturn's rings taken by Voyager 2 showing 'spokes', the dark radial markings.

The simultaneous integration of the current balance and the equation of motion represent the basic approach of 'gravito-electrodynamics', that considers the motion of charged dust grains where electrodynamic forces are just as important as gravity.

Dynamics of charged dust

The equation of motion of a charged dust grain (of mass m and charge Q) using an inertial coordinate system fixed to the planet's center, is

$$\ddot{\boldsymbol{r}} = \frac{Q}{m}(\dot{\boldsymbol{r}} \times \boldsymbol{B} + \boldsymbol{E}_c) - \frac{\mu}{r^3}\boldsymbol{r} \tag{4}$$

where $\boldsymbol{r}$ is the grain's position vector, $\boldsymbol{B}$ is the magnetic field, and μ equals the gravitational constant times the planet's mass. For an infinite conductivity magnetosphere that rigidly co-rotates with the planet with a rotation rate of Ω, $\boldsymbol{E}_c = (\boldsymbol{r} \times \Omega) \times \boldsymbol{B}$ is the co-rotational electric field. On the right-hand side there could be other terms describing forces due to satellites, higher-order terms in the planet's gravitational field, radiation pressure, and plasma and neutral drag forces, for example.

The magnetic fields of Jupiter (J) and Saturn (S) can be approximated as that of a simple dipole located at the center with its magnetic moment aligned with the rotation axis of the planet (ignoring, for the moment, the 10° tilt between the rotation axis and the dipole moment of Jupiter). In the equatorial plane of a dipole $B = B_0(R/r)^3$, where B_0 is the magnetic field at the surface and R is the radius of the planet ($B_0^{\rm J} = 4.2$, $B_0^{\rm S} = 0.21$ G and $R_{\rm J} = 7.1 \times 10^4$, $R_{\rm S} = 6 \times 10^4$ km). The magnetic field lines pierce the equatorial plane at right angles pointing anti-parallel to Ω. The resulting co-rotating electric field points radially outward with an amplitude of $E_c = E_0(R/r)^2$ ($E_0^{\rm J} = 5.8 \times 10^{-5}$, $E_0^{\rm S} = 2.4 \times 10^{-6}$ V m^{-1}). The force acting on dust particles associated with the co-rotational electric field also depends on their charge, $F_{\rm E} = QE_c$. The charge in turn, as discussed above, is a function of the plasma environment, the material properties of the grain and its charge.

For an average density of $\rho = 1$ g cm^{-3} the ratio of the electrostatic force to gravity

$$F_{\rm E}/F_{\rm G} = \alpha\phi_{\rm v}a_\mu^{-2} \tag{5}$$

($\alpha^{\rm J} \simeq 6\times10^{-3}, \alpha^{\rm S} \simeq 5\times10^{-4}$). In the typical range of $-50 < \phi_{\rm v} < +10$, for particles with $a_\mu \gg 1$, electrostatic forces represent a perturbation only and these grains follow approximate Kepler orbits. On the other hand, particles with $a_\mu \ll 1$ can be dominated by electromagnetic forces and gravity becomes a perturbation. Below we discuss examples of observations that can be best explained by recognizing electromagnetic effects coupling dust and plasma in the magnetospheres of Jupiter and Saturn (Horányi 1996) (see also JUPITER: MAGNETOSPHERE, SATURN: MAGNETOSPHERE).

Jupiter's ring

Jupiter's faint ring, similarly to Saturn's E-ring, provides an opportunity to study forces acting on single dust particles, as collisions and self-gravity do not hide single-particle dynamics.

The Jovian ring system has a complex spatial structure (see JUPITER: RINGS). The main ring is located at $1.71R_{\rm J} \le r \le 1.81R_{\rm J}$ with an optical depth $\tau \simeq 10^{-5}$. The main ring consists of 'large bodies' in the cm–km size range that are responsible for the charged particle absorption detected by Pioneer 11 and also a large population of small dust particles in the $0.1 \le a \le 100$ μm size range. At its inner edge the main ring suddenly turns into a vertically extended, toroidal halo with a maximum scale height of 3000 km. The halo comprises small dust grains with a similar size distribution to the dust population of the main ring. The size distribution of the dust in the main ring and in the halo appears to follow a power-law size distribution $n(a)\,{\rm d}a \sim a^{-\gamma}\,{\rm d}a$ with $\gamma = 2.5 \pm 0.5$. The third component of the ring system is a much fainter outward extension of the main ring that reaches near the orbit of the moon Amalthea at $2.54R_{\rm J}$.

The plasma environment of the ring is likely to be dominated by photoelectrons escaping from Jupiter's ionosphere. Close to Jupiter ($r < 3R_{\rm J}$) the expected equilibrium potential of the dust particles $\phi_{\rm eq} > 0$ and, due to the decreasing contribution of the ionospheric electrons at larger distances, $\partial\phi_{\rm eq}/\partial r > 0$. This radial dependence of $\phi_{\rm eq}$ can be responsible for much of the observed structure of the Jovian ring by causing very fast transport from the ring to the atmosphere.

An alternative model is based on resonances with the higher-order terms in Jupiter's magnetic field. This model requires slow transport of the ring material in

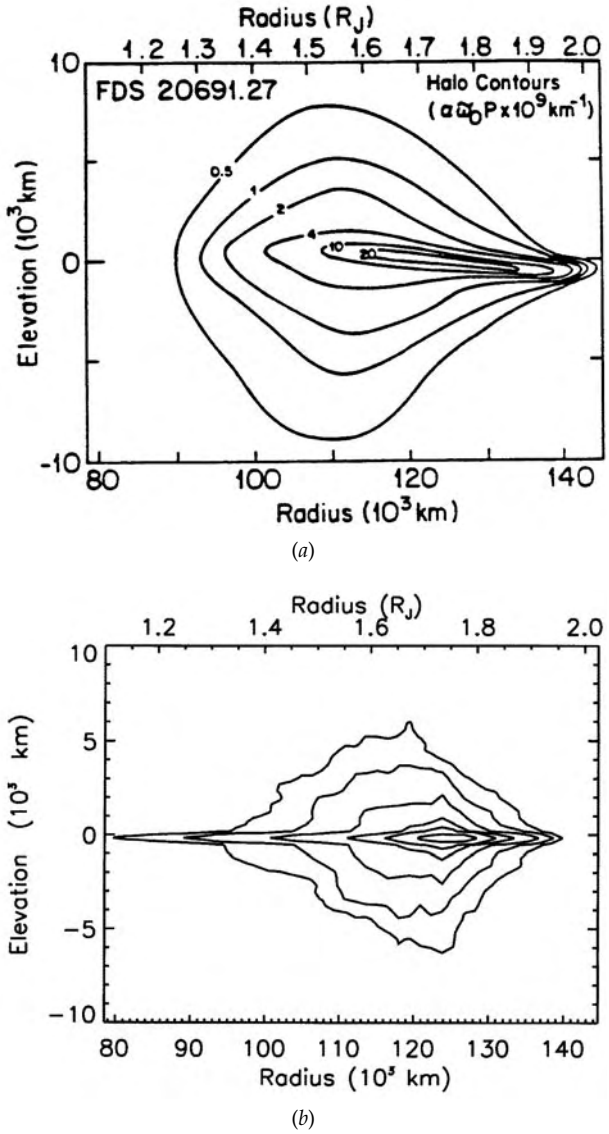

Figure 2. (*a*) The intensity contours, based on a Voyager image, of a halo slice reprojected into a rectangular coordinate frame. (*b*) The calculated contour plots of the normalized brightness distribution. The contour levels are (as in *a*) 0.025, 0.05, 0.1, 0.25 and 0.5. The model calculation reproduces the optical depth and the size and spatial distribution of dust in this region.

order to induce the observed vertical extent via trapping in resonances. The 3D spatial structure predicted by these models is quite different. However, the VOYAGER observations were not sufficient to restrict 3D models and did not allow for the detection of any time-dependent behavior.

In figure 2, the structure seen by Voyager was modeled by following a large number of particles generated via bombardment of the bigger boulders in the main ring and transported towards Jupiter's atmosphere. The 'tilted' nature of the Jovian magnetic field results in out-of-the-ring-plane forces and torques. Particles moving around the equatorial plane will 'see' a component of the magnetic field, $\boldsymbol{B}_{\parallel}$, that is parallel to the equatorial plane periodically changing its orientation. Particles on a prograde (counter-clockwise) trajectory experience a Lorentz force pushing them above (below) the ring plane as they cross the sectors where $\boldsymbol{B}_{\parallel}$ points toward (away from) Jupiter. This effect will force particles onto orbits with increasing inclinations explaining the large vertical extent of the halo.

Dust streams from Jupiter

Jupiter was first recognized as a source of dust particles during Ulysses' encounter with the planet in 1992 as very high-speed intermittent streams of very small grains were discovered (see SOLAR WIND: ULYSSES). The first estimates for the mass and velocity of these stream particles were uncertain since the detector was not calibrated in the suggested size and velocity range. Similar fluxes were seen with the identical dust detector on board the GALILEO MISSION TO JUPITER.

The suggested mechanism to eject dust particles from within the Jovian magnetosphere recognizes that grains can become positively charged to ≈+3 V near the moon Io. Once a grain charges positively it will be accelerated by the outward-pointing co-rotational electric field and leave Jupiter's magnetosphere. Outside the magnetosphere the azimuthal component of the solar wind magnetic field periodically accelerates the dust particles ejected from Jupiter toward and away from the ecliptic plane. This can explain the intermittent nature of the observed dust streams since both Ulysses and Galileo stayed in the ecliptic plane on their approach to Jupiter.

In fact, the detailed analysis of the propagation of the stream of dust particles in the solar wind led to the recognition that they must be much smaller in size and move much faster than first suggested. The best estimate for the size range of the dust grains seen by Ulysses is $0.005 \leq a_\mu \leq 0.015$ with velocity $v > 100$ km s^{-1}.

Positively charged particles escaping from the volcanoes of Io are accelerated outward and gain energy, W, from the co-rotating electric field

$$W = \int_{6R_J}^{50R_J} E\,Q\,\mathrm{d}r \simeq 2 \times 10^{-8} a_\mu \text{ J} \qquad (6)$$

where the lower limit of the integral is the location of Io and the upper limit is the approximate size of Jupiter's magnetosphere. Ignoring gravity, the work done by the electric field is the kinetic energy of the ejected dust particle; its exit velocity at the outer boundary of the magnetosphere can be estimated as

$$v_{\text{exit}} \simeq \frac{3}{a_\mu} \text{ km s}^{-1}. \qquad (7)$$

According to this model, particles in the size range of $0.005 < a_\mu < 0.015$ are expected to stream out of the Jovian magnetosphere with velocities in the range of $200 < v_{\text{exit}} < 600$ km s^{-1}, in agreement with the observations.

Saturn's E-ring

This faint ring extends from 3 to $8R_S$ with a sharp peak in its optical depth ($\tau \simeq 10^{-6}$) at the orbit of ENCELADUS at $r \simeq 4R_S$. The suggested particle size distribution to explain the wavelength dependence of the brightness in this region is surprisingly narrow, concentrated around $1 \pm 0.3\ \mu$m. The vertical extent of the ring has a minimum at Enceladus.

If the gravitational potential due to a central body changes as $1/r$ (Kepler problem) or r^2 orbits remain closed (i.e. the orientation of an eccentric orbit remains fixed in space). Any additional forces due to charging or higher-order terms in the planet's gravitational field, for example, result in orbital precession.

At Saturn the angular rate at which the pericenter (longitude of closest approach to the planet) of an orbit (with semimajor axis a_K) of a grain moves due to its electric charge is

$$\omega_\phi = -2\frac{QB_0}{mc} \simeq -5\frac{\phi_v}{a_\mu^2}\left(\frac{R_S}{a_K}\right)^3 \text{ deg day}^{-1} \qquad (8)$$

and the rate of change due to oblateness (equatorial bulge)

$$\omega_J = \frac{3}{2}\omega_K J_2 \left(\frac{R}{a_K}\right)^2 \simeq 50\left(\frac{R}{a_K}\right)^{3.5} \text{ deg day}^{-1} \qquad (9)$$

where ω_K is the Kepler angular rate and J_2 is the coefficient of the second-order term in the spherical expansion of Jupiter's gravitational field. For charged grains the net pericenter motion, $\omega_\phi + \omega_J$, can be positive, negative or even zero depending on the particle's size, charge and location in the magnetosphere.

Solar radiation pressure causes periodic changes in the angular momentum and hence orbital eccentricity of a dust particle in orbit around Saturn. The maximum eccentricity solar radiation pressure can induce is

$$e_{max} \approx \frac{3hf}{2\mu(\omega_\phi + \omega_J)} \qquad (10)$$

where h and f are the specific (i.e. per unit mass) angular momentum and acceleration due to radiation pressure.

In the plasma environment at the E-ring, the characteristic surface potential of the dust particles is expected to be in the range of $-8 < \phi_v < -4$ resulting in a near cancellation of the precession for $a_\mu \simeq 1$ grains. Due to continuous bombardment by micrometeorites and the E-ring particles themselves, Enceladus is the likely source of particles with a range of sizes. The magnetosphere selects particles with $a_\mu \simeq 1$ and forces them to follow highly eccentric orbits. Smaller or bigger particles will stay close to the orbit of their source. The vertical structure of this ring is caused by the out-of-the-ring-plane component of the radiation pressure. In figure 3 many of the observed features are captured using computer simulations.

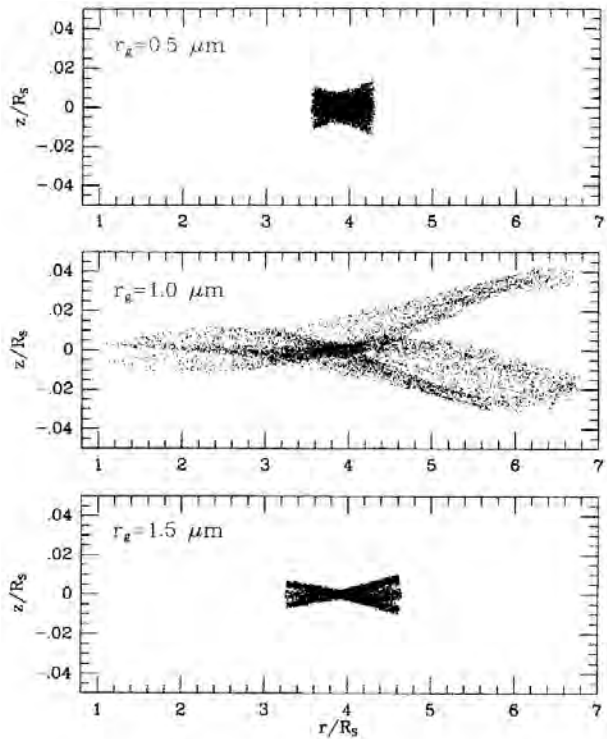

Figure 3. A scatter diagram of the simulated E-ring shown in cylindrical coordinates (r, Z), from randomly sampled orbits of 0.5 (top), 1(middle) and 1.5 μm (bottom) radius particles.

Future studies

Since December 1995 the Galileo spacecraft—now an artificial satellite of Jupiter—has been returning *in situ* and remote-sensing data from Jupiter's dusty magnetosphere. New Galileo images reveal much more detail about the ring/halo region and indicate time-dependent azimuthal asymmetries and large radial variations. Azimuthal brightness differences are likely to be related to short lifetimes, since Kepler shear would swiftly wash them away. Most likely, these features are related to the stochastic production of new material in the ring via meteoroid bombardment. The *Galileo* data—especially images taken while crossing the ring plane—are expected to show in great detail the spatial structure and size distribution of dust in the ring/halo region. New measurements in the Io plasma torus will help understanding of the charging history and subsequent energization and ejection of dust streams from the magnetosphere.

The CASSINI MISSION launched in October 1997 will reach Saturn in July 2004. Its cameras, plasma and dust detectors will monitor the activity of the 'spokes' and show in detail the spatial and size distribution of dust throughout its ring system. These and other missions to comets, the Moon or any other object in our solar system will find other examples, where observations will only be explained by recognizing dust–plasma interactions.

Magnification

When a telescope is used visually, its magnification is the ratio of the angular diameter of the image as seen by the eye to the angle subtended by the object when viewed directly without the aid of the telescope. The magnification, or magnifying power, of a telescope (M) is given by the ratio of the focal length of the objective or mirror (F_o) to the focal length of the eyepiece (F_e) (i.e. $M = F_o/F_e$). For example, a telescope with a focal length of 2 m (2000 mm), used with an eyepiece of focal length 20 mm, would have a magnification of $2000/20 = 100$. The same telescope used with an eyepiece of 10 mm focal length would have a magnification of $2000/10 = 200$.

The magnification of a telescope is also equivalent to the ratio of the aperture of the collector (objective or primary mirror) to the diameter of the exit pupil (the image of the collector produced by the eyepiece). If all the light collected by the telescope is to enter the observer's eye, the exit pupil must be no larger than the diameter of the dark-adapted eye (about 0.007 m). To achieve this, with a telescope of aperture D (meters), the magnification should be at least $D/0.007 \approx 140D$ (i.e. about 140 for a telescope of 1 m aperture, or about 14 for a telescope of 0.1 m aperture). The maximum practicable magnification is limited by factors such as image contrast (the higher the magnification, the fainter the image) and by 'seeing' conditions (turbulence in the Earth's atmosphere causes sources to twinkle, shimmer and shake; this affects the quality of the image). For small and moderate-sized telescopes an approximate guide to the highest practicable magnification that is likely to give usable images is about 20 per centimeter of aperture (e.g. about 200 for a telescope of 10 cm aperture). In practice, it is seldom worthwhile to use magnifications greater than 200–300.

Magnitude Scales and Photometric Systems

More than any other aspects of astronomy, the subjects of magnitude scales and photometric systems are encumbered by history. The intensity of light from stars and other cosmic objects is usually expressed in magnitudes, an inverse logarithmic scale that confuses physicists who work in SI units, but that is practical for astronomers. The apparent magnitude of an object is a measure of the intensity of radiation within a particular wavelength interval received from that object at the Earth. The absolute magnitude is the magnitude that the object would have were it situated at a distance of 10 parsecs (pc, about 32.6 light-years (ly)) from the Sun. The relation between apparent magnitude m and absolute magnitude M is $m - M = 5 \log d - 5$, where the distance d is in parsecs.

The total energy, integrated over all wavelengths, received at the Earth from an object is also expressed as a magnitude, the bolometric magnitude. The difference between the bolometric magnitude $M_{\rm bol}$, and the magnitude $m_{\rm A}$ in bandpass A is called the bolometric correction $\rm BC_A$. BC without a qualifier normally refers to the correction to the visual magnitude; BC or $\rm BC_V$. The zero point of the bolometric magnitude scale is usually set by adopting $M_{\rm bol}(\rm Sun) = 4.75$, which implies $\rm BC_{Sun} = -0.07$.

Early astronomers compared star with star, a procedure that still retains great benefits. The surface temperatures of common stars range from 30 000 K down to 3000 K, and their apparent brightnesses cover a range of almost a factor of 10^{10}, from the sky background upwards (this range does not include the Sun). The majority of stars are constant in total light output and in temperature and as no laboratory lamps have energy distributions very similar to those observed in stars it is natural that astronomers seek to use the standard candles in the sky. Photometric systems represent attempts to define standard bandpasses and sets of standard sources, measured with these bandpasses, that are well distributed about the whole sky. Different photometric systems measure different wavelength bands. All photometric systems enable the measurement of relative fluxes, from which can be inferred particular properties (such as temperature) of the emitting object, but different systems claim to do it more precisely or more efficiently than other systems. Some of the systems were developed and modified by different astronomers over many years and the literature contains confusing versions and calibrations. Some people have despaired that it is too confusing and have suggested that we should start again with a well-defined ultimate system, but recent analysis has shown that modern versions of the existing photometric systems can be placed on a firm quantitative basis and that more care with passband matching will ensure that precise and astrophysically valid data can be derived from existing, although imperfect, systems.

Several recent large-scale astronomical projects are providing significant new magnitudes for large numbers of a wide range of astronomical objects. Firstly, the gravitational lensing projects, such as MACHO, EROS, OGLE and AGAPE, are identifying a range of variable stars and measuring light curves in the GALACTIC BULGE and the MAGELLANIC CLOUDS; secondly, wide-field survey projects, such as the SLOAN DIGITAL SKY SURVEY, are measuring the magnitudes of all objects above a certain brightness in the northern sky. Finally, the remarkable astrometric satellite HIPPARCOS measured extremely precise magnitudes for more than 118 000 stars, mostly brighter than 9th magnitude, over the whole sky and from outside the atmosphere. These projects are indicative of the quality and quantity of data that are becoming available and that will be a great challenge for standard magnitude calibrations.

The magnitude scale of Hipparchus; the intensity scale of Pogson

In the earliest recorded star catalog, HIPPARCHUS (2nd century BC) divided the stars in the sky into six groups. Twenty of the brightest stars that could be seen were called first-magnitude stars and those at the limit of visibility were called sixth-magnitude stars. Intermediate-brightness stars were put in intermediate magnitude classes. In the 18th century, astronomers were using telescopes and had begun to measure the light intensities of stars by closing down the telescope aperture until the image of the star under study just disappeared (the disappearance aperture). By taking the ratio of the squares of the disappearance apertures of two different stars, the relative intensity of the stars' light could be calculated. This was the beginning of astronomical visual photometry. Norman R Pogson (in 1856) at the Radcliffe Observatory compared his measurements of stellar brightness with stellar magnitudes given in contemporary star catalogs (such as those of Stephen Groombridge and the zone observations of Friedrich Argelander and Friedrich Wilhelm Bessel) and suggested the simple relationship $m = 5 \log a + 9.2$ to relate the magnitude m of a star and the disappearance aperture a (in inches). This relation implies a coefficient of 2.5 for the relation between magnitude and the logarithm of the intensity as $I \propto a^2$. Around that time, Gustav Theodor Fechner and Wilhelm Edward Weber (1859) were investigating the response of the eye to light and proposed the following psychophysical law: $m - m_0 = s \log I/I_0$, where m is a perceived brightness and the constant s defines the scale. Pogson's work implied a scale of -2.50 for astronomical visual (eye) photometry, and we thereby have the basis for the inverse logarithmic scale. There was continuing disagreement concerning the adoption of this exact scale of 2.5 and it was not until almost 30 yr later, after the Harvard photometry results were published in 1884, that adoption was ensured. The constant m_0, which defines the zero point, has undergone much refinement since Pogson's estimate and was officially set by the specified visual magnitudes of stars in the 'north polar sequence'. The early photometry catalogs are based on

this sequence but the magnitude scale today is established by the contemporary whole-sky photometric standard star catalogs.

New magnitudes from new detectors

Technological advances over the last 100 yr have provided a series of light detectors to supplement the eye. These detectors, in general, respond differently to light of different wavelengths from the eye; that is, they are more sensitive to blue light or to red light than is the eye. The advent of photography in the late 19th century revolutionized astronomy, as did the introduction of photomultiplier tubes with their light-sensitive photocathodes in the mid-20th century and sensors such as silicon charge-coupled devices (CCDs) and infrared detectors over the last 20 yr. Light intensities, or magnitudes, measured with these new detectors naturally differ from the visual magnitudes and depend on the color of the star. Initially, there was only the difference between visual magnitudes and 'blue' photographic magnitudes to be considered, but several factors resulted in a proliferation of different passbands and photometric systems: the extension of photographic and photocathode sensitivities to a wider wavelength range, the use of colored glass filters and interference filters to sample the starlight in narrower bands within the total wavelength sensitivity range of the detectors and, more recently, the requirements of survey instruments to provide maximum sensitivity for the detection of faint objects.

Rationale for multicolor photometry

Much photometry of astronomical objects is carried out in order to measure the apparent total brightness of objects and their relative brightnesses at different wavelengths, that is, their energy distributions. It is possible to characterize the temperatures of most objects from the overall shapes of their energy distributions. It is also possible to infer the metal content of stars from depressions in their energy distributions at particular wavelengths. These depressions (absorption lines) are due to the absorption of flux, principally by Fe and Ti (which have very rich line spectra), Ca, Mg and the molecules CN and CH (which have very strong lines in the blue–violet region of cool stars). There are many other molecular absorption bands (such as TiO, CO and H_2O) that depress the continuum in very cool stars; such molecular features are also used to provide information on the temperature, chemical composition and luminosity. The energy distributions of galaxies and star clusters can be analyzed to extract the relative numbers of different kinds of stars making up these composite objects. REDSHIFTS of very distant galaxies and quasi-stellar objects can also be measured from the positions of depressions or peaks in their energy distributions. These are called photometric redshifts and have been used very successfully with data from the Hubble Space Telescope and the Sloan Digital Sky Survey.

Multicolor photometry is best thought of as very-low-dispersion spectroscopy. The entire high-resolution spectrum of a star or other cosmic object contains a large amount of information, but, when dealing with extremely faint objects or with large numbers of objects, it is a great advantage to measure a small number of wavelength bands in as short a time as possible. Such a minimal technique is invaluable if it enables the derivation of many of the same parameters obtainable from a complete (and very redundant) description of the spectrum. A great deal of effort therefore has gone into accurately measuring and calibrating colors and depressions in terms of temperatures, metal abundances and other parameters, and investigating which of competing minimal descriptions of a star's spectrum is the most accurate or most practical.

Finally, GRAVITATIONAL LENSING results in changes in the brightness of the object independently of the color measured. Most intrinsically variable stars, however, have different amplitudes in red and blue light. Consequently, gravitational MICROLENSING surveys are efficiently carried out by splitting the light between a blue and a red channel for simultaneous direct comparison. Equal-amplitude variations in blue and red channels imply a lensing event, not a variable star.

Photometric systems: natural and standard

A light detector, a telescope, a set of filters and a method of correcting for atmospheric extinction make up a natural photometric system. Each observer therefore has their own natural system. The standard system is indirectly defined by a list of standard magnitudes and colors that have been measured for a set of typical stars, using the natural system of the originator. These are often called the primary standards. Later lists comprising more stars and fainter stars but based on the primary standards are called secondary standards. However, in the case of all photometric systems, recently published secondary standards effectively redefine the standard system because they tend to be more accurately measured than the primary lists and to represent contemporary detectors, filters and practice.

The term 'color' is an abbreviation for color index, which is the difference between the apparent magnitudes in two different spectral regions. Photometry results have generally been published as a series of colors and a single magnitude. The zero points of many color systems are set so that α Lyrae (Vega) has zero colors. In the southern hemisphere (where Vega is inaccessible) and often also in the north, the zero point is set by requiring that an ensemble of unreddened A0 stars have colors of zero magnitude. (See also STELLAR PHOTOMETRY.)

The original standard systems

The most influential of the early works of photoelectric photometry were the broadband Johnson UBVRI and Kron RI systems, which covered the wavelength region between 310 and 900 nm (3100 and 9000 Å). The natural systems of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Harold L Johnson and of Gerald E Kron and coworkers served as 'standard' systems for many other users who attempted with varying success (owing to differences in detectors, filters, telescopes and techniques) to duplicate the originators' natural systems. That is, using their own detectors and filters, astronomers measured stars from the Johnson and Kron lists and linearly transformed their natural magnitudes and colors to be the same as the Johnson and Kron colors and magnitudes. They then applied those same linear coefficients to transform the colors and magnitudes of unknown stars onto the Johnson or Kron system. The original blue and yellow filters were chosen by Johnson from readily available glasses so that when used with the 1P21 photomultiplier tube they approximated the ordinary blue (B) photographic response (~436 nm) and the visual (V) response (~545 nm). A more violet magnitude U (~367 nm), which is useful for very hot stars, was obtained by using a common violet glass. In retrospect, these choices should have been based more on astrophysics and less on glass availability, but so much work has been done in this UBV system that the weight of history ensured its continuation. Intercomparison of much of the published broadband photometry (in particular, photometry carried out more than 15 yr ago) often shows scatter of more than 0.03 magnitudes, but more recent photometry obtained using better equipment, better matched natural systems and better secondary standard stars agrees to better than 0.01 magnitude, or 1%.

The 1P21 phototube was a remarkable invention and its high blue sensitivity dominated the development of photometric systems for over 30 yr. There were red-sensitive devices available but observations were made only for bright stars because for many years these devices were much less sensitive, noisier and less reliable than the 1P21. In the mid-1970s new detector materials became available; in particular, the gallium arsenide and multialkali phototubes, which provided high ($\gg$15% quantum efficiency) sensitivity between 300 and 860 nm, and the infrared-sensitive InSb (indium antimonide) photodiodes together with low-noise preamplifiers, which revolutionized photometry between 1000 and 4000 nm. Both developments enabled photometry to be done on faint stars that had hitherto been the sole province of the blue-sensitive detectors. Photometry done with the new red-sensitive tubes was placed on either the Kron or the Johnson standard system, again with mixed success, and it has only been in the last 10 yr that A W J Cousins' RI 'near-natural' standard system (based on the Kron system) has gained widespread acceptance. It has also been very useful that the Cousins system's R (~638 nm) and I (~797 nm) bands are similar to the contemporary photographic R and I bands.

Johnson also introduced the infrared alphabetic JKLMN (approximately 1.22, 2.19, 3.45, 4.75 and 10.4 μm) system in the mid-1960s, using PbS (lead sulfide) detectors and bolometers. The water vapor in the Earth's atmosphere defines a series of wavelength bands (windows) through which observations from the ground can be made; Johnson used interference filters (and, unfortunately, the atmospheric H_2O absorption bands) to define what he called the J, K, L, M and N bands. Ian S Glass, in his early observations with an InSb detector, used the additional band H (~1.63 μm), between I and K, and in his choice of filters attempted to match the other Johnson bands. All infrared observers have proceeded in a similar fashion and have concentrated mainly on copying the Johnson K magnitude scale. Identical detectors have been used but a range of slightly different filters and observatory altitudes have produced subtly different systems. The publication of sufficient numbers of stars in common from the different natural systems has helped delineate the differences, and transformations between the systems are now quite reliable.

Passbands or response functions

The most important specifications of a photometric system are the passbands or response functions of its magnitudes. For a variety of reasons, technical and historical, the passbands of the original broadband photometric systems have not been known with certainty and this has inhibited close matching of natural systems and has prevented computation of accurate synthetic colors from theoretical spectra. The recent availability of spectrophotometry for many stars combined with the increased precision of second-generation photometric catalogs has, however, enabled the passbands to be derived indirectly by computing synthetic colors from spectrophotometry of stars with well-defined standard colors and adjusting the passbands until the computed and standard catalog colors agree. This technique has enabled the passbands of the major systems to be well defined, which in turn has permitted filters to be designed that still will result in good passband matches with a variety of detectors. In addition, when it is not possible to match passbands exactly with some detectors, such as photographic plates, it is possible to predict accurately the differences between photographic and photoelectric magnitudes by computing the synthetic magnitudes using the different passbands.

In figure 1 the normalized passbands of the Johnson-Cousins UBVRI system are shown plus an added Z band for CCD observations. The F_ν (flux per unit frequency interval) spectrum of an A0 star is shown for orientation. Table 1 lists the effective wavelengths $\lambda_{\rm eff}$, the approximate bandwidth $\Delta\lambda$, which is the full width at half-maximum of the passband, and the absolute calibration of the UBVRIJHKL system, based on the flux of Vega, for a zero-magnitude A0 star. Note that the effective wavelengths of the broad bands change with the color of the objects. The effective wavelengths listed are for an A0 star.

Other photometric systems

Real or perceived drawbacks in existing photometric systems (the UBV system in particular) stimulated the design of other photometric systems better suited for measuring temperatures, metal-line blanketing, effective

gravity and interstellar reddening. Some of these systems used broad bands comparable with the UBVRI system, while others used narrower bands defined by different mixes of glass filters or interference filters. Effective wavelengths and other specifications of some of the better-known systems are given in table 2 and are discussed below.

Geneva and Walraven systems

Difficulties with matching natural systems have been eliminated by the strategy employed by proponents of the Geneva ($UBB_1B_2VV_1G$) and Walraven (VBLUW) systems. The latter takes its name from Th and J H Walraven. These multiband photometric systems are supervised by small groups who control the instrumentation and supervise the data reduction and calibration. The colors have been well calibrated in terms of gravity, temperature and abundance. Such closed systems have excellent precision but not necessarily greater than that possible from the open Cousins UBVRI system with careful bandpass matching.

Washington system

This CMT_1T_2 system was devised to use the wideband sensitivity of the extended-red detectors, to improve the sensitivity of blue–violet colors to metallicity and gather more violet light in cool stars and to try to separate the effects of CN from other metal lines. We have found that the violet C band is a very useful metallicity indicator for faint K giants but that the M band contains little more information than does V; T_1 and T_2 have no advantages over R and I. The minimal CVI system is very useful for metal-weak K stars.

Strömgren four-color system

The uvby system was devised by Bengt Strömgren to measure better the Balmer discontinuity, the metallicity and the temperature of A, B and F stars. The bands are essentially separate unlike the UBV bands, which overlap. The u band is completely below the Balmer jump; v measures the flux near 400 nm, a region with much absorption due to metal hnes; b is centered near 460 nm and is affected much less than B by metal-line blanketing; y is essentially a narrower V band. The u filter is colored glass, the others are interference filters. Two special indices are derived: $m_1 = (v - b) - (b - y)$, which measures metallicity, and $c_1 = (u - v) - (v - y)$, which measures the Balmer discontinuity. The index $b - y$, like $B - V$, is used primarily as a temperature indicator. The system is capable of very high precision but, unfortunately, errors in the width of v filters manufactured some years

ago resulted in nonstandard filters being supplied to many users. Since then, published photometry has exhibited some systematic differences in c_1 and m_1, and there are difficulties in computing these colors from theoretical spectra, particularly for cool stars. Recent standard catalogs of new and more homogeneous observations are of high precision and internal consistency and it should now be possible to define better the v band. Two additional interference filters (15 and 3 nm wide) centered on the Hβ line are often used together with the four colors. The Hβ index is used to derive luminosities in B stars and reddening in F and G stars. The Strömgren system was the first photometric system devised to measure specific stellar features. Because of the short-wavelength baseline of its four color filters, 1% photometry at least is required to utilize the system's advantages over the UBVRI system.

DDO (35, 38, 41, 42, 45, 48) system
This system (also built around the sensitivity of the 1P21 photomultiplier) was designed for the analysis of G and K dwarfs and giants. The 35 filter is the u filter of the four-color system; the 38 filter is also a glass filter and better measures metal blanketing than the v filter, being further to the violet and wider; 41 measures the CN band; 42, 45 and 48 are continuum filters. The color 35–38 (the 3538 index) measures the Balmer jump, 3842 measures the metallicity and 4245 and 4548 are used for gravity and temperature measurements. By restricting the measurements to the blue spectral region, complicated corrections for spectral line blanketing are necessary to derive temperatures and gravities. Good results, especially for faint K dwarfs, can be obtained by using $V - I$ or $R - I$ as the temperature indicator. Because of the narrow bandwidth of some of the filters, the DDO (David Dunlap Observatory) system has been mainly restricted to relatively bright stars.

Thuan–Gunn system
The uvgr system of Trinh Xuan Thuan and James E Gunn was devised in the mid-1970s from the UBVR system for use with an S20 photocathode detector and in order to avoid the strong mercury emission lines from city lights and [O I] lines in the night sky. The g and r bands are of similar width to the V and R bands whereas the u and v bands are about half the width of the U and B bands. The $g - r$ color has a longer baseline than $V - R$ but transforms well.

Photographic systems

Originally photographic emulsions were only sensitive to light blueward of 490 nm. These were the O emulsions. Different chemical sensitizing shifted the red sensitivity cutoff to longer wavelengths: G 580 nm, D 650 nm, F 700 nm and N 880 nm, approximately. By using blue-cutoff glass filters and the red cutoff of the emulsions, various photographic passbands were made. Photographic U used a violet filter for both blue and red cutoffs. Attempts were made to convert the photographic colors onto the photoelectric UBVR system but these were not often very accurate because of limitations in iris photometry and poor matches of the bandpasses. In recent years, astronomical photography has undergone a renaissance caused, first, by the development of new fine-grain emulsions (Kodak IIIaJ, IIIaF and more recently TechPan) and the utilization of methods of greatly increasing the sensitivities of the J, F and TechPan emulsions (using hydrogen gas) and of the N emulsions (using silver nitrate solution) and, second, by the use of new scanning microdensitometers and better methods of intensity calibration. Averages of several wide-field Schmidt camera plates or higher scale prime-focus plates can now produce photometry to a few per cent to very faint limits. Theoretical investigation of bandpasses enables better filter design for bandpass matching or predicts the relevant transformations and systematic differences between photoelectric and photographic photometry. Photographic photometry these days is usually restricted to attempted matches to the Johnson U and B or the Thuan–Gunn g systems using IIIaJ plates, to Cousins R or Thuan–Gunn r using IIIaF plates, and to Cousins I using IVN plates. Direct photographic calibration from step wedges is usually supplemented by direct magnitude measurements of stars in each field using a CCD array.

CCD photometric systems

The high quantum efficiency of CCDs and their inherent linearity have made them the detectors of choice in recent years for most areas of photometry. Unfortunately, the advantages of the CCDs were initially not fully attained because some users paid insufficient care to define their passbands and to standardizing their photometry. This resulted in internally precise results but an inability to relate these results with much confidence to the standard system data or to theoretically derived magnitudes and colors. Astronomers now realize the importance of matching their CCD passbands to standard passbands or deriving accurate passbands for their natural systems to enable them to be calibrated using synthetic photometry.

The standard BVRI system can easily be realized with thinned CCDs and colored glass filters but the U system is more problematical owing to the lower UV response of many CCDs. The Z band, between I and J, is also now often added to CCD UBVRI-based systems.

The HST WFPC2 photometric system

The Wide Field Planetary Camera (WFPC2) on the HUBBLE SPACE TELESCOPE has a suite of interference filters that cover both the space UV and the optical spectrum. Although not identical to the well-established UBVRI and uvby systems, there are passbands that are quite similar. A lot of attention has been given to calibrating the WFPC2 system both from actual ground-based observations where possible and from synthetic photometry so that excellent transformations are possible to the older standard systems and reliable temperature calibrations can be made from model atmosphere fluxes. Figure 2 shows some of the WFPC2 bandpasses. Table 3 lists effective wavelengths

(for an A0 and M0 star) and FWHM of some of the HST passbands and those of the other CCD systems discussed below.

The Hipparcos and Tycho photometric systems

The ESA Astrometric Satellite, Hipparcos, used three independent photometric detectors. The main Hipparcos passband (H_p) corresponded primarily to the spectral response of the S20 photocathode of the image dissector scanner combined with the transmission of the optics. The Tycho photometric data were derived from the star trackers and measured magnitudes in B_T and V_T, with passbands somewhat similar to standard B and V. Figure 3 shows the Hipparcos and Tycho passbands in relation to the standard BVR passbands. The large width of the H_p passband results in significant systematic differences between the H_p magnitudes and standard V magnitudes, depending on reddening, metallicity and luminosity. Nevertheless, the extremely high precision H_p magnitudes (∼0.0015) and the lower but still good precision (∼0.012) for the Tycho V_T magnitudes combined with the whole-sky coverage make these catalogs an invaluable resource, not only for measurements of individual stars, but for enabling intercomparisons to be made between and within ground-based photometric systems.

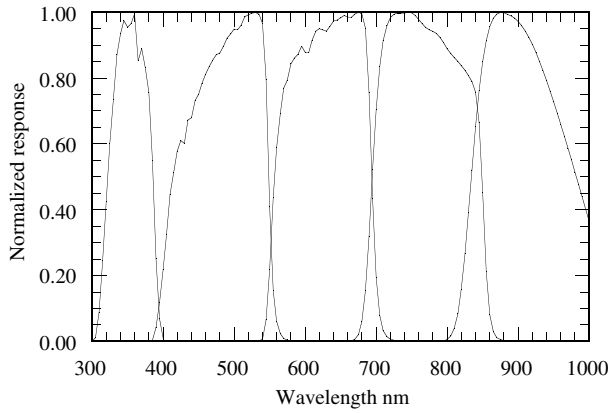

Figure 4. The Sloan Digital Sky Survey passbands.

The Sloan Digital Sky Survey photometric system

This photometric system comprises five color bands (u′, g′, r′, i′ and z′) that divide the entire CCD sensitivity range between the atmospheric UV cutoff near 300 nm and the CCD cutoff near 1100 nm. The passbands, related to those of the Thuan–Gunn system, and shown in figure 4, are essentially nonoverlapping and most are wider than those

of the UBVRI system, ensuring high efficiency for faint object detection. For ease of transformation into other systems or duplication of the system by others, it would have been better were the bands to have overlapped more with a less rectangular profile but the system itself will be very well defined by observations made with a duplicate detector and filters on a separate telescope. Unlike most other photometric systems, the zero points of the SDSS system have been placed on the spectrophotometric AB magnitude system defined by the absolute fluxes of four F subdwarfs. The passbands are essentially filter defined and in general have blue edges defined by a colored glass and red edges by a short-pass interference coating (see FILTERS).

Gravitational lensing projects

The MACHO photometric system

The MACHO project for monitoring gravitational microlensing events utilizes simultaneous CCD imaging in two passbands by sharing the light between two cameras using a dichroic beam splitter. The blue and red bands are further limited using an interference filter on the red side and the sensitivity cutoff of the thick CCDs on the blue side. The blue band approximates a broad blue-shifted V band while the red band approximates the R band. Good transformations are possible to the VR system and reliable calibrations are possible using synthetic photometry. As well as detecting many microlensing events, the MACHO project has provided unique and invaluable data on variable stars in the Magellanic Clouds and the Galactic Bulge.

The EROS photometric system

The EROS1 observations were taken consecutively through two broadband filters B_E and R_E that produced respectively passbands midway between B and V and R and I. Two different sets of filters were used during the course of the observations and the $B_E - R_E$ colors were transformed into V–I. EROS2, like MACHO, has two cameras and the light is divided using a dichroic beamsplitter. The division is made at a redder wavelength ($\sim$650 nm) than for the EROS1 system and the EROS2 blue band more resembles the Hipparcos passband.

Maidanak Observatory

Located on Mount Maidanak in Uzbekistan. The most important instrument is a 1.5 m telescope designed for high-resolution imaging.

Until 1991, several republics of the former Soviet Union had their observatories at Maidanak. The Moscow Sternberg Astronomical Institute was the most powerful co-owner of Mount Maidanak.

After the fall of the USSR, the facility became the property of the Ulugh Beg Astronomical Institute in Tashkent. Economic difficulties have not allowed the observatory to be fully used and maintained. However, astronomers from the Sternberg Astronomical Institute (Moscow), the Astronomical Observatory of Kharkov University (Ukraine), and the Ulugh Astronomical Institute continue to use Maidanak Observatory and the 1.5 m telescope.

Grants from the Maidanak Foundation in Scandinavia are the main source of funds. These permit astronomers to cover their travel expenses, to make observations and to maintain the instruments.

For further information see http://www.maidanak.org/.

Major Planets

A collective term for the largest planetary bodies in the solar system: Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune and Pluto. Pluto, included in this category since its discovery in 1930, was found in the 1970s and 1980s to be smaller and less massive than seven of the solar system's planetary satellites, and just over twice the size of the largest asteroid, Ceres. In the 1980s and 1990s, calls for Pluto's demotion from major planet status led to a number of attempts to define 'major planet' more closely. Arbitrary size limits (diameters of 1000 km or 2000 km, excluding Ceres but including Pluto) or mass limits (similarly set so as to exclude Ceres but include Pluto) have been proposed. An alternative suggestion is that a body should be called a major planet if it is large enough for its own gravity to have overcome the structural strength of its material and made it roughly spherical (this definition would admit not only Pluto and Ceres, but also other large asteroids). Another criterion defines a major planet as a body whose gravitational influence extends over a particular range of distance from the Sun. By most versions of this definition, both Ceres and Pluto are denied major planet status.

Maksutov Telescope

A modification of the Schmidt telescope devised in the early 1940s by D D Maksutov, in Moscow and, independently, by A A Bouwers, in Holland. The Maksutov uses a thin concave meniscus lens, located at the front of the telescope tube, to compensate for the spherical aberration (an optical defect) that would otherwise be introduced by its concave spherical primary mirror. Because the lens is thin, it has negligible chromatic aberration. The convex side of the meniscus lens, which itself has a spherical curve, faces towards the primary mirror. Because its corrector lens can be placed closer to the focus than that of a conventional Schmidt, a Maksutov is shorter and more compact than a Schmidt is. Like the Schmidt, the Maksutov has a low focal ratio and a wide field of view, which makes it particularly useful as a photographic survey instrument.

As with the Schmidt, the Maksutov has a curved focal plane, which lies inside the instrument. Consequently, in its original form, it can be used only for photography and cannot be used for visual observations. It can be adapted for visual observation by introducing a small secondary mirror that reflects light to a focus at the side of the tube (Matsutov–Newtonian) or, through a hole in the primary mirror, to a focus at the rear of the tube (Maksutov–Cassegrain). In the Maksutov–Cassegrain design, the secondary mirror can be figured as a small central reflective surface on the rear of the meniscus lens.

Maksutov, Dmitri Dmitievich (1896–1964)

Soviet optician and telescope maker. After fighting in the Russian Revolution and the First World War, he worked on astronomical optics at Odessa, Moscow and Pulkovo, and invented the *Maksutov telescope*. The design is a development of the Schmidt telescope, replacing the aspheric lens with a negative meniscus lens with spherical surfaces which are easier to make. The telescope tube is also more compact, with consequential financial savings.

Malin, David (20th century)

Lancashire-born astrophotographer, used the Anglo-Australian Telescope and the UK Schmidt Telescope to create spectacular, beautiful and educative photographs of celestial objects, based on techniques developed to suit the fine-grain, sensitive, high-information content photographic material used for scientific pictures. His technique of unsharp masking filters out the diffuse content of the picture (to make it possible to see delicate detail within bright areas of nebulae and galaxies). His implementation of JAMES CLERK MAXWELL's technique of three-color addition combines three separate black and white pictures obtained through different colored filters (to give true color pictures revealing the broad spectral differences in the features and thus the astrophysical interest). Influential best-selling author and dynamic lecturer.

Malmquist Bias and Completeness Limits

Many problems in observational astronomy concern a particular statistical distribution function of some quantity such as the number of objects with some attribute, x. Examples of x would include parallax, apparent magnitude, absolute magnitude, linear separation of binary stars, stellar mass, galaxy mass, x-ray luminosity, the occurrence frequency of novae and supernovae, distances to stars from measured parallaxes, Cepheid distances to galaxies, etc, all when the relevant data are sampled in some specified way. The precepts used in the sampling, such as limits on apparent magnitudes, or the way the parallax stars were chosen, or the period limits that were put on the observed Cepheid period–luminosity relations usually determine the form of the *observed* frequency distribution and how it differs from the true, unbiased, distribution. The problem of recovering the true underlying distribution from the various different observed distributions is a fundamental subject of statistical astronomy.

To set a basis for the discussion of observational selection bias, we mention two of the many examples that illustrate the problem:

(a) The Yale *Bright Star Catalog* in its latest edition (the fourth) lists much information on the 9110 stars brighter than $V = 6.5$ apparent magnitude over the sky. The distribution of absolute magnitudes of the entries is highly biased toward giant and supergiant stars; the limit of $V = 6.5$ apparent magnitude is so bright that no intrinsically faint late M dwarfs are listed. The reason is that for an intrinsically faint star with an absolute magnitude say of $M_V = +10$ to make the catalog, the apparent magnitude limit of $V = 6.5$ requires that its distance modulus be $m - M = -3.5$, or a distance of 2 parsecs. The number of stars with such a small distance is nil. To reach any significant number of M dwarfs would require the apparent magnitude limit of the catalog to be fainter than $V = 10$ if it were to encompass a more representative distance of greater than 10 parsecs for stars with absolute magnitude +10.

(b) Consider the opposite case of the apparent distribution of absolute magnitudes of stars in a catalog that is complete in a *fixed volume of space*, say within 25 parsecs of the Sun. One such catalog is by the staff of the Royal Observatory (Woolley *et al* 1970). The intrinsically faint stars that are missing in the *Bright Star Catalog* appear in large numbers in the *Nearby Star Catalog*, while the intrinsically bright stars are now missing. Their space density is simply so low that the volume of space within 25 parsecs is too small to include even one. The distant-limited *Nearby Star Catalog* is biased in the opposite way from the *Bright Star Catalog*.

It is obvious that to obtain an unbiased luminosity function (i.e. the true distribution of the number of stars at absolute magnitude M in an interval of $M + dM$ and $M - dM$ per unit volume) one must combine in some way both catalogs, each biased at opposite ends of the true luminosity function. This can be done by sampling the flux-limited listings in the *Bright Star Catalog* to fainter apparent magnitudes and by increasing the spatial volume sampled in the distance-limited *Nearby Star Catalog*. But even then selection effects remain, caused by the fact that there will still be limits of completeness, although widened, that must be corrected for.

These examples of the two different biases due to observational selection contain many of the elements of general bias problems in statistical astronomy. The most famous of such problems is that of the Malmquist bias. It appears as the difference in the mean absolute magnitude, $\langle M \rangle_{\mathrm{FL}}$, of a set of objects that are chosen in a flux-limited way (i.e. complete to a given apparent magnitude) compared with $\langle M \rangle_{\mathrm{DL}}$ for the same class of object chosen to be complete within a given volume of space.

The purpose of this article is to explain why the Malmquist bias exists, to describe how to identify it in any given sample of objects (stars or galaxies), to show a method of how to correct for it in statistical investigations, and to show how to identify the distance-limited subset of the complete flux-limited data that defines the true, bias free, distribution function.

An early example of how an observational limit on radio flux produced a highly biased distribution of intrinsic luminosities of radio sources

As soon as the early positions of RADIO SOURCES became accurate enough in the early 1960s to mount optical identification programs, it became evident that most of the radio sources were intrinsically bright early type (E) galaxies. Distances to these galaxies could be obtained from their optically measured REDSHIFTS using the linear Hubble expansion law with an assumed value of the HUBBLE CONSTANT. Absolute radio power could be calculated using the distances and the observed radio fluxes.

The result was the curious strong correlation of absolute radio power, L_{R}, with redshift shown in figure 1. Plotted as ordinate is the intrinsic radio power (erg s^{-1} over the frequency range of 10^7 to 10^{10} Hz). The abscissa is the distance modulus (based on a Hubble constant of 50 km s^{-1} Mpc^{-1}) calculated from the redshift of each source.

The apparent increase of L_{R} with increasing redshift has a close z^2 dependence. This drastic increase of absolute radio luminosity (by six orders of magnitude) with distance (squared) could have been interpreted as a real increase in radio power with look-back time (i.e. an evolutionary effect) until it is realized that the apparent correlation is in fact due to the flux limitation of the radio catalogs. Note the lines of constant radio flux of 1, 3 and 10 janskys.

The explanation of this being due to the flux limitation was soon proved by adding a fainter sample of the optical

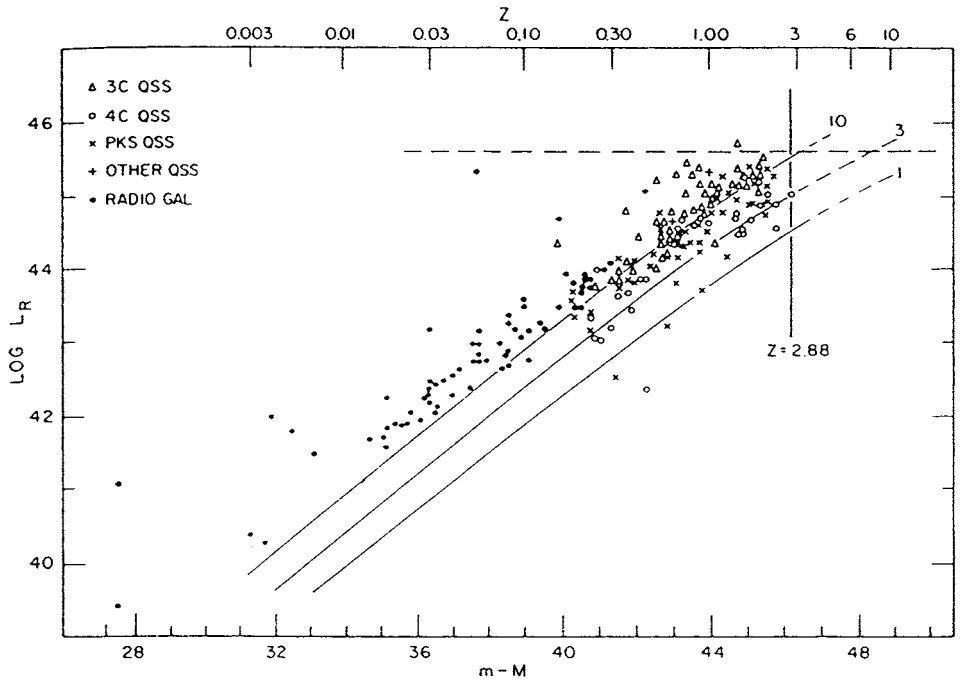

Figure 1. Relation between absolute radio power, L_R, over a band width from 10^7 to 10^{10} Hz and redshift (distance) for flux-limited data from various radio catalogs. The apparent correlation is due to the selection bias caused by the bright flux limitation in the relevant radio catalogs and the existence of a very broad intrinsic radio power luminosity function. (Diagram from *Astrophys. J.* **178** 25 1972.)

identifications to flux levels that soon reached 0.01 janskys, fully 100 times fainter in radio flux than the data in figure 1. The resulting diagram then filled the triangular region at the lower right half of figure 1. Clearly, the radio luminosity function is extremely broad, covering power limits between 10^{40} and 10^{46} ergs s^{-1}, and is also so steep that the spatial volume sampled at small redshifts is too small to include even one of the most powerful sources at such small distance moduli. Note the similarity of this selection effect to that of the *Bright Star Catalog*.

Figure 1 has the form of what is called a Spaenhauer diagram in the current bias literature. Its use is powerful, first as a diagnostic to identify the presence of bias, and then as an aid to devise methods of correction. Bias in any data sample can always be proved using such a diagram by adding a fainter sample to see if the bias disappears at the original bright limit but reappears with the same pattern near the limit of the fainter sample.

The Spaenhauer diagram approach is not the only method to discover and to correct for observational selection bias. A powerful parallel method, useful for example in the problem of bias in the TULLY–FISHER RELATION for distance determination, is that of 'normalized distances' (Teerikorpi 1997). That reference describes the development by a Franco-Finnish group on the analysis of data that are germane for the extragalactic distance scale.

The Malmquist bias

What is the bias?

Consider the properties of Spaenhauer diagrams that are used here to explain the Malmquist bias in flux-limited data sets. For the demonstration we use data for galaxies from the flux-limited revised *Shapley–Ames Catalog of Bright Galaxies* (the RSA), although the same general bias properties apply to many other types of flux-limited distributions in statistical astronomy.

It is known that the general luminosity function over all galaxy types is very broad, spanning the range of absolute magnitudes from $M_V = -23$ to -14 (see LUMINOSITY FUNCTION OF GALAXIES). A Spaenhauer diagram using such a large intrinsic dispersion would resemble the 'open' diagram of figure 1. A more 'closed' diagram is obtained by treating a subsample of the complete galaxy data by restricting the discussion to specific Hubble types and van den Bergh luminosity classes where the individual type and class-specific luminosity functions have much smaller intrinsic dispersions.

Figure 2 shows a typical Spaenhauer diagram of the 'closed' type where the intrinsic dispersions are fairly small. Absolute magnitude, calculated from the known redshifts (assuming $H_0 = 50$ km s^{-1} Mpc^{-1}) is the ordinate. Log redshift is the abscissa. The data are from the complete set of Sc galaxies of van den Bergh luminosity class I (see GALAXIES: CLASSIFICATION) as listed in the RSA. This catalog contains the all-sky sample of galaxies brighter than apparent magnitude $B = 13$.

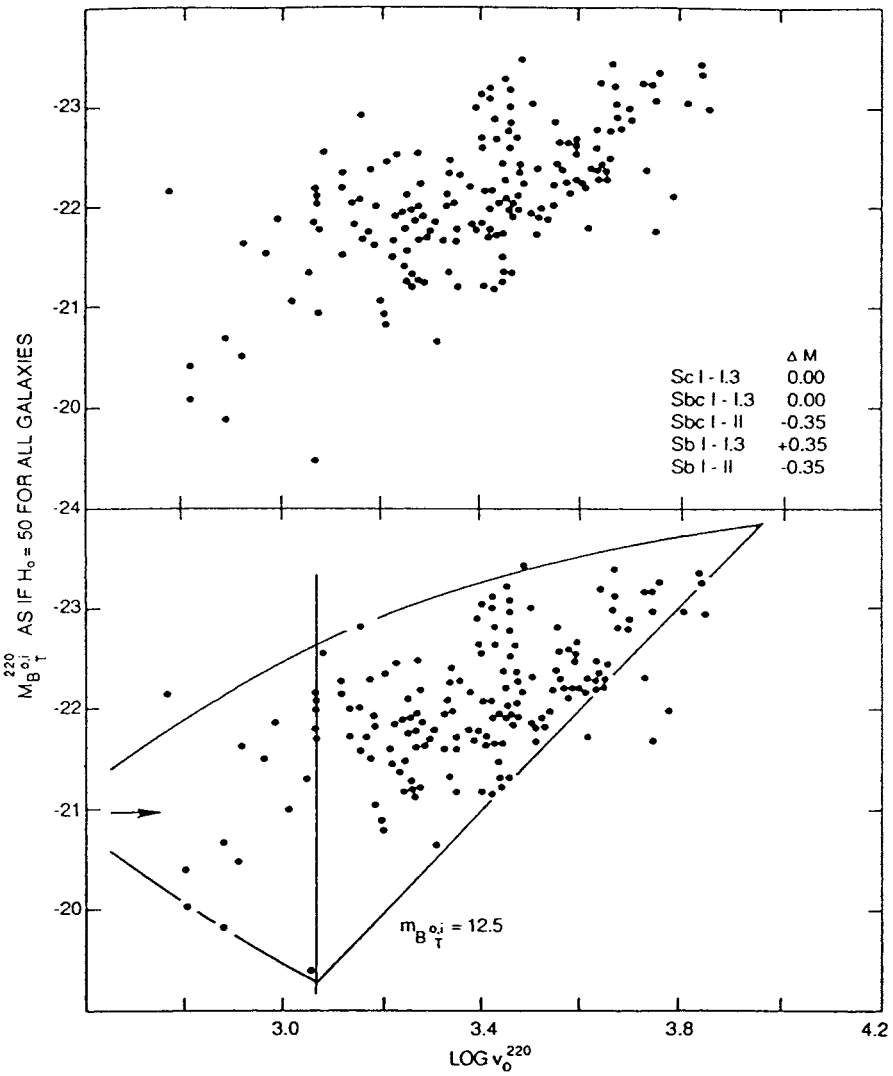

Figure 2. Top: The apparent correlation of redshift and the absolute magnitudes ($H_0 = 50$) of ScI galaxies in the flux-limited RSA catalog. Bottom: Same as top but with the limit lines of the Spaenhauer configuration superposed. The apparent correlation in the top panel is due to selection bias. The faint end of the luminosity function to the right of the vertical line is progressively cut away at increasingly large redshifts.

Because it is a flux-limited catalog, it has the same bias properties as the *Bright Star Catalog* described earlier. Intrinsically faint galaxies are underrepresented relative to an unbiased (true) distribution (per unit volume) in its absolute magnitude distribution.

The Malmquist bias is defined as *the difference in absolute magnitude between the flux-limited and distance-limited distributions*. How is it detected? How is it calculated and corrected for?

The top panel of figure 2 shows that the mean absolute magnitude of the sample becomes progressively brighter with increasing distance in the same way as for the radio sources in figure 1. As in figure 1, there is a sharp lower bound to the distribution caused in both diagrams by the flux-limit of each catalog; 1 jansky in figure 1 and near the effective apparent magnitude limit of $B = 12.5$ for the RSA (the nominal limit of $B = 13$ is made brighter here by the correction for internal absorption that has been applied to the data).

The straight-line flux limit at $B = 12.5$ is drawn in the bottom panel of figure 2. The upper and lower curved envelope lines are the theoretical expectation loci for one galaxy to be detected in the sample. These envelope lines are from a calculation using an assumed Gaussian luminosity function with a fixed dispersion of 0.7 mag, and individual volume elements enclosed within redshift (distance) limits of $v + \mathrm{d}v/2$ and $v - \mathrm{d}v/2$ for a uniform density distribution of objects. (The shape of the envelope lines is independent of the value assumed for the Hubble constant.)

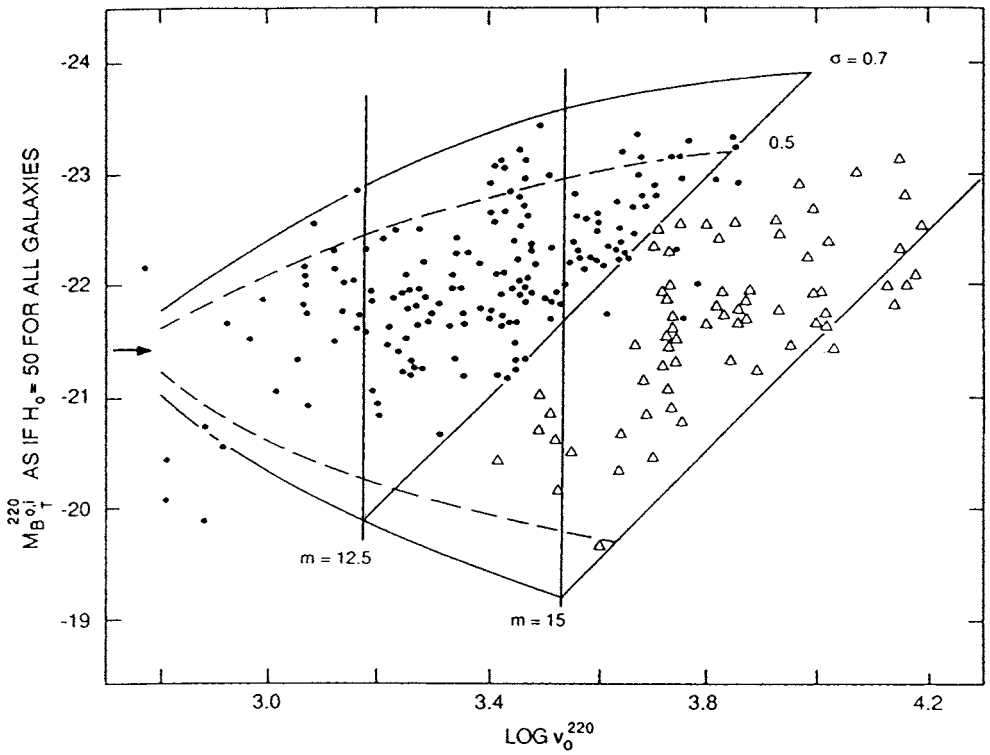

Figure 3. Same as figure 2 but with a fainter sample of ScI galaxies added to a flux limit of $B = 15$. This figure illustrates how adding a fainter sample decides between a real variation of $\langle M \rangle$ with distance versus the effect of bias in any given flux-limited data set.

A family of Spaenhauer envelopes can be computed for different dispersions. Also, different forms of luminosity functions (i.e. non-Gaussian) can be assumed to make any number of different sets of templates. The set of Gaussian templates used here is described by Sandage (1994).

The vertical line in figure 2 is put at the junction of the lower curved envelope line and the flux limit line at $B = 12.5$. The part of the Spaenhauer configuration that is to the left (smaller distances) of the vertical line is the distance-limited subset of the complete data. There is no bias in this region because the sampling of the luminosity function is complete. However, all data to the right of the vertical line are progressively biased at progressively larger distances because the luminosity function is progressively cut from the sample by the flux-limit line. The mean absolute magnitudes calculated in vertical strips of velocity width dv to the right of the vertical line become brighter with increasing distance. This is the detailed bias property of any flux-limited sample.

The classical Malmquist bias is defined as the *integral* of this detailed effect, integrated over the complete data set. Clearly, the mean absolute magnitude of the distance-limited subset (all galaxies to the left of the vertical line in figure 2) is the magnitude of the apex point shown by the arrow. This magnitude is fainter than the average magnitude of all the points in the complete data set, i.e. taken over the total sample in the top panel of figure 2. As stated above, the difference between the distance-limited mean absolute magnitude and the average over the complete data set is defined as the Malmquist bias as he originally calculated it in 1920.

The calculation of this 'integrated' Malmquist bias is a straightforward problem in statistical astronomy. Modern derivations can be found in Mihalas and Binney (1968) and Sandage (1995). The formal equation is

$$\langle M \rangle_{\mathrm{DL}} - \langle M \rangle_{\mathrm{FL}} = (\mathrm{rms})^2 A(m)^{-1}\, \mathrm{d}A(m)/\,\mathrm{d}m$$

where DL and FL refer to distance-limited and flux-limited mean absolute magnitude, $A(m)$ is the number of objects at m in interval dm, and d$A(m)$/dm is the slope of the growth of $A(m)$ with m at m. For a uniform space distribution, $\log A(m)$ grows as $0.6m$ and the Malmquist correction is clearly

$$\langle M \rangle_{\mathrm{DL}} - \langle M \rangle_{\mathrm{FL}} = 1.382\ (\mathrm{rms})^2.$$

How to detect the bias

The infallible signature of bias in any sample is an apparent brightening of the individual absolute magnitudes with increasing distance in a flux-limited sample. If the effect is due to bias, the bias can be proved by plotting a Spaenhauer diagram (i.e. M versus distance). To test that the correlation is due to bias rather than say due to 'evolution', we need only to add a fainter sample. If the effect is due to bias, the effect will disappear at bright

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

magnitude and will reappear at the limiting magnitude of the fainter sample.

This proof for bias in the ScI flux-limited distributions in figure 2 is made in figure 3 where a fainter sample to the magnitude limit $B = 15$ is added for ScI galaxies. *The extended Spaenhauer configuration also fits the added data*. The distance-limited unbiased portion of the data is now increased to a redshift of $\log v = 3.55$, but the distribution begins to become biased again (the faint part of the luminosity function drops out for larger redshifts), but now at larger redshifts in the added fainter sample.

Detailed correction for the bias must either be made at every redshift interval by accounting for the brightening at every redshift, or by restricting the sample to the distance-limited subset of the data to the left of the vertical lines in figures 2 and 3.

Malmquist bias in a more subtle form is also present in flux-limited samples that use the Tully–Fisher relation for distance determination. A large literature exists, an introduction to which can be had in the review article by Teerikorpi (1997), and in the bias series of papers of which Sandage (1994) is the first.

Other types of bias similar to Malmquist

Other important types of bias problems in statistical astronomy are central to many calibration problems. They can only be mentioned here, with literature citations given in the bibliography.

Bias in trigonometric parallax data sets

Selection procedures for sets of trigonometric parallax data determine the bias characteristics of the resulting parallax database. The problem can be seen in its progressive development by reading the following references in the order Eddington (1940), Wallerstein (1967), West (1969), Lutz and Kelker (1973), Hanson (1979). Other references to the problem are listed therein. It is an extremely important problem in using trigonometric PARALLAXES to calibrate the absolute magnitudes of many different types of objects such as subdwarfs, for example, with the resulting distances to the system of globular clusters.

Bias in Cepheid distances using the P–L relation

Because the CEPHEID PERIOD–LUMINOSITY RELATION has an intrinsic dispersion in absolute magnitude at a given period due to the finite width of the instability strip in the HR diagram, bias is present at the faint end because all discovery programs are flux-limited. The method to detect and correct for the bias is given in Sandage (1988).

Malmquist, Gunnar (1893–1982)

Swedish astronomer, worked on statistical astronomy, for example the populations of stars in the Galaxy. The *Malmquist bias* is a statistical effect by which the fainter members of a population are more represented in a brightness-limited sample than they should be—there are more of them to cross by accidental measuring error above the cut-off line than there are above the limit to fall below.

Mantle

The Earth's mantle is composed of a thick layer of solid rock extending from the molten alloy of iron which is the Earth's CORE, 2891 km below the surface, to the so-called Mohorovicic discontinuity or Moho, a few kilometers below the surface. Roughly, it can be considered as a succession of spherical concentric shells which are, from the shallower to the deeper: the lithospheric mantle (from the Moho to 80 km), the upper mantle (from a low velocity zone below the lithosphere to 400 km), the transition zone (from 400 to 660 km), the lower mantle (670 to 2800 km) and the D″ (thermal and/or compositional layer above the core). The increases in temperature and pressure with depth are responsible for this layering which mainly follows the mineralogical phase changes of olivine, the main mineral component of mantle rocks. However, at the present state-of-the-art we cannot definitively preclude the possibility of compositional changes with depth. Actually, the Earth's mantle is much more complex than a simple succession of concentric layers. For short time scales, it behaves like a perfect solid, transmitting seismic elastic waves with almost no attenuation while for geological time scales it behaves like a very viscous fluid. The original accretion energy and the still active long-life radioactive elements act as a powerful energy supply which animates the mantle engine: thermal convection. The convective motions within the mantle are ultimately responsible for the surface plate tectonics, the generation of oceanic lithosphere at mid-oceanic ridges and for the return of lithospheric plates to the mantle at subduction zones. These water-rich sinking plates which have cooled at the Earth's surface for hundreds of millions of years interact with the hot mantle to generate subduction zone volcanism. Their final fate, either to be reincorporated into the upper mantle or to sink deep into the lower mantle and feed the D″ zone, is still vigorously debated within the geophysical community (see also EARTH'S INTERIOR).

A short history

The Earth's mantle is inacessible to direct observations. Our technologically sophisticated civilization remains defeated by the huge pressures and high temperatures which are prevalent even at depths as shallow as a few kilometers. Thus, the deepest drilling experiments have rapidly encountered technical problems due to the increase in temperature with depth (roughly 30 °C per kilometer within the continental crust). Until now, no drilling experiment has succeeded in penetrating all the way through the Earth's continental or oceanic CRUST. The Moho, which separates the crust from the mantle, is roughly 30 km below the surface of the continental crust but only at 6 km below the surface of the oceanic crust. This seismic discontinuity, which is due to the sudden increase in the density of the rocks, characteristic of the mantle, has taken its name from A Mohorovicic, who was the first to detect it in 1907 in the Balkans.

The only direct access that scientists can have to mantle rocks is the very rare ophiolitic or kimberlitic outcrops which have been brought to the surface by tectonic or volcanic events. The ophiolites form groups of mafic and ultra-mafic rocks ranging from basalt to peridotite which have been obducted onto continental crust. This phenomenon occurs when a piece of oceanic lithosphere is carried along during the closure of an OCEAN and is piled onto continental crust. When they are denuded by erosion, outcrops may expose, as is the case in Oman, the whole sequence of lithospheric plate rocks from the pillow lava of the oceanic crust to the upper mantle material below the Moho. The kimberlites are very different in nature. They are composed of peridotite rocks set intrusively by violent volcanic eruptions from deep upper mantle into the continental crust.

Too deep to observe directly, the interior of the Earth has been explored recently by the use of simulations which have allowed scientists to construct a model step by step.

The thickness of the Earth's mantle (2.88×10^6 m), its mass (4.043×10^{24} kg) and the ranges of the characteristic times of physical phenomena which affect it (from fractions of a second for seismic wave propagation to billions years for continental drift), make its behavior difficult for us to understand without the help of high-accuracy metrology. It has only been during the 20th century that improvements in mathematics, physics, chemical sciences and, more recently, the advent of the computer, have allowed significant progress to be made.

Eratosthenes was the first to measure the radius of the Earth around 250 BC. Newton proposed in 1687 that the Earth is an ellipsoid with flattening of 1/230. In 1736 the French Academy of Sciences organized two scientific expeditions in Laponia (directed by A Clairaut and P L de Maupertuis) and in Peru (Directed by P Bouguer and Charles de la Condamine), which confirmed the flattening of the Earth. In 1798, Lord Cavendish proposed an experiment to weigh the Earth and found a mean density of 5.5×10^3 kg m^3. This value, which is roughly twice the density of surface rocks, implied that there was an increase in density with depth. In 1838, William Hopkins, Profesor at Cambridge University, took account of the two modes of heat transfer—conduction and convection—and proposed three possibilities for the internal structure of the Earth: a thin crust overlying a molten Earth, a thick crust and a solid core separated by molten rocks and an entirely solid Earth. The thin crust model was refuted by part of the scientific community, which reasonably argued that such a liquid layer would have been subject to huge tidal effects by the Moon and the Sun, which would have broken the crust. On the other hand, astronomical considerations about the moment of inertia of the Earth also suggested an increase in the density of material near the center of the Earth. This proposal was in agreement with meteorite composition that required a silicate mantle overlying a denser iron core. However, at the end of the 19th century, the inaccessibility of the Earth resulted in some highly speculative inferences about the internal structures of the Earth and the mantle.

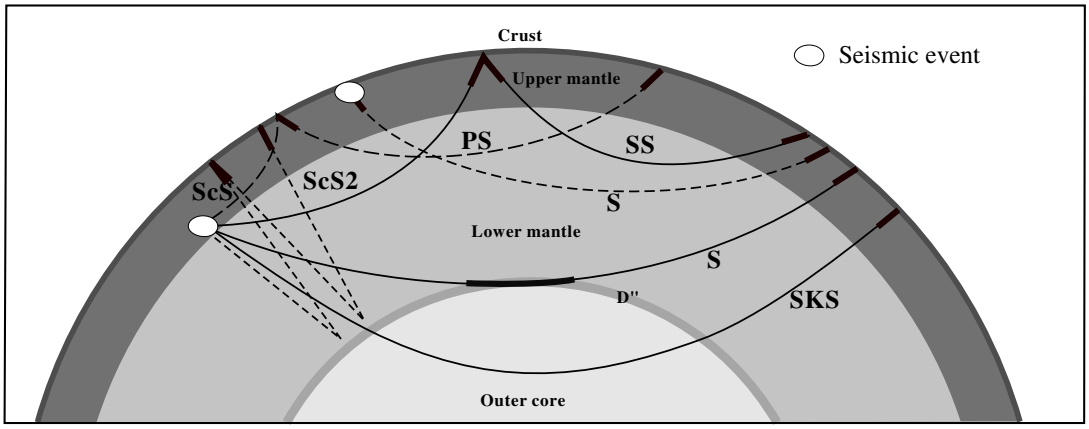

Figure 1. The energy released by seismic events propagates within the Earth's interior and therefore through the mantle as P-waves and S-waves. When encountering obstacles or discontinuities these waves may bounce, be converted from one type to the other, be transmitted through the interfaces or be split. A 'PS'-wave starts from the focus of a seismic event as a P-wave, it propagates through the mantle, bounces under the Earth's surface and continues its journey through mantle as an S-wave. The c in ScS, denotes the reflection of an S-wave on the core surface. K is used for transmission within the core, as for SKS. In this case the S-wave is converted to a P-wave at the core–mantle boundary (CMB), transmitted as a P-wave within the core and is converted back to an S-wave on reaching the mantle. The study of these different wave propagations, the arrival times of which are known to be a function of the surface angular distance of the recording station to the epicenter, allows information to be deduced about its particular path within the mantle.

The elastic mantle

The real birth of modern geophysics occurred with the fortunate detection of a Japanese earthquake in Potsdam on 18 April 1889. A new science was born that would allow scientists to explore the deepest parts of the Earth and to compare the results of observations with models.

The energy released by an earthquake propagates through the deep Earth as elastic waves for which propagation properties depend intimately on the density, compressibility and rigidity of the medium. Encountering discontinuities or obstacles, the compressive waves (P-waves) or shear waves (S-waves) can bounce, be converted from one type to the other, be transmitted or be split. During the first few decades of seismological study, scientists learned to recognize the different types of waves from the times they took to travel from the earthquake focus to recording stations. They defined a nomenclature for these waves according to their propagation within the Earth. Figure 1 shows the different paths of the simplest P- and S-waves within the mantle and their names.

The analysis of arrival times of waves at at least four independent recording stations allows retrieval (if a velocity law is assumed along the path) of the origin time and the geographical location of the epicenter (the point located at the surface above the focus of the earthquake). Conversely, the knowledge of the initial parameters of earthquakes has allowed the velocity models inside the mantle to be refined. During the first two decades of the 20th century, the core, the inner-core, and the main discontinuities of the mantle were discovered. Radial models of the interior properties of the Earth have been regularly improved, leading to the so-called preliminary reference earth model (PREM) which was published by Dziewonski and Anderson in 1981 (figure 2). This model gives the evolution of the gross Earth properties with depth (density, pressure, compressibility, P- and S-wave velocities). The propagation of S-waves in the mantle proves that it is composed of solid rock (S-waves disappear in the liquid outer core but reappear in the inner core). From the evolution of density with depth it is easy to conclude that the mantle is composed of compressible rock. However, density discontinuities (and therefore wave velocity discontinuities) do exist in the PREM, mainly at 670 and at 400 km below the crust and at the Moho level (or from more recent estimations, 660 and 410 km). The two deepest discontinuities bound the transition zone that separates the upper mantle from the lower mantle (below 660 km). A question which is still debated amongst geophysicists is: do these sharp density jumps correspond to compositional discontinuities or to phase changes in the mineralogical structure of the silicate rocks composing the Earth's mantle?

Mantle composition

The Earth is a part of the solar system in which the planets and the Sun have been built by the collapse of a nebula and the ACCRETION of planetesimals. The METEORITES, which still regularly fall on the surface of the Earth, are a surviving witness to those early times. Meteorites can be classified into three main categories: irons or siderites, which are made principally of native metal; stones or aerolites which contain mainly silicate rocks but little metal; and stony irons or siderolites which contain abundant silicates and metals. The stone meteorites (CHONDRITES) represent 86% of the meteorite population and are thought to have a chemically primitive composition. The chondrites are

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

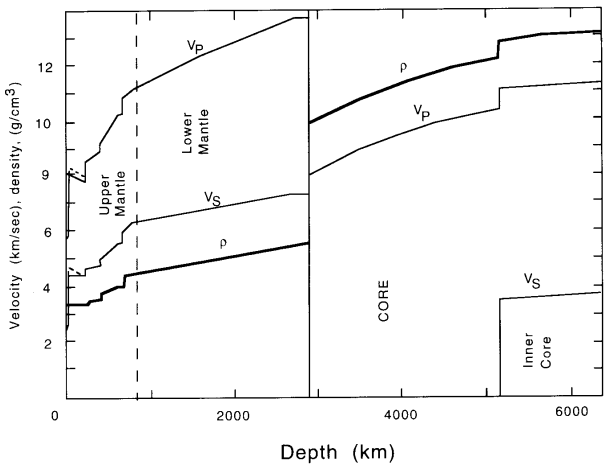

Figure 2. The PREM gives the evolution of density, pressure, compressibility and mean seismic velocity for P- and S-waves within the Earth's interior. P- and S-waves do exist within the mantle while S-waves do not propagate within the core because of its liquid state but reappear in the inner core.

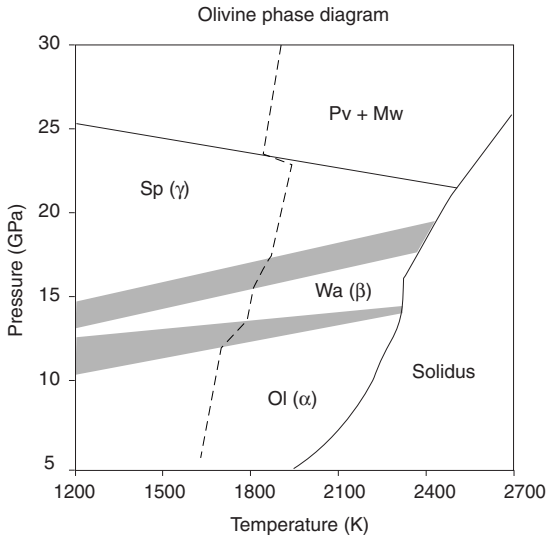

Figure 3. Stability diagram of the olivine mineral phase as a function of temperature and pressure. The Clapeyron slope is the slope of the phase stability in a temperature–pressure diagram. Transitions from α to β phases and from β to γ phases are exothermic (positive Clapeyron slope) while the transition from γ phase to perovskite and magnesiowustite is endothermic (negative Clapeyron slope).

chemically similar but differ by the presence of volatile components (CARBONACEOUS CHONDRITES) or by their iron content and the ratio of oxidized to metallic iron (ordinary or enstatite chondrites). Table 1, which gives the relative distribution of the main silicate minerals in chondrites, shows that olivine is the most abundant mineral. During the accretion phase of the Earth, the conversion of kinetic and gravitational energy into thermal energy raised the temperature above the melting point and induced the segregation of an olivine rich mantle floating above a denser Ni–Fe rich core. Thus, the composition of the Earth, and therefore of its mantle, is broadly chondritic even though it does not exactly match any one particular type of chondrite.

Table 1. Normative mineralogy of ordinary chondrites.

Species	High iron	Low iron
Olivine	36.2	47.0
Hypersthene	24.5	22.7
Diopside	4.0	4.6
Feldspar	10.0	10.7
Apatite	0.6	0.6
Chromite	0.6	0.6
Illmenite	0.2	0.2
Troilite	5.3	6.1
Ni-Fe	18.6	7.5

From these considerations, scientists have proposed dividing the Earth into three reservoirs: the bulk silicate Earth (primitive mantle), the depleted mantle and the bulk Earth (the core, the mantle and the crust). Several compositions have been estimated for the silicate portion of the Earth, based on meteorites and on samples of upper mantle and crustal rocks. The pyrolite, defined by A E Ringwood from complementary composition of melts and residual mantle material, is one of the mixtures representative of the Earth's mantle rocks which are now used to study the behavior of mantle material (see the review by Horton E Newsom in Ahrens (1995)).

Mantle mineralogy

Besides olivine, the main silicate minerals in the upper mantle are orthopyroxene, clinopyroxene, garnet, illmenite and chromite. As the stability of these minerals is only achieved at limited pressure and temperature ranges (see figure 3), the mineralogy of mantle rocks changes with depth, due to solid–solid phase changes. The elastic properties of the rocks are therefore very sensitive to the phase changes of olivine, which induce clear signatures on the seismic velocity profiles. These discontinuities at depths of around 410 and 660 km correspond to the transition from α to β forms of olivine minerals and to the transition of the spinel phase of olivine to perovskite and magnesiowustite minerals.

High-pressure experiments, which are now conducted with multi-anvil presses and with diamond-anvil presses, allow the study of the temperature–pressure stability domains of olivine. This apparatus consist of a thin sample of rock between two diamonds, heated with a laser device. It is then possible to reach pressures corresponding to the outer core pressure. The main problems encountered concern the small size of the samples and the actual control of the temperature and pressure during the experiment. Nevertheless, it has been possible to draw the Clapeyron slopes of the olivine mineral phase changes.

The Clapeyron slope marks the boundary of the phase existence domain in a temperature–pressure diagram. The agreement between mineralogical studies and seismically recorded discontinuities has proved the implication of the olivine phase changes in the mantle discontinuities nature of the rock mantle phase changes. However, this cannot preclude that a part of the discontinuity may also arise from a compositional change. It is important to note that the α to β olivine phase change, at a depth of 410 km, is characterized by a positive Clapeyron slope (exothermic reaction), while the transition from γ-spinel to perovskite, at a depth of 660 km, displays a negative Clapeyron slope (endothermic behavior). These values of the Clapeyron slopes will strongly influence the dynamics of convection currents within the mantle.

Thermal state of the mantle

Scientists still use direct methods to measure the temperature inside the Earth. However, the stability domains of olivine minerals give reference points to fix the temperature at phase change levels. Thus, according to the Clapeyron slope of the γ-spinel to perovskite phase change, the mean temperature at a depth of 660 km is around 1900 to 2000 K. Similarly, the temperature around 410 km should be close to 1600 K. From geochemical considerations, the rate of partial melting observed near the mid-oceanic ridge basalts leads to a temperature of 1400 K under the lithospheric plates. Temperatures can be extrapolated downward through the mantle on the basis of an adiabatic increase which should rise about 1000° above the CMB temperature. On the other hand, recent progress in high-pressure and high-temperature experiments allow the behavior of iron in physical conditions close to those prevailing within the Earth's core to be studied. At the inner core boundary, under the effects of pressure, the core material reaches a transition from liquid to solid which is proved by the reappearance of S-wave propagation. Unfortunately, uncertainties about the actual composition of the core and about the effects the alloy has on the decrease of the crystallization temperature, lead to quite important uncertainties in the determination of the inner core temperature. It may be around 6000 K for pure iron, but extrapolation towards the surface suggests a temperature of around 4000 K at the CMB, approximately 1000 K for the effect of the alloy on the crystallization temperature and 1000 K for the adiabatic decompression through the outer core. In this case, the temperature jump at the CMB could be a few hundred degrees to a thousand degrees. These results are in agreement with the presence of a low velocity layer at the CMB, the D" layer, in the seismological Earth models. The thickness of this layer varies from a few hundred kilometers in some areas to places where it seems disappear. The high thermal gradients in such a thin layer may induce partial melting for sinking material and may be a good place to generate new rising plumes through the mantle. Many in the geophysical community believe that it is the final destination of sinking slabs and the origin of the hot spot volcanism. This could explain the particular signature of the oceanic island basalts which are more primitive in character than the depleted mid ocean ridge basalts.

The fluid mantle

For short time scales such as the time taken for the passage of an earthquake wave through the Earth, the Earth's mantle rocks behave as perfect solids with a very weak attenuation of seismic energy. Thus, the most powerful earthquakes generate free oscillations and long-period surface waves which may last for several hours or even days. This perfect elastic behavior does not occur when the characteristic times of the events are comparable with geological time scales. This is well illustrated by the observation of post-glacial rebound which is occuring today following the melting of the ice sheets which covered the old Canadian and Fenno-scandien cratons during the last glacial period. The relaxation of constraints due to the disappearance of the ice loads on the continent provokes, a few tens of thousand years later, a visco-elastic rebound of the surfaces; these are currently rising by a few millimeters a year. These post-glacial rebounds can be detected from coastline evolution and from gravitational anomalies. Numerous models have been proposed to quantify these trends based both on the elastic (explaining the reaction to unloading) and the viscous behavior (explaining the time delay) of the mantle. The comparison of these models with geological observations make it possible to estimate a viscosity of 10^{23} to 10^{24} Po for the mantle, which is no longer considered as a solid but as a very viscous fluid. This viscosity is so high that it is impossible to make laboratory deformation experiments on rocks. For much longer times such as those of continental formation and drift (several million to several billion years) it is possible to consider the mantle as a perfect fluid. The continents, for which the mean density is lower, float on the mantle like icebergs in water. They display deep cold roots, which may reach several hundreds of kilometers within the mantle. They are dragged along by the deep mantle motions and have supported several episodes of accretion and dispersion of supercontinents during the history of the Earth.

The convective mantle

At the beginning of the history of the Earth, around 4.55 billion years ago, a phase of intense planetoid accretion occurred which continued for approximately 100 million years. During this phase, the kinetic energy of the accreting masses was transformed into heat that caused the whole planet to melt and the gravitational segregation of iron to create the core. A significant proportion of that heat is retained within the Earth's mantle and is currently still escaping. World-wide heat flow measurements at the surface of the Earth have shown that the flux dissipated by the mantle is approximately 42×10^{12} W. This is roughly twice the heat release which would be expected from the radioactive disintegration of the four remaining long-life radioactive elements (^{40}K, ^{235}U, ^{238}U and ^{232}Th). However, silicate rocks conduct heat badly (a simple calculation

shows that it would take approximately 40 billion years to cross the entire mantle by conduction). Therefore, a large proportion of the heat which accumulated during the Earth's accretion, and also that which is continuously produced by RADIOACTIVITY, is available to drive convection within the mantle by inducing density anomalies through thermal expansion. The effects of these density anomalies are counteracted by the adiabatic cooling, the thermal dissipation of heat to the surrounding fluid and the viscous friction. All these effects are gathered into one dimensionless number: the Rayleigh number.

This quantity is representative of the geometrical aspects of a fluid layer but also of the thermodynamical and mechanical properties of the fluid. When the Rayleigh number is lower than a critical value, heat only escapes from the fluid layer by conduction. However, when the Rayleigh number is higher than the critical value, the fluid cannot stay at rest. Convection starts and proceeds to evacuate heat much more efficiently than conduction. It is possible to calculate the Rayleigh number of the mantle by considering the values of the physical parameters revealed by seismology, and the viscosity value obtained from post-glacial rebound. The over-adiabatic temperature and the internal heating can be estimated from composition, mineralogical studies and heat flux measurements. The value finally obtained for the Rayleigh number is around 10^6, that is to say several thousand times higher than the critical value. Therefore, the Earth's mantle cannot stay at rest but is churned by the very efficient motions of convection. The technological improvements to computers have allowed the development of more and more sophisticated numerical models of mantle convection which have recently concluded that the mantle is not only convecting but that this convection is highly chaotic.

Effects of the phase changes on mantle convection

The two main discontinuities in the Earth's mantle at depths of 410 km and 660 km will influence the structure of the convection currents which are crossing them. Indeed the density jumps, due to phase changes, are locally much stronger than the density anomalies due to thermal expansion. When a sinking convection current (i.e. a current colder than the surrounding material) encounters the endothermic phase change at a depth of 660 km, its low temperature implies that the phase change will occur deeper than the mean depth of the discontinuity, according to the negative Clapeyron slope. Then, the upper mantle material may be blocked in the light phase, and its sinking buoyancy may be too weak to reach the actual phase change level. In this case, the sinking current may be unable to cross the discontinuity that may separate upper and lower mantle into independent convective systems. The reverse situation is analogous for rising currents (i.e. a current hotter than the surrounding material) which attempt to cross an endothermic discontinuity from below. Conversely, when a sinking current encounters an exothermic discontinuity, as at a depth of 410 km, the phase change occurs at lower pressure and the fluid easily reaches the actual transition level.

Figure 4 shows the effects of such an endothermic phase change on the structure of convection. In panel (a), the Clapeyron slope is set to zero (i.e. no phase change) and the convection can cross the discontinuity without difficulty. In panel (c), the phase change is set to -4×10^6 Pa K^{-1}, the convection currents are blocked at the discontinuity which can no longer be crossed by the fluid. The most interesting case is given in panel (b); there the Clapeyron slope has been set to -2×10^6 Pa K^{-1} (this value is very close to the experimental value for the spinel-perovskite phase change). Fluid accumulates for a while at the discontinuity and when the threshold is crossed sudden and violent avalanches begin which draw huge quantities of matter from the upper to the lower mantle. This effect, which occurs for a Clapeyron slope close to that of mantle rock, has been found to be a common feature for a very broad range of geophysical and geometrical parameters (Brunet and Machetel 1998).

Evidence for mantle convection

Theoretical studies of fluid mechanics are therefore able to describe the chaotic behavior and global structure of convection within the mantle. This phenomenon is the huge engine which is responsible for the large-scale tectonic motions that are observed at the Earth's surface. Nowadays, the connection between the lithospheric plate motions and mantle convection have to be more accurately studied in order to be quantified. Indeed, the lithospheric plates are much more rigid than the underlying mantle and cannot be rigorously taken into account by the numerical models of convection which assume a fluid behavior for the mantle. The continuous generation of lithosphere at the mid-ocean ridges, its journey at the Earth's surface and its return to the mantle at subduction zones cannot be understood without the churning of matter induced by mantle convection. Similarly, continental drift and the cyclic creation and dispersion of supercontinents necessitate mechanisms of comparable amplitudes within the mantle to those which are observed at the surface.

The chaotic thermal anomalies, induced by mantle convection, result in local density and temperature anomalies within the mantle which affect the velocity of wave propagation mainly through the rigidity of the rocks. Therefore, a cold anomaly induces a positive velocity anomaly and, conversely, a high temperature creates a slow zone. On the basis of radial seismic Earth models (e.g. PREM), seismologists have been able to calculate local departure to mean values, thanks not only to the improvement in seismological networks but also to improvements in computer performance which have allowed the treatment of more numerous data and more complex computations. To reach this goal, the Earth has been decomposed into small cells for which a global inversion of all the ray paths is used to calculate local velocity. It would be tempting to consider that this procedure will give us a detailed map

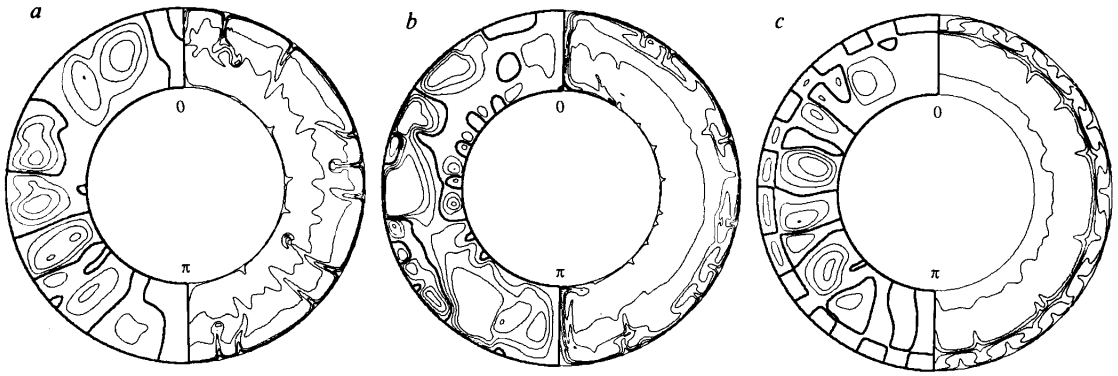

Figure 4. Isocontours of stream functions (left part of the spheres) and temperature fields (right part of the spheres) for a model mantle with endothermic phase change at 670 km. When the Clapeyron slope is set to 0, no influence of the phase change can be deciphered on the global mantle circulation (panel a). With a Clapeyron slope of -4×10^6 Pa K^{-1}, the endothermic phase change prevents convection from crossing the discontinuity that results in a two-layered convection between lower and upper-mantle (panel c). With a Clapeyron slope close to the value given par mineralogical studies (-2×10^6 Pa K^{-1}), a partly layered regime prevails with occurrence of mantle avalanches (panel b).

of the temperature field within the mantle. Unfortunately, seismic sources are not evenly distributed on the surface of the Earth; they are concentrated mainly at plate borders leaving large areas of oceanic plates without seismic sources. Furthermore, seismic stations are, for obvious commodity and maintenance reasons, mainly installed on continents that are better able to cover the northern hemisphere. Additionally, the interpretation of seismic velocity anomalies in terms of temperature is only an approximation since other effects such as anisotropy or compositional anomalies may affect the wave velocity. Therefore, the tomographical studies only give a rough (but improving continuously) idea of the thermal structure of the mantle. Up to now the results do not allow conclusions to be drawn either for two-layer convection, whole layer convection or partly layered convection within the Earth's mantle. Figure 5 gives the result of a tomographical study by Van der Hilst and Seno (1993). It seems from the most recent seismological results that certain slabs can cross the endothermic discontinuity at a depth of 660 km, as in the Mariana Trench, whilst others bend at this discontinuity without crossing it.

The convective thermal anomalies also induce perturbations of the gravity field of the Earth. Indeed, a rising convection current corresponds to the rising of hot, and therefore lighter, material that results in a negative density anomaly. However, the thermal effects of convection cannot be separated from the dynamical effects of the convection currents on the surface and discontinuity topographies. The strength of the rising currents pushes and deforms the surface leading to an opposite effect on gravity (creation of a positive density anomaly). Furthermore, for a rising convection current crossing the entire mantle, the surface would be deflected upward, resulting in a positive density anomaly; the 660 km discontinuity would also be deflected upward, but the 400 km exothermic discontinuity would be deflected

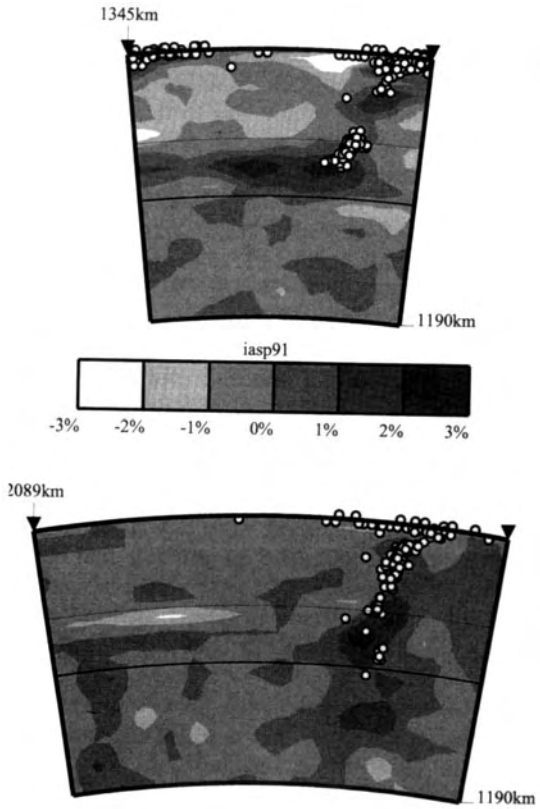

Figure 5.

downward. The compensation of these effects at different depths depends strongly on the viscosity contrasts, which are assumed between the different parts of the mantle. This quantity remains very badly constrained. The relationship between the global gravity field and

convection will strongly depend on the global structure of convection, which may not extend over the whole thickness of the mantle.

Avalanches and large scale tectonic features

Recent numerical models of mantle convection, based on the existence of mantle avalanche phenomena, have been used to propose self-consistent mechanisms for large-scale tectonic features such as huge volcanic events, the world-wide increase of basalts generated at mid-oceanic ridges, periods of low-reversal of the magnetic fields, the pulsation of super-continents, and the brutal acceleration of continental motions (as for India during its journey toward Eurasia). The avalanches are characterized by the accumulation at the 660 km discontinuity of sinking cold material, which are not immediately able to cross the discontinuity. When the avalanche starts (figure 6), a brutal transfer of matter occurs from the upper to the lower mantle. This sinking matter is compensated by return flows from the lower mantle into the upper one. While the avalanches are localized on the sphere, these return flows imply huge world-wide arrivals of hot lower mantle near the surface that may induce faster and more efficient dorsal evacuation of heat. The cold material sinking during an avalanche is colder and therefore more viscous than the surrounding material. It quickly reaches the core surface where it sweeps the hot, less viscous material into very high unstable temperature anomalies which may start as vigorous new plumes toward the surface. These plumes cross the lower mantle to spread at shallow depth under the surface. The low-viscosity zones which are created may lubricate the motion of the converging continents above the avalanche inspiration. At the same time, the arrival of cold material at the core surface increases the heat transfer from the core to the mantle, which may increase the stability of the convective structure into the outer core and to stabilize the dynamo.

Conclusions

Our knowledge of the Earth's mantle has progressed rapidly over recent decades thanks to improvements in metrology, seismology and computing power. However, it is not yet known whether convection in the Earth's mantle occurs in cells that extend throughout the entire depth of the mantle, or if convection in the upper and lower mantle is separated. A mixed situation could prevail with partial layering of the mantle. The more and more accurate seismic tomography results describe a complex situation with no general rules but a strong sensitivity to the local constraints of global plate motion. The slabs either bend at the 660 km discontinuity or cross it deep into the lower mantle. A slow cooling has decreased the Earth's internal temperature since the Archean era. Geochemical studies of lavas show that it may have reached a few hundred degrees, which may have changed the global regime of convection from layering to whole mantle convection. This trend, if it were confirmed by future studies, would imply that at least for a period, an avalanche regime might have occurred. Such a possibility could have provided a mechanism powerful enough to have gathered and dispersed the supercontinents several times during the Earth's history.

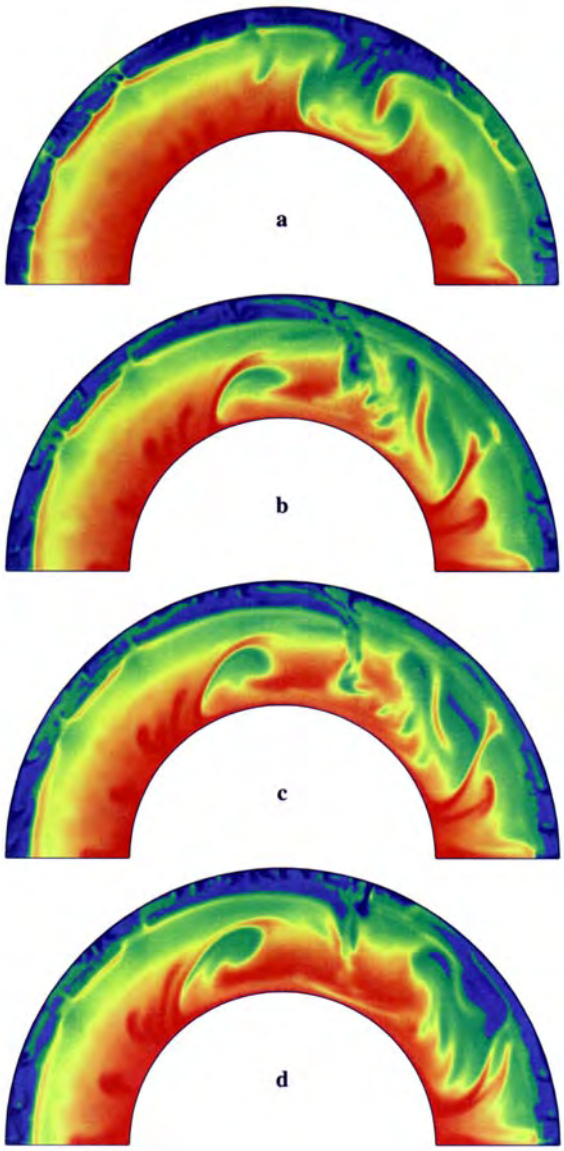

Figure 6. Evolution of the temperature field of a model mantle during an avalanche. If their existence is confirmed, such phenomena may be invoked to explain most of the large- scale tectonic features and in particular the apparent pulsation of supercontinents at the Earth's surface. **This figure is reproduced as Color Plate 35.**

Mare (pl: maria)

A dark lunar plain. The name, which is Latin for 'sea', was first used on maps of the Moon in the seventeenth century, when astronomers believed the Moon to be Earthlike, and that the light and dark areas were land (sometimes called 'terrae') and water. In fact the maria are composed of basalt, solidified lava which erupted between 3 and 4 billion years ago after the Moon had suffered large impacts which weakened or, in some cases, penetrated its crust. 'Mare' has become so well established that it is retained in lunar nomenclature. The maria range in size from huge lava floodplains such as Oceanus Procellarum (2568 km across) and the large impact features Mare Orientale and Mare Imbrium, down to the 150 km Mare Anguis. Maria are much more prevalent on the Moon's nearside; on the farside the crust is thicker and withstood impacts better. They are smooth areas with few craters: by the time they had formed the great episode of cratering was over, and they bear the scars only of recent impacts, which in the past 3 billion years have been much less frequent.

The term 'mare' was also formerly used for dark regions on Mars (e.g., Mare Tyrrhenum, named after the Tyrrhenian Sea, between Italy and Sicily), which in the nineteenth century were also assumed to be 'seas'. However, in general they do not correspond to topographic features, and are now used only on albedo maps (showing areas that appear light and dark) of the planet.

Mariner Missions

Mariner was the name given to the earliest set of American space missions to explore the planets and to the spacecraft developed to carry them out. The missions were planned and executed by the JET PROPULSION LABORATORY (JPL) of the California Institute of Technology, which had been designated by the National Aeronautics and Space Administration (NASA) as its lead center for planetary missions.

Birth Pangs of the Planetary Program—1960–1962

In January 1959, shortly after NASA had been established and JPL had become affiliated with it, the laboratory proposed a program of space missions that contemplated sending two spacecraft to VENUS and two to MARS at each opportunity starting in 1960. With some modifications, this program was adopted by NASA and titled VEGA. In the next few months, as it became clear that launch-vehicle development was falling short of expectations, Vega was canceled and replaced by less ambitious programs—RANGER for lunar and Mariner for planetary missions. The Mariner program, approved by NASA in July 1960, would be carried out by a series of increasingly capable spacecraft, beginning with Mariner A to fly by Venus in 1962 and Mariner B for missions to Venus and Mars (possibly with landers) beginning in 1964. The spacecraft were to be launched by the Atlas–Centaur launch system.

Considerable progress was made at JPL in developing the spacecraft and the missions for Mariners A and B, including the scientific payloads and the teams of scientists to implement them, but the development of the Centaur upper-stage rocket ran into continual problems so that Mariner A was canceled in August 1961. To replace it, JPL proposed to use a simpler Ranger-type spacecraft on top of the Atlas–Agena launch system for the first observation of Venus. The scientific payload would have to be severely curtailed. In recognition of its Ranger heritage, the project was called Mariner R.

Mariner 1 was launched from Cape Canaveral on 22 July 1962. A small error in the launch-guidance equations in the computer onboard the Atlas caused it to fly erratically, and it was destroyed by the range safety officer after 290 s.

The features of Mariner spacecraft are summarized in table 1.

Mariner 2 to Venus—1961–1963

The identical Mariner 2 spacecraft was launched on 27 August, and it carried out its mission by flying by Venus on 22 December at a distance of 34 762 km. It carried a payload of only six scientific instruments weighing only 18 kg, but each of them operated essentially as intended. The Microwave Radiometer measured the temperature of the planet surface to be about 425 °C and the Infrared Radiometer registered the cloud-top temperature as −35 °C.

The other experiments operated continuously during most of the flight, providing the first long-duration monitoring of conditions in interplanetary space. The Micrometeorite Detector registered the impacts of dust particles, detecting only two. The Charged-Particle Experiment monitored cosmic rays. The Magnetometer Experiment monitored the interplanetary field. The Solar-Wind Experiment determined for the first time the density, velocity, temperature and composition of the plasma streaming out from the solar corona.

The spacecraft continued to operate nearly faultlessly for 21 days beyond Venus encounter (130 days total) out to 87.4 million km from Earth. It thus demonstrated the efficiency of its three-axis stabilized design, its capability of effective two-way communication with Earth over vast distances with a transmitter power of only 3 W and the ability of the Deep Space Network for precise tracking throughout the flight. It was the most successful space mission in history up to that time.

Mariner 4 to Mars—1962–1965

The Mariner B mission was originally authorized in July 1960 for a landing on Venus or Mars in 1964. In February 1961 the Venus lander was dropped from consideration, but in April 1962 it was reinstated, and the Mars landing was dropped. In May 1963 the Mars landing was postponed until 1966 and redesignated Mariners E and F, and these were effectively canceled in July 1964. This sad history resulted from the troubles with the Atlas–Centaur.

Meanwhile, a much less ambitious Mars flyby mission, called Mariner C, with a spacecraft barely half the weight of Mariner B, was proposed in midsummer 1962, approved in March 1963 and ready for launch by the Atlas–Agena in November 1964. The launch of Mariner 3 on 5 November appeared normal, but the signal of solar-panel deployment was not received, and communication ceased as the battery ran down. It was soon determined that the nose cone (appropriately called the 'shroud') had failed to jettison. This information prompted a frantic effort to design and fabricate a new shroud in the three weeks before the launch period closed.

Mariner 4 was launched on 28 November 1964 and flew by Mars on 14 July 1965 at a range of 9844 km, taking a sequence of 21 photographs of the surface. The mission revealed two very important new facts: (1) that the surface was covered with impact craters; (2) that the atmosphere was mainly carbon dioxide at a pressure of less than 7 mbar. The latter was determined by the Radio Occultation Experiment, which had not even been accepted as part of the mission until after launch. The other scientific experiments were three to detect charged particle radiation, a Solar Plasma Probe, a Magnetometer and a Cosmic Dust Detector.

Mariner 5 to Venus—1965–1967

A project to revisit Venus with a spare Mariner 4 spacecraft was authorized in December 1965, and Mariner 5 was launched on 14 June 1967. It flew past Venus at 10 151 km

Mariner Missions © Kluwer Academic Publishers 1997

Table 1. Mariner spacecraft.

Spacecraft	Target	Mass (kg)	Science payload (kg)	Data rate (bits s^{-1})	Data storage (megabits)
Mariner 2	Venus	203	18	8.33	0
Mariner 4	Mars	261	16	33.3	5.24
Mariner 5	Venus	245	10	33.3	1
Mariners 6, 7	Mars	413	58	670	195
Mariner 9	Mars	998[a]	63	16 200	180
Mariner 10	Mercury	534	78	117 600	180

[a] This includes 466 kg of propellant to put the spacecraft into Mars orbit.

from the center on 19 October and successfully conducted seven experiments, one day after the Soviet Venera 4 had dropped on the surface a landing capsule that failed to provide any data.

The Plasma Probe (1), the Magnetometer (2) and the Energetic Particle Detectors (3) were designed to investigate the interaction between the planet and the interplanetary plasma. They determined that the magnetic field of Venus (if any) is much weaker than the Earth's and too weak to hold off the solar wind and produce an Earth-like magnetosphere. However, when the solar wind reaches the top of the atmosphere it is deflected by the ionosphere so that it flows around the planet without touching the surface. The Ultraviolet Photometer (4) found large quantities of hydrogen in the upper atmosphere at a very low temperature, but no oxygen was detectable.

Three experiments utilized the radio links to and from the spacecraft. The S-band Occultation Experiment (5), by analysing the downlink signal, obtained profiles of refractivity, temperature, density and pressure in the neutral atmosphere and of electron density in the ionosphere. These data demonstrated that the temperature was 475 °C and the pressure was 90 atm at the surface. The Dual-Frequency Occultation Experiment (6), using two radio transmissions from Earth that were analysed on the spacecraft, obtained very detailed information on the ionosphere. Range and Doppler tracking of the spacecraft provided the Celestial Mechanics Experiment (7), which determined the masses of Venus and the Moon with unprecedented accuracy.

Mariners 6 and 7 to Mars—1965–1969

For the 1969 missions to Mars, the availability of the Atlas–Centaur launch system made possible major increases in the size and sophistication of the spacecraft and their scientific payloads. Mariner 6 was launched on 25 February and its twin, Mariner 7, on 27 March; they flew by the planet on 31 July and 5 August, respectively. Each spacecraft carried two vidicon cameras—wide angle and narrow angle—and a much higher data transmission rate provided 200 times the picture data of Mariner 4. The two spacecraft acquired 143 pictures before encounter that showed the entire visible disk or a considerable fraction of it and 59 pictures near encounter that covered small areas, about half of which had resolutions of 0.2 km or better. All the close-up pictures were in the southern hemisphere and, although they covered only about 10% of the surface, they did reveal some new surface features and laid to rest the myth of the Martian canals. Later missions, however, showed that most of the interesting features of Mars had been missed or misinterpreted.

The Infrared Radiometer measured a temperature of 150 K on the south polar cap, indicating it to be carbon dioxide ice and not water ice. The Ultraviolet Spectrometers on both spacecraft detected carbon monoxide in the atmosphere but, surprisingly, saw no trace of nitrogen. The Radio Occultation Experiment confirmed the Mariner 4 finding on the atmospheric pressure and detected an ionosphere. The Celestial Mechanics Experiment measured the planet's mass with unprecedented precision.

Mariner 9 to Mars—1968–1972

For the next Mars opportunity in 1971, the plan was for a dual-spacecraft orbiting mission that promised a large increase in information over the three earlier flybys. However, on 8 May the Centaur booster failed to boost Mariner 8 into orbit. Mariner 9, successfully launched on 30 May, arrived at Mars on 14 November to find the planet shrouded by the most intense global dust storm that had ever been observed. Settling into its intended orbit, the spacecraft simply waited out the storm, which had cleared by March, and in 349 days of operation it achieved virtually all of the objectives of the dual mission.

Mariner 9 revolutionized our understanding of Mars. The camera returned 7329 photographs and 54 billion data bits—27 times as much as the three preceding missions. It discovered many volcanoes, including OLYMPUS MONS, 27 km tall, an enormous system of deep canyons, dubbed VALLES MARINERIS, that stretch about one-quarter of the way around the planet, a plethora of channels of five different types, many of them appearing to be ancient river beds, numerous evidences of eolian erosion and deposition, a variety of meteorological phenomena and many other things.

The Infrared Radiometer Experiment measured the thermal inertia of the surface over much of the planet and found the surfaces of PHOBOS AND DEIMOS to be very poor thermal conductors. The Infrared Spectrometer Experiment detected carbon dioxide, water, dust and ice crystals in the atmosphere, monitored the atmospheric

temperature and determined the atmospheric pressure at numerous points. The Ultraviolet Spectrometer Experiment measured the atmospheric pressure over much of the surface, thus determining the relative altitude in many places, and measured ozone and atomic hydrogen in the atmosphere.

The S-band Occultation Experiment, with more than 300 occultations to analyze, made many measurements of the atmospheric temperature profile, the surface pressure, and the electron density in the ionosphere. The Celestial Mechanics Experiment, by analyzing the metric information in the tracking data, determined a more accurate description of the gravity field of the planet, improved the ephemeris of Mars by an order of magnitude, and obtained topographic data with a precision of 100 m.

Mariner 10 to Venus and Mercury—1969–1975

A mission to MERCURY was authorized by NASA in December 1969. For the first time in the Mariner program, the spacecraft was not to be built by JPL in house, and the Boeing Corporation won the contract to build it. Mariner 10 was put on a course to Venus by an Atlas–Centaur rocket on 3 November 1973 and flew by the planet on 5 February 1974 at just the proper location to be deflected by the gravitational field into an orbit to Mercury. This was the first employment of the 'gravity-assist' technique of interplanetary navigation. Mariner passed Mercury on 29 March at a distance of 703 km and was deflected into a new orbit that took it around the Sun in 176 days and back to Mercury at intervals of exactly two Mercurian years. The second encounter occurred on 21 September at about 50 000 km, the larger distance being chosen to extend the photographic coverage at good viewing angles. The third, on 16 March 1975, was targeted to the dark side of the planet at 327 km altitude in order to maximize the information about the magnetic field and the magnetosphere.

Mariner 10 exhausted its attitude-control gas supply on 24 March 1975, and the spacecraft transmitter was turned off for the last time, terminating the mission after 506 days and nearly 1.6 billion kilometers of travel.

Mariner 10 was the most complex and sophisticated of all the Mariner spacecraft, and its mission achieved many space firsts. It was the first mission to visit two planets and to fly by the same planet three times. It was the first to return photographs in real time instead of storing them, as the tape recorder failed before the second Mercury encounter. Rotatable solar panels were used for the first time to maintain their temperature and power output through the large change in solar distance. 'Solar sailing' was attempted and used successfully for the first time, as the positions of the solar panels and the high-gain antenna were manipulated to maintain the orientation of the spacecraft by radiation pressure without the expenditure of attitude-control gas; this technique made the third encounter possible. Optical navigation was employed for the first time as the cameras provided the angles between Mercury and stars. The Celestial Mechanics Experiment had available, for the first time, radio signals in both X- and S-band.

The TV camera was equipped with two CASSEGRAIN TELESCOPES to provide high- and low-resolution pictures and a filter wheel to permit photography in several wavelength bands, including the ultraviolet. It returned more than 1000 pictures of Earth and Moon, 3500 pictures of Venus and 3700 pictures of Mercury, a small number of which had resolution as small as 134 m. They provided very detailed coverage of the clouds of Venus (made possible by the ultraviolet sensitivity of the cameras) and the surface of Mercury. The motion of the clouds appeared to indicate that the primary circulation pattern on Venus is vertical upward motion at the subsolar point and subsidence over the poles.

Mercury was found to look generally like the MOON, but with some distinctly non-lunar features, including large scarps or cliffs nearly 3 km high and as much as 500 km long, probably indicative of crustal shrinkage. The density of small craters was surprisingly similar to that on the Moon and Mars, implying that all these planets received similar intensities of meteorite bombardment, contrary to earlier assumptions.

A major and unexpected discovery was an intrinsic magnetic field, which, although about 60 times weaker than Earth's, was sufficient to produce a bow shock and a magnetosphere that was a miniature copy of Earth's.

The scientific payload included also a Radio Science Experiment, a Solar Plasma Experiment, a Charged Particle Telescope, an Infrared Radiometer and two Ultraviolet Spectrometers. One of these was designed for detecting planetary airglow; the other, intended for sounding Mercury's atmosphere by looking at the sun as it was occulted, also made observations on Comet Kohoutek and the Gum Nebula. It detected a very sparse atmosphere of helium on Mercury. Surface temperature extremes of 90 K and 460 K were measured by the radiometer. The Radio Science Experiment measured the diameter and mass of Mercury with unprecedented precision and detected no trace of an ionosphere.

The exploration of the solar system, ably initiated by the Mariner series, was continued by spacecraft called VIKING and VOYAGER.

Marius [Mayr], Simon (1573–1624)

Astronomer, born in Gunzenhausen, Bavaria, Germany, competitor of GALILEO. Educated in astronomy and meteorology, he was appointed mathematician of the Margrave of Ansbach in 1601, printing an annual almanac as part of his duties. Went to Prague to study with TYCHO BRAHE, moved to Padua to study medicine. Observed the nova of 1604 with BALDESSAR CAPRA and helped Capra published a book on it. Capra lost his reputation by flagrantly plagiarizing a manuscript by Galileo and was expelled from the university. The scandal tainted Marius, who moved back to Ansbach where he learned in 1609 from an artillery officer, Freiherr Hans Philip Fuchs, that a Dutchman had tried to sell him a telescope. Marius grasped the concept and realized it with a telescope which he used to observe Jupiter. He claimed in a book of 1614, *Mundus Iovialis Anno M.DC.IX Detectus Ope Perspicilli Belgici (The Jovian World, discovered in 1609 by means of the Dutch Telescope)*, that he had first observed Jupiter's moons in December 1609, a month before Galileo. The claim infuriated Galileo, coming from someone involved in an earlier theft of Galileo's work, and especially as there were unresolved inconsistencies in the observations and dates. Whatever the truth of that matter, Marius's names for the satellites stuck. *Mundus Iovialis* contains Marius' telescopic observation of M31, the Andromeda nebula, something that he independently discovered, although it had been observed around AD 905 and documented in AD 964 by the Persian astronomer AL-SUFI, in his *Book of Fixed Stars*.

Mars

Mars is the fourth planet from the Sun and the most Earth-like. Its radius is only half that of the Earth, it is significantly colder and has a much thinner atmosphere (table 1). However, the Martian environment is the most similar to the terrestrial one in the solar system: most atmospheric and geologic processes have their equivalent on our planet, for instance the global atmospheric circulation and the volcanic processes. One of the major differences is related to the absence of liquid water at the surface in the present conditions, although there is much evidence that liquid water existed in the past.

Initial data from NASA's Mars Odyssey gamma ray spectrometer instrument suite has been used to detect hydrogen, which indicates the presence of water ice in the upper meter (three feet) of soil in a large region surrounding the planet's south pole. The amount of hydrogen detected indicates 20 to 50% ice by mass in the lower layer. Because rock has a greater density than ice, this amount is more than 50% water ice by volume.

Mars is one of the brightest objects in the sky and therefore has been known since the earliest antiquity. Because of its distinct red color, strong brightness and strange movement in the sky, it has often been associated with death or war by the oldest civilizations; its modern name is actually that of the Roman god of war. Historically, the observation of Mars has often triggered important astronomical progress. This is still true in the modern era, since Mars has been the target of more than 30 spacecraft as of this writing. The reasons for this situation are not only that Mars is the most accessible planet but also that it has the most Earth-like environment and is probably the most favorable location for the development of life in the solar system: although the current conditions at the surface are actually very hostile to life, this was almost certainly different in a distant past. Mars is therefore likely to become the first planet where humans will go, although this still appears a rather distant issue.

The two satellites of Mars are also interesting objects. They were discovered only in the late 19th century because of their very small size and proximity to Mars. Both satellites are very dark and have a very low density, indicating that they are most probably captured asteroids (see PHOBOS AND DEIMOS). Because of their orbital position around Mars, they are the most easily accessed objects of this type, although they probably suffer processes that are not common on other asteroids, in particular higher impact fluxes.

Table 1. Mars' main characteristics.

	Mars	*Earth*
Mass	6.4185–10^{23} kg	59.75–10^{23} kg
Mean radius	3389.92 km	6 388 km
Mean density	3.9335 g cm^{-3}	5.52 g cm^{-3}
Moment of inertia	0.3662±0.0017	0.3308
Semimajor axis	227.94–10^6 km	149.6–10^6 km
Eccentricity	0.0934	0.0167
Orbital period	686.98 Earth days	365.256 Earth days
Sinodic period	779.94 Earth days	—
Rotational period	24.6229 h	23.9345 h
Obliquity	25.19°	23.45°
Equatorial surface gravity	3.727 m s^{-2}	9.78 m s^{-2}
Equatorial escape velocity	5.027 km s^{-1}	11.18 km s^{-1}
Mean atmospheric pressure	5.6 mbar	1013 mbar
Mean surface temperature	–63 Â°C	13 °C

Observations and space exploration

The physical study of Mars began with the invention of the telescope at the beginning of the 17th century. Galileo first demonstrated the spherical shape of the planet from his telescopic observations. Some 70 yr later, Christiaan Huygens and G D Cassini had recognized the main characteristics of the planet (see MARS: SURFACE). The study of Mars improved very quickly at the end of the 19th century, when the progress of optical instruments made it possible to observe the high variability of the surface and atmosphere. However, it was only in the 1950s that atmospheric studies really developed, and many incorrect ideas were widely accepted at the beginning of the space era (see MARS: ATMOSPHERE). The first synthesis of modern observations was published by G de Vaucouleurs in 1954; it was generally considered at this time that the atmosphere was mainly composed of nitrogen, with a total pressure of 85 mbar—15 times the actual value—and that, although chlorophyll plants were certainly absent, surface variations could be due to the seasonal growth of lichen at the surface. Mars is therefore a dramatic example of how space exploration completely changed our perception of the solar system (see SOLAR SYSTEM: EXPLORATION). The earliest attempt to visit Mars was made by the Soviet Union in 1960. After six failures on the US and Soviet sides, Mariner 4 (see MARINER MISSIONS) finally returned images of Mars in 1965, during the first flyby of another planet. The results of the mission were actually surprising, since the oldest terrains resembled the Moon much more than the Earth—a view confirmed during the next flybys by Mariner 6 and 7 in 1969.

Mariner 9, the first spacecraft orbiting Mars in 1971, produced the first systematic mapping and analysis of the atmosphere. These data allowed us to obtain a full view of Mars' complexity, in particular concerning the surface characteristics of the planet and its very complex geologic history. In 1976 Viking (see VIKING MISSION), a very complete mission consisting of two orbiters and two

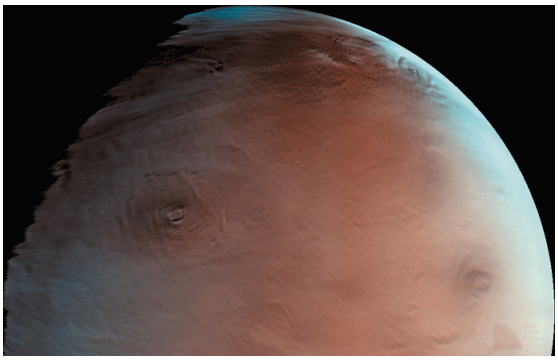

Figure 1. View of Mars acquired in June 1998 by Mars Global Surveyor, taken from low orbit, centered on northern Tharsis. Olmypus Mons is left of center and Ascraeus Mons at the lower right. Olympus Mons is about 550 km across. The image was taken during northern winter; clouds and haze can be seen to the north (up) above Olympus Mons. The morning terminator runs left of Olympus Mons. (Mars Global Surveyor image MRPS88925.)

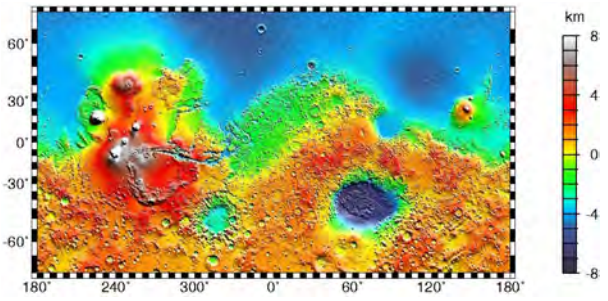

Figure 2. Topographic map of the equatorial regions of Mars, retrieved from radar measurements by Mars Global Surveyor (Mercator projection). The vertical acuracy is approximately 5 m. Obvious on the map are the hemispheric dichotomy, with cratered highlands in the south and younger low plains in the north, the Tharsis and Elysium domes at 260° and 150° longitude, the giant volcanoes of Tharsis, Olympus Mons (18°N, 228°E) and Elysium Mons (25°N, 150°E), Valles Marineris and the outflow channels (0°N, 340°E), and the two large basins in the southern hemisphere, Argyre (50°S, 320°E) and Hellas (45°N, 110°E) has been interpreted as further evidence for a possible ancient seafloor from these data. (Credit: NASA–MOLA Science Team.)

landers, was successfully delivered to Mars and performed observations until 1982. Most of our current knowledge of Mars is still derived from the analysis of these data. Other, more limited, results were acquired by Mars 2 and 3 (1971), Mars 4, 5 and 6 (1973), Phobos 2 (1989), and Mars Pathfinder (1997). After the failures of two major missions (Mars Observer in 1992 and Mars-96 in 1996), the exploration of Mars was revived with the launch of Mars Global Surveyor (NASA) (figure 1 and figure 2) in 1996 and the approval of the Mars Express mission (ESA), which should complete the phase of global characterization of the planet. The next major step will focus on *in situ* analyses, most notably with the Mars sample return project (NASA–CNES–ASI) scheduled for the period 2003–8.

Another, unexpected source of data concerning Mars was identified in the early 1980s. Several volcanic meteorites (called the SNC METEORITES) were identified as Martian in origin because of their young crystallization ages (150 My–1.3 Gy) and particular isotopic ratios similar to the Martian atmosphere. There are currently 13 SNC meteorites in collections that are thought to have been ejected during large impact events. The analysis of these rocks has helped put very strong constraints on the evolution of Mars, notably concerning its formation. They are not as useful as collected samples, however, because their source area is unknown and because we do not know to what extent they are typical of the Martian rocks.

Dynamics and climate

The movement of Mars in the sky is spectacular since, like all external planets, it has a retrograde motion when it approaches Earth at its closest distance. In the case of Mars the variation of the apparent speed is very quick, and the magnitude of this movement is much more marked than for Jupiter or Saturn. The very large variation of Mars' brightness with distance from Earth (about a factor of 50) was one of the major drawbacks of the antique geocentric system. In the modern period, the precise observations of Mars by Tycho Brahe led Kepler to state his laws of planetary motion, and in particular to reject the old assumption that planetary orbits are circular—indeed, Mars has by far the largest eccentricity among the 'regular' planets.

This orbital particularity has a deep impact on the Martian climate: there is a marked difference in seasonal length between the two hemispheres, with a longer and colder winter in the south at present, resulting in compositional differences between the polar caps, with a permanent water-ice cap exposed only in the north. This situation reverses every 25 000 yr, which may have induced large climatic variations in the past. On a time scale of 10 Myr, the periodic variations of obliquity (15°–35°) probably govern the climatic change, by changing the magnitude of seasonal effects. On longer time scales, these variations are chaotic and obliquity may range between 0° and 60°. This situation is unique among terrestrial planets, because Mars has not been stabilized by a massive satellite, like the Earth–Moon system, or by tidal dissipation like Mercury or Venus. As a consequence, Mars may have suffered very different climatic environments in the distant past, with a very different repartition of volatiles between the main reservoirs (polar caps, regolith, permafrost, atmosphere and possible water bodies). Indeed, the morphologic evidence suggests that liquid water ran at the surface not only at the end of the period of heavy bombardment when the

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

atmosphere was thicker (3.8 Gyr ago) but also much more recently during several different episodes. In both cases, this would have required higher surface temperatures than at present, and therefore a GREENHOUSE EFFECT with larger atmospheric pressures. This is specially true during the early stages of the solar system (see ORIGIN OF THE SOLAR SYSTEM): according to stellar evolution models the Sun was 30% dimmer than it is today, so that the CO_2 pressure had to be at least 2–3 bar to permit such temperatures, which is consistent with estimates of planetary outgassing (see PLANETARY ATMOSPHERES). However, one of the main issues concerning the evolution of Mars is related to the stability of the primordial atmosphere and to the transition to a colder, lower-pressure environment. Another controversial topic concerns the possible existence of lakes or oceans during later episodes of climatic warming.

Internal structure and composition

Although the Viking landers were equipped with two seismometers, these experiments provided very few results about the internal structure of Mars. Most ideas in this field are derived from orbiting spacecraft and from the composition of SNC meteorites.

Mars, like the other terrestrial planets, is probably divided into a crust, mantle and core (see PLANETARY INTERIORS). The thickness and density of the core can be constrained from the knowledge of mass, radius and moment of inertia of the planet, with a rather large uncertainty. Although Mars Pathfinder measured the moment of inertia with a sufficient accuracy in 1997, two models are compatible with the current data: Mars could possess either a small core of high density (a core of iron would represent 15% of the planet's mass for a radius of 1300 km), or a large low-density core (a mixture of sulfur and iron representing 25% of the planet's mass for a radius of 2000 km). The first model is more similar to the Earth's core, but studies of the SNC meteorites' composition rather suggest a large fraction of nickel (~45%) and sulfur (~12%) in the core. The latter figure, while uncertain, is important because a high fraction of sulfur would slow down the solidification rate of the core through geologic times. The lack of strong magnetic field on a global scale implies that the core is not convecting and is therefore either completely solid or liquid. A magnetic field does exist at the surface, however, which was perhaps induced by a past planetary field, suggesting that a dynamo effect has existed, but stopped at a certain time as the core became solid and stably stratified.

The mantle thickness is estimated to be between 1500 and 2100 km, depending on the core properties. Globally, Mars is richer than Earth in Fe and poorer in Al. The mantle itself is traditionally divided into an upper and a lower mantle, the limit corresponding to the olivine–spinel phase transition. The upper mantle is estimated to be 900–1100 km thick and to be mainly composed of olivine and orthopyroxenes plus clinopyroxenes at moderate depth, like on Earth. The amount of water is estimated to be between 0.004% and 1% in mass. In the lower mantle, olivine is replaced by spinel and orthopyroxene by majorite. Other, higher-pressure phase transitions (e.g. β-spinel to γ-spinel) may occur in the lower mantle, depending on the core size and composition, and on temperature at the base of the mantle. The spinel–perovskite transition may have been present only early in the history of the planet, when mantle temperatures were higher.

The mantle is covered by a crust with significantly lower density, the thickness of which is poorly constrained (it depends on the density difference between the crust and the mantle). Estimates of the mean crustal thickness vary between 28–40 km and 150 km. Large spatial variations exist anyhow, with minimal and maximal values beneath the Hellas basin and the Tharsis dome respectively (8–10 km and up to 70 km in the first model mentioned). The hemispheric asymmetry is interpreted as related to a thickening of the crust under the southern highlands. The SNC meteorites suggest that the crust is primarily basaltic in composition, although a material similar to that of the terrestrial continents or the lunar highlands may exist.

Formation and thermal evolution

Mars has accumulated from planetesimals with composition slightly different from the Earth. Models of the primitive nebula and SNC meteorites' composition suggest that the material was richer in iron and volatile elements than the Earth. Consequently, Mars' interior would have been richer in water initially. Most outgassing probably took place very early when the heat flow was very high (prior to 4.2 Gyr ago), contributing to the early atmosphere.

The isotopic and elemental ratios measured in the SNC meteorites demonstrate that core formation happened very early and was finished just after accretion 4.6 Gyr ago. This implies that accretional heating alone was large enough to melt all the material very early, like on Earth and Venus, so that Mars was initially hot and differentiated. This is in strong contrast with previous ideas concerning the thermal history of Mars, where heating was assumed to result mostly from radiogenic activity, therefore taking place after accretion and much more slowly. Consequently, the initial thermal profile was assumed to be of the present kind, i.e. temperature decreased with increasing distance from the center. Another very large amount of energy was released during core formation itself as the denser materials sank to the center, enough to heat the whole planet by about 300 K. As a consequence, mantle convection was very active during the first few 100 Myr, producing substantial

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

volcanic activity at the surface. It has been proposed that the Martian surface was completely melted in the early times and was covered by a magma ocean like the Moon. The estimated heat flow decreased from 200–400 mW m^{-2} after formation to ~150 mW m^{-2} at the end of the heavy bombardment and to ~30 mW m^{-2} today. An important topic in future space missions is actually to measure the present heat flow to better constrain the evolution models.

During differentiation, as the core formed, metallic iron reacted with water in the interior to form iron oxides, and a massive hydrogen loss probably accompanied this process. The different models and estimates disagree on the amount of water left in the mantle and surface at the end of the heavy bombardment, i.e. at the time when the oldest terrains formed. However, the equivalent of several hundred meters of water precipitated on the surface seems required to explain the erosional features observed.

After most of the heat was dissipated to space, mantle convection slowed down and volcanic activity was restricted to local areas. The internal structure of the planet was not modified, except for a slow thickening of the lithosphere (the external and most rigid shell) as the planet cooled down; the present thickness is estimated to be ~120 km. Rapid interior cooling was accompanied by a global contraction, which produced the wrinkle ridges observed in oldest terrains. The dense atmosphere which is assumed at the time when oldest terrains were exposed probably dissipated at the same period, as a consequence of the end of widespread volcanic activity. Volcanism was then restricted to discrete areas of the surface, in particular to the domes of Tharsis and Elysium.

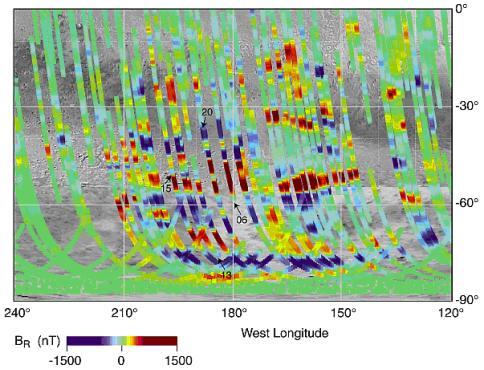

Figure 3. Map of the magnetic field in the southern hemisphere, measured by Mars Global Surveyor in 1999. The global magnetic field itself is much smaller than the Earth's, but significant magnetic anomalies were measured in the old terrains of the southern hemisphere. The strongest anomalies form stripes of alternating polarities ~1000 km long and 200 km wide, which are oriented east–west. They are thought to be fossils of a past planetary field that would have stopped early in the history of the planet. The stripes could result from occasional reversals of the magnetic field, like on Earth, suggesting lateral motions of the surface materials on early Mars. (Credit: NASA.)

Constraints on structure and evolution

After a long controversy during the 1970s and 1980s, the first detailed measurements of the magnetic field were performed by Mars Global Surveyor in 1999 (figure 3). No global field was detected, but strong magnetic anomalies were observed in the highlands of the southern hemisphere. This remnant magnetism is thought to have been induced in surface materials at a time when the planet had a global magnetic field related to a dynamo effect, and therefore had a convective core. Younger plains in the northern hemisphere show no evidence of magnetism, suggesting that the dynamo had stopped when the hemispheric dichotomy formed, and that these regions suffered major heating (either from impacts or from volcanism) that obliterated all remnant magnetic signature. In the south, magnetic anomalies display a regular pattern of stripes with alternating polarity. The stripes are ~1000 km long and 200 km wide and are oriented east–west, presenting a similarity to magnetic patterns observed on the terrestrial seafloors. It has been proposed that these anomalies are traces of successive reversals of the polarity of the early magnetic field which were trapped in surface materials drifting over the mantle. This would imply that some form of lateral plate tectonics had been active in the southern hemisphere of Mars just after surface formation and had stopped when the northern plains formed. However, the Martian surface is globally dominated by extensional tectonics rather than plate tectonics, so that this possible process, if it really occurred, stopped early in the history of the planet.

Modeling shows that the mantle convection is dominated by deep upwelling in the form of cylindrical plumes, similar to the terrestrial hot spots. In contrast, sheet-like, shallow upwelling similar to terrestrial plate tectonics cannot occur on Mars at present because of the thick lithosphere. Convection models can be run with different temperature profiles inside the planet. When most of the mantle heating comes from below (hot core), a larger number of plumes is produced (from 6 to 15 when using reasonable profiles for Mars). The presence of phase transitions of olivine appears to be an important factor in the plumes' geometry. They act to merge the plumes and reduce their number, and to concentrate their energy, and therefore models using these phase transitions give a better match of the general characteristics of the Martian surface. Some of these plumes would have a prominent surface expression in the surface topography and volcanic flux. This mechanism could explain the origin of the two major volcanic domes of Mars (Tharsis and Elysium) and of the hemispheric dichotomy. In the latter case, a very small core size (20% of the radius) is required to produce a strong asymmetry, so that the dichotomy, if related to mantle convection, should have formed very early, contemporaneously with core formation and accretion; alternatively, the dichoto-

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

my could be related to a giant impact after the end of the heavy bombardment. Concerning the two volcanic centers, they are likely to be the results of strong mantle plumes beneath the two regions. Because there are only two such regions at the surface, they probably formed early in the history of the planet when the heat flow was largest.

Biology and search for life

Although the idea that some form of life probably existed on Mars was widely accepted at the end of the 19th century, this view changed with the first studies of the atmosphere, which demonstrated that Mars is a cold planet with a rather unfavorable environment. The picture of an Earth-like Mars itself did not survive the first flyby by Mariner 4; the 22 close-up pictures transmitted by the spacecraft were acquired in the old terrains, and showed only very craterized areas, much more similar to the Moon than to the Earth. In addition, the first spectroscopic measurements at high resolution showed that the present atmosphere is too thin to allow for liquid water or to protect the surface from the ultraviolet radiation.

The situation changed again with the first complete mapping in 1971 by Mariner 9. It indicated that Mars had once been a very active planet and that water had run on the surface, possibly forming lakes or even transient oceans. In these conditions, it was possible that a complex prebiotic chemistry had developed in the distant past or even that life had originated on Mars. If so, there was a possibility that it had survived the worsening conditions, so that the search for extant life was one of the main goals of the Viking mission in 1976. Three biology experiments were embarked on the Viking landers to test whether biological activity was still detectable at the surface. All results are consistent with simple oxidation reactions in inorganic materials, although some results were considered marginally positive at first and are not completely understood today. There is a general agreement as to the results of the Viking biological experiments, that no biological process has been caught in action. These do not imply, however, that ancient Martian life could not have survived in particular places where more favorable conditions would have lasted longer, if it ever existed.

The debate was renewed in 1996 when the group of D McKay announced that it had found possible evidence of fossil life in one of the SNC meteorites, called ALH 84001 (figure 4). The possible fossils are very primitive bacteria, i.e. monocelled organisms with no nuclei, that would have lived ~3.6 Gyr ago. The meteorite was found in Antarctica in 1984 and was identified as Martian in origin because of the composition of its gaseous inclusions; however, it differs from other SNC meteorites by its age, being much older than the others (4–4.5 Gyr, versus 1.3 Gyr). It was ejected from Mars by a meteoritic impact 16 Myr ago, and fell on Earth about 13 000 yr ago.

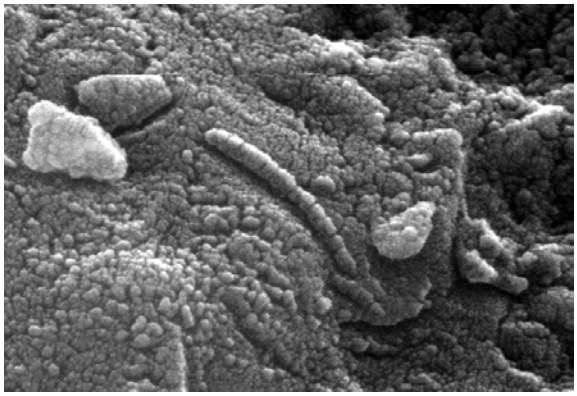

Figure 4. Electron microscope image of ALH 84001, one of the SNC meteorites. The globules of carbonates present in this essentially volcanic rock contain very small, elongated structures similar in size and shape to modern terrestrial bacteria (their sizes range from 20 to 100 nm). Although 100 times smaller than organisms that were widespread on Earth 3.5 Gyr ago, these structures have been tentatively interpreted as fossils of primitive Martian bacteria, although other teams have proposed different interpretations. (Credit: Science + NASA.)

Although essentially basaltic, it contains small globules of magnesium carbonates than were probably formed in liquid water about 3.6 Gyr ago. At this time, the Martian atmosphere was probably much thicker than today and valley networks formed in the southern highlands, suggesting abundant liquid water at the surface.

In 2001, high-resolution pictures taken by the Mars Orbiter Camera on NASA's Mars Global Surveyor spacecraft show distinct, thick layers of rock within craters and other depressions, suggesting that they may have formed in lakes or shallow seas. Such layered rock structures where there were once lakes are common on Earth. The pancake-like layers of sediment have compressed and cemented to form a rock record of the planet's history. The regions of sedimentary layers on Mars are spread out and scattered around the planet. They are most common within impact craters of Western Arabia Terra, the inter-crater plains of northern Terra Meridiani, the chasms of the Valles Marineris, and parts of the northeastern Hellas Basin rim.

D McKay's group identified three types of peculiar objects inside the carbonate grains. They consist of small structures resembling terrestrial bacteria, small mineral grains similar to those produced by bacteria on Earth and organic compounds (polycyclic aromatic hydrocarbons (PAHs)) that resemble the decay products of bacteria on Earth. All these structures could have a different origin not related to life, but taken together they were considered as strong evidence for ancient life, although not conclusive proof. Three years later, and after a large mobilization of the scientific community on this topic, the issue is very uncertain. ALH 84001 is certainly the most studied rock in the world, and all the observations

are on the edge of what can be done with the current techniques and instruments; in particular, the possible fossils are only ~100 nm long—this is actually from very different fossils of bacteria that lived at the same time on Earth, which were 100 times larger although similar in shape. Some of the structures observed are definitely not related to measurement artifacts, but it has not been demonstrated that the structures mentioned above are not terrestrial pollutants that entered the meteorite after its fall, although there is still no consensus as to their Martian origin. The weakest point in the demonstration is probably related to what is not observed: in particular there is no observation of bacterial growth or reproduction, and nothing looking like cell walls.

Apart from its proper interest, the study of hypothetical early Martian life would be of primordial interest to understand how life developed on Earth. The two planets were in many ways similar during their early years, so that the same processes should have acted on the two planets. There are very few traces of the early stages of life on Earth, because most of the older rocks have been recycled by plate tectonics or destroyed by erosion. Even if life has never developed on Mars, the study of prebiotic chemistry would give precious clues as to the apparition of terrestrial life.

The search for extant life is still a priority for future missions to Mars. The relatively recent discovery of life in very hostile environments on Earth, such as hot submarine springs or dry deserts in Antarctica, is actually a strong indication that life can survive in extreme conditions. Although the most favorable locations on Mars are not known, three ingredients seem required to maintain life: liquid water, protection from the solar UV flux and some source of energy. Accordingly, the most favorable locations include older volcanic vents, possible lacustrine deposits in the canyons, hydrothermal deposits, and high-latitude water-rich deposits where transient liquid water may still exist today inside the regolith. Liquid water probably also exists at the base of the permafrost, where the geothermal flux melts the ice in the ground. In all cases, living organisms would preferably dwell underground, at depths large enough to protect them from the UV flux.

Conclusion: main issues

There have been two main phases in the history of Mars. The first billion years were characterized by high internal temperatures, vigorous mantle convection, high heat flow, intense volcanic activity and perhaps a significant magnetic field. Volcanic activity probably helped to maintain a thick atmosphere of CO_2, and several hundred meters of liquid water were apparently available at the surface to shape the valley networks in the oldest terrains. Then, as accretional and differentiation heat dissipated, and as radiogenic heating decreased, the whole planet cooled down very quickly. Mantle convection slowed down, the magnetic field froze as the core probably became less convective and atmospheric recycling became inefficient, so that the total pressure became too low to sustain high temperatures and liquid water. This major change took place shortly after the end of the heavy bombardment period, 3.8 Gyr ago.

Although Mars now appears as an old, exhausted planet with only marginal geologic activity, there are numerous hints of large climate changes in a much more recent period. Variations of obliquity probably result in major climatic changes by governing the magnitude of seasonal effects. In the long run, these variations are chaotic and may have produced episodes of hot climate, when liquid water could have formed lakes or even oceans in more or less stable conditions.

NASA's Global Surveyor has revealed images which suggests the Martian climate is changing significantly, even today. The observations were made during a full Martian year, 687 Earth days and show that pits—often referred to as the 'Swiss cheese' terrain—at the southern polar ice cap of Mars have dramatically increased in diameter, indicating the material has evaporated rapidly compared to last year. Images of the south polar cap taken in 1999 were compared with images of the same locations taken in 2001, and it was discovered that pits had enlarged, mesas had shrunk, and small buttes had vanished. In all, the scarps that enclose the pits and bound the mesas and buttes retreated about 3 m in one Martian year. This rapid retreat of polar scarps can only occur if the ice is frozen carbon dioxide (dry ice). Retreat of scarps made of water ice is much slower and would not have been measurable from one Martian year to the next.

Early Mars was apparently very similar to early Earth, so that the study of the red planet can give useful hints about the Earth's evolution. In particular, the issue of prebiotic chemistry and the origin of terrestrial life could be addressed by the future Mars exploration program. Other major questions arise, especially concerning the evolution of the atmosphere and climate, the internal structure and the formation of the surface. These questions can be answered by understanding the types of rocks present at the surface and in the mantle, the absolute age of the surface regions, the distribution of volatiles, the history of volcanic activity and heat flow, the origin of the hemispheric dichotomy and Tharsis and their relationship with mantle convection, and by comparisons with other solar system bodies. These issues can be addressed by combining remote sensing observations, *in situ* analyses and laboratory studies of returned samples. Remote sensing is expected to provide a global knowledge of mineralogic and elemental composition related to morphology and a better map of the remnant magnetic field and of the gravity

field, so as to better constrain the geologic evolution and processes that shaped the surface; in addition, it should help identify the most promising landing sites. Concerning *in situ* measurements, a seismic network and a set of small meteorological stations are among the highest priorities, together with rock analyses and biologic experiments. Finally, only laboratory studies of Martian samples will provide the opportunity to determine the absolute ages and detailed composition. These points will constitute the bulk of the on-going Mars exploration program that will culminate with a sample return.

Mars

Series of Soviet spacecraft designed to return data about the planet Mars 1960–74. After several launch failures, Mars 1 successfully left Earth orbit in 1962 but contact was lost en route. Mars 2 and 3 arrived during the 1971 global duststorm which obscured the planet's surface, so no useful pictures were obtained. They also carried landers and the first automated planetary roving vehicles, but these either crashed or failed to operate in the duststorm conditions. Mars 4 failed to go into orbit around the planet in 1974. Some images were returned by Mars 4 and 5 orbiters. Atmospheric data were returned during descent of the Mars 6 lander, but contact was lost prior to touchdown. The Mars 7 lander missed the planet by 1300 km.

Mars Global Surveyor

NASA Mars orbiter. Launched November 1996, arrived at Mars in September 1997. Carries an advanced camera system to map the planet at high resolution, a thermal-emission spectrometer and two magnetometers. Discovered regional magnetic fields and mapped global topography. Prime mapping mission, delayed when a faulty solar array prevented aerobraking, began in March 1999.

Breaking News Update (30 April 2002)

NASA's Global Surveyor has revealed images which suggests the Martian climate is changing significantly, even today. The observations were made during a full Martian year, 687 Earth days and show that pits—often referred to as the 'Swiss cheese' terrain—at the southern polar ice cap of Mars have dramatically increased in diameter, indicating the material has evaporated rapidly compared to last year. Images of the south polar cap taken in 1999 were compared with images of the same locations taken in 2001, and it was discovered that pits had enlarged, mesas had shrunk, and small buttes had vanished. In all, the scarps that enclose the pits and bound the mesas and buttes retreated about 3 m in one Martian year. This rapid retreat of polar scarps can only occur if the ice is frozen carbon dioxide (dry ice). Retreat of scarps made of water ice is much slower and would not have been measurable from one Martian year to the next.

Mars Odyssey

Mars Odyssey is part of NASA's Mars Exploration Program, a long-term effort of robotic exploration of the red planet. 2001 Mars Odyssey was launched on 7 April 2001 and arrived at Mars on 24 October 2001, 02:30 Universal Time. Firing of the main engine slowed the spacecraft's speed and allowed it to be captured by Mars' gravity into an elliptical orbit around the planet. Aerobraking—using atmospheric drag on the spacecraft—has reduced the long, highly elliptical orbit into a shorter, 2 h circular orbit of approximately 400 km (about 250 miles) altitude for the mission's science data collection.

Mars Odyssey has begun its science mapping mission, turning its science instruments towards Mars on Monday, 18 February, 2002. Odyssey's primary science mission will continue through to July 2004. The primary mission objective is to map the amount and distribution of chemical elements and minerals that make up the Martian surface, including hydrogen (most likely in the form of water ice in the shallow subsurface of Mars). It will also record the radiation environment in low Mars orbit to determine the radiation-related risk to any future human explorers.

The three primary instruments carried by 2001 Mars Odyssey are as follows:

THEMIS (Thermal Emission Imaging System), for determining the distribution of minerals, particularly those that can only form in the presence of water;

GRS (Gamma Ray Spectrometer), for determining the presence of 20 chemical elements on the surface of Mars;

MARIE (Mars Radiation Environment Experiment), for studying the radiation environment.

During and after its science mission, the Odyssey orbiter will also support other missions in the Mars Exploration Program. It will provide the communications relay for US and international landers, including the next mission in NASA's Mars Program, the Mars Exploration Rovers to be launched in 2003. Scientists and engineers will also use Odyssey data to identify potential landing sites for future Mars missions.

One of the first images returned by the Mars Odyssey was a thermal infrared image of the Martian southern hemisphere that captured the polar carbon dioxide ice cap at a temperature of about –120 °C (–184 °F). The image, taken as part of the calibration process for the instrument, shows the nighttime temperatures of Mars, demonstrating the 'night-vision' ability of the camera system to observe Mars, even when the surface is in darkness.

The Martian Radiation Environment Experiment (MARIE) began gathering science data on 13 March, 2002, after communications were successfully re-established with the instrument. Engineers had been working since late February, 2002, trying a variety of techniques to communicate with the instrument, which stopped working in August, 2001. The results of their tests indicate the problem may be related to a memory error in the onboard software of the radiation instrument.

Initial science data from the spacecraft suggests possible identification of significant amounts of frozen water. The gamma ray spectrometer instrument suite has been used to detect hydrogen, which indicates the presence of water ice in the upper meter (three feet) of soil in a large region surrounding the planet's south pole. The amount of hydrogen detected indicates 20–50% ice by mass in the lower layer. Because rock has a greater density than ice, this amount is more than 50% water ice by volume.

Mars Pathfinder

First of NASA's Discovery missions. Launched in December 1996 and arrived at Mars on 4 July 1997. Mainly intended as a technology demonstration mission. Used airbags to cushion the landing on Mars. The Carl Sagan Memorial station returned images of an ancient flood plain in Ares Vallis. The 10 kg Sojourner rover used an x-ray spectrometer to study the composition of rocks and travelled about 100 metres. Relayed an unprecedented 2.3 gigabits of data, including 16 500 images from the lander's camera, 550 images from the rover camera, 16 chemical analyses of rocks and soil, and 8.5 million measurements of atmospheric pressure, temperature and wind. Operations ceased after 83 days on 27 September 1997.

Mars Surveyor 2001

Two NASA missions to explore Mars, originally due for launch in April 2001 but now postponed. The orbiter will carry a high-resolution infrared imaging spectrometer and a gamma ray spectrometer to map surface composition and hydrogen in the soil. The lander will carry an infrared spectrometer and a small roving vehicle with a robotic arm to collect soil samples, a radiation environment experiment and a plant to make liquid oxygen from the atmosphere.

Mars: Atmosphere

The atmosphere of MARS is much thinner than the terrestrial one. However, even the simplest visual telescopic observations show a set of atmospheric events such as seasonal exchange of material between polar caps, temporal appearance of clouds and changes of visibility of dark regions on the disk of the planet. In 1947 the prominent CO_2 bands in the near-infrared part of the Martian spectrum were identified. Later, after 1960, weak bands of H_2O, CO and O_2 were also discovered. The Doppler shift was used to separate Martian H_2O and O_2 lines from much stronger terrestrial ones. Flights of spacecraft to Mars opened new possibilities of bringing instruments close to the planet and even onto its surface. Remote sensing measurements were made initially from fly-by spacecraft (Mariner 4 in 1965, Mariner 6 and 7 in 1969) and later from orbits (Mariner 9 and Mars 3 in 1971–2, Mars 5 in 1974, Viking 1 and 2 in 1976–80, Phobos 2 in 1989, Mars Global Surveyor since 1997). *In situ* studies were fulfilled by means of descender/landers: Mars 6 in 1976, Viking 1 in 1976–82, Viking 2 in 1976–80 and Mars Pathfinder in 1997. Measurements from the orbit included TV imaging, spectrometry (by nadir and limb viewing), radio occultation (a method of sounding of planetary atmospheres using Earth based measurements of a radio signal emitted by a spacecraft when it approaches or leaves the limb of the planet; the phaseshift and attenuation due to refraction appears by the passage of radio waves through the ionosphere and troposphere), photometry and IR radiometry. *In situ* chemical composition and meteorological measurements were provided by means of instruments on the landers. All these observations not only revealed the current Martian atmosphere, but also suggested that in the long past Mars possibly had a denser atmosphere, warmer climate and open water on the surface. The history of water on Mars is one of the most interesting problems in solar system studies. It is directly connected with the possible presence of life on Mars, at least in the distant past (see EXOBIOLOGY, LIFE ON OTHER WORLDS). The book by Kieffer *et al* (1992) may be recommended as a comprehensive source for professional use.

Chemical and isotopic composition

The most abundant gaseous components of the Martian atmosphere are carbon dioxide (its volume mixing ratio—ratio of the number density of the given gas to the full number density—is 95%); nitrogen (2.7%) and argon (1.6%). The average column abundance of CO_2 is ~80 m atm, about 20 times more than in EARTH'S ATMOSPHERE. Column abundance is the amount of gas above 1 cm^2 of the surface in units of cm atm or m atm. Column abundance in cm atm equals the number of molecules in the column divided by Loschmidt's number (= 2.687×10^{19} cm^{-3}). Other identified gases are so-called minor or trace constituents: oxygen (0.13%), carbon monoxide (0.07%), water vapor (0–0.1%), ozone (0–0.2×10^{-4}%), helium (1.1×10^{-4}%), neon (2.5×10^{-4}%), krypton (0.2×10^{-4}%) and xenon (0.08×10^{-4}%). The average molecular weight is equal to 43.4 amu below the level of the homopause (~125 km on Mars). (The homopause level H_t is the height where values of two diffusion coefficients, eddy and molecular, are equal. It divides the atmosphere into two parts, the homosphere, below H_t, and the heterosphere, above H_t. Eddy diffusion dominates in the homosphere. All gases are well mixed there. The average molecular weight is constant, and its value should be used in barometric formula. In the heterosphere every gas follows its own barometric equation. Consequently, light gases like H and He are the main constituents of the outer parts of the upper atmosphere (>500 km).)

The average H_2O column abundance is ~1 cm atm. This is equivalent to a ~10 μm layer of precipitated water covering the whole surface of the planet. On recent Mars almost all water is hidden in permafrost, polar caps and hydrated minerals. The atmosphere is extremely dry. The abundance of water vapor varies with latitude, season, time of day and from place to place, mainly due to condensation/sublimation and adsorption/desorbtion processes. Latitudinal and seasonal variations according to measurements from VIKING 1 and 2 orbiters are presented in figure 1. Asymmetry between south and north polar regions is clearly visible there: during the summer the residual north polar cap sublimes and the H_2O abundance above the northern polar region reaches the maximum (~90 μm of precipitated water) in difference from the southern cap. The probable reason is that southern cap saves some quantity of CO_2 condensate even in summer time. The vertical H_2O distribution has not been thoroughly studied.

Some data were obtained in the PHOBOS mission. They showed that the mixing ratio decreases from about 0.01% at heights of 15–20 km to 3×10^{-4}% at 30–40 km. The duration of these observations was short (~1 month during northern spring) and limited by near equatorial regions.

Ozone on Mars was identified initially at the polar regions, but later it was also found at low latitudes, although with much lower abundance. These observations were made with UV spectrometers installed on board spacecraft and the ozone band near 0.27 μm was used. Recently, successful measurements have also been made from Earth in the IR band at 9.6 μm using heterodyne spectrometry, a super high-resolution spectrometric technique using a mixing of detected radiation with a laser beam at very close frequency, the radio frequency signal being measured on the output. A global average mixing ratio of 1.7×10^{-8} has been found.

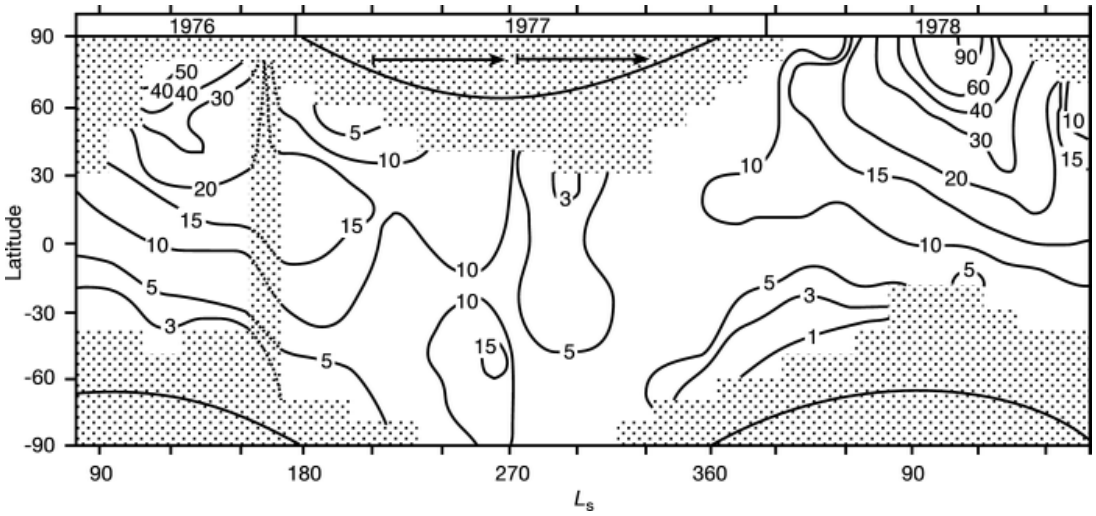

Figure 1. Water vapour cycle on Mars according to measurements from Viking orbiters: column water abundance (in μm of precipitated water) as a function of season and latitude. The absorption band at 1.38 μm was used in the observations. Seasonal longitude L_s is given along the x-axis. $L_s = 0°$ corresponds to the northern spring equinox, 90° to northern summer. These observations covered more than full Martian year (=686 terrestrials days). Local variations along areographic longitudes and daily variations also exist, but they were averaged in this presentation. Shaded areas indicate no observations, and smooth curves are the latitude poleward of which the Sun will not rise above the horizon (Jakosky and Farmer 1982).(Copyright 1982 by the American Geophysical Union.)

There are also observations from the Hubble Space Telescope in the UV.

The only *in situ* measurements of gases in the Martian atmosphere have been provided by means of mass spectrometers aboard Viking 1 and Viking 2 landers. An example of the mass spectra obtained is shown in figure 2(*a*). The most important achievement was the identification of noble gases (Ne, Ar, Kr, Xe) and their isotopes. It was found that abundance of their non-radiogenic isotopes per unit of mass is a factor of 100 less than on Earth (figure 2(*b*)). It was found also that $^{14}N/^{15}N$ and H/D ratios are lower on Mars than on Earth (twice for nitrogen and six times for hydrogen). These differences are consistent with the idea about the primordial Martian atmosphere being more dense than the recent one. The Martian isotope composition of noble gases is so specific that about dozen meteorites (SNC METEORITES) showing the same composition of captured gases are seriously believed to have originated from Mars.

Temperatures, pressures, winds

The globally/annually averaged surface temperature of Mars is ~210 K. This is only about 4 K more than Mars would have without atmosphere. So the GREENHOUSE EFFECT (a warming of the planet arising due to the lower opacity of the atmosphere for the solar radiation than for the planetary one; quantitatively it may be described by the difference $\Delta T = T_s - T_e$, where T_s is the globally averaged surface temperature, T_e is the effective temperature of the planet (= the temperature of a blackbody that would radiate the same flux as the planet)—on the Earth ΔT = 38 K, about 10 times more than on Mars) is much weaker on Mars than on Earth due to the thinner atmosphere. The minimum surface temperature is about 145 K; it is achieved in the polar regions during winter, and the atmospheric CO_2 is partially transformed there to the solid phase. The maximum temperature (in middle latitudes at summer noon) reaches ~300 K.

The globally/annually averaged pressure near the surface of Mars is ~5.6 mbar. Surface pressure varies with seasons and amplitude by ~25% (figure 3). This is mostly due to a global variation in the mass of the atmosphere resulting from seasonal condensation and sublimation processes of the carbon dioxide in polar regions and, locally, to the effect of the general circulation. The average tropospheric scale height (the vertical scale corresponding to a pressure decrease by a factor of e) on Mars is ~10 km, near to the terrestrial value (8 km). The local pressure depends drastically upon topography (see MARS: SURFACE). For instance, the highest point on the planet (the huge volcano Olympus Mons) is some 25 km above zero level, the lowest (Hellas Planitia) about 6 km below.

A typical vertical profile of the Martian atmosphere is shown in figure 4. It is colder than the terrestrial atmosphere at all heights. In general the vertical structure of both atmospheres can be divided into three main regions: low atmosphere, middle atmosphere (mesosphere) and upper atmosphere (thermosphere). The mesosphere is the region of minimum temperature. Here is the sink for the thermal energy

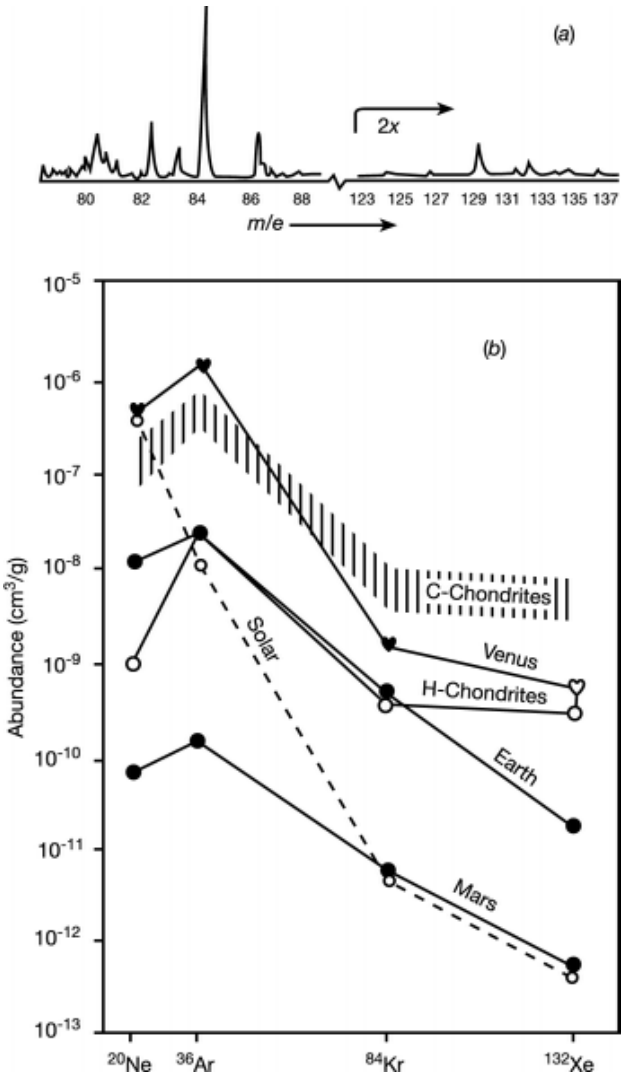

Figure 2. Noble gases on Mars. (*a*) Examples of mass spectra obtained by Viking landers, Kr (on the right) and Xe (on the left). (*b*) Comparison of abundance of non-radiogenic isotopes of noble gases in the atmosphere of Mars with the same on Earth, Venus, the Sun and in the material of chondrites (Owen and Bar-Nun 1995). Two conclusions follow from the results presented here: (a) Mars is more depleted in volatiles than the Earth and (b) the relative abundance of Kr and Xe isotopes corresponds neither to C- nor to H-chondrites.

flux coming from the surface and the troposphere (heated by solar visible and near-IR radiation) and also from the thermosphere (heated by solar extreme UV radiation). A key component of the mesospheric thermal balance is the absorption of solar near-IR radiation by CO_2. There are some important qualitative differences between Martian and terrestrial atmospheres: (*a*) the most abundant Martian atmospheric gas (CO_2) participates in condensation/sublimation processes, (*b*) diurnal temperature variations near the surface of Mars reach ~100 K, (*c*) there is no temperature maximum inside the Martian middle atmosphere (on Earth such a maximum is created by ozone), (*d*) the influence of the aerosols on atmospheric heating is stronger on Mars, (*e*) unlike on Earth, the redistribution of heat by evaporation and condensation of water is negligible on Mars. Diurnal temperature variations in the Martian atmosphere are large below a few kilometers, but relatively small higher up. The amplitude of diurnal variations in the troposphere and mesosphere depends on the aerosol content. During dust storms the upper part of the troposphere and mesosphere are warmer, and daily variations are stronger than under ordinary conditions.

Horizontal differences in temperature lead to differences in pressure, but they are smoothed by winds. Winds transfer heat together with air masses. This influences local temperature profiles. Also the dust can be lifted from the surface and change its solar heating. Condensation is another way of forming aerosols, also with a feedback effect on temperatures. Winds are strongly affected by topography. *In situ* measurements by Viking landers showed wind velocities from 1 to 10 m s^{-1} at a height of 1.6 m with prominent diurnal and seasonal variations. The daily maximum was observed often near 12 h local solar time. Maximal wind speeds were observed during periods of GDS (great dust storm—see below). Only indirect estimates are available for larger heights. They are based mainly on temperature profiles retrieved from results of IR sounding. Zonal wind velocities estimated in this way sometimes reach 20–100 m s^{-1} at heights of 5 to 40 km. The meteorological packages on Viking and MARS PATHFINDER landers recorded daily variations of surface pressure and wind well explained by atmospheric thermal tides (figure 5).

On Earth the equatorial excess of heat obtained from Sun is transferred by atmospheric motion to the poles and leaves the planet as thermal IR radiation. The Coriolis force reduces the atmospheric flow from the meridional direction to the zonal, creating a zonally symmetric or Hadley regime of circulation. The general circulation on Mars is somewhat different. First, because the atmosphere of Mars is very thin (and the thermal inertia of the surface is low, especially compared with Earth's oceans) the Martian ground is never far from from radiative equilibrium: the transport of heat by the atmosphere does not change the radiative balance as strongly as on Earth. Second, during most seasons except around the equinoxes, one hemisphere is usually warmer than the other, and the circulation tends to occur from one hemisphere to the other. In particular, around the summer solstice, mean surface temperatures are indeed highest in the summer polar region, with a monotonic decrease toward the winter pole. As the consequence, the Hadley circulation is then characterized by one unique and intense cell between summer hemisphere and winter hemisphere.

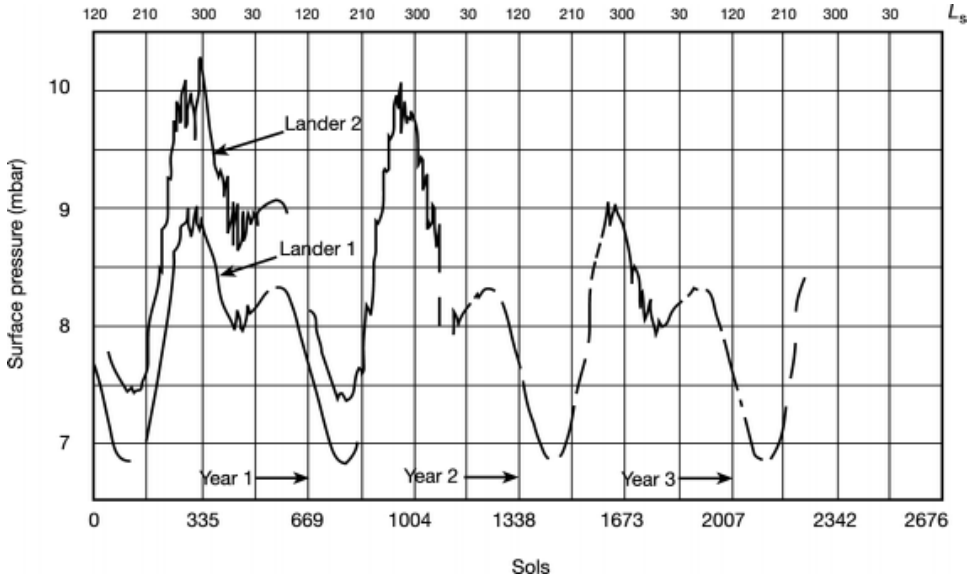

Figure 3. Seasonal changes of surface pressure on Mars. Sols (along the *x*-axis) are solar Martian days). These data were obtained from meteorological measurements by Viking landers. One of them (Viking 1) worked for about 6 Earth years and 4 months.

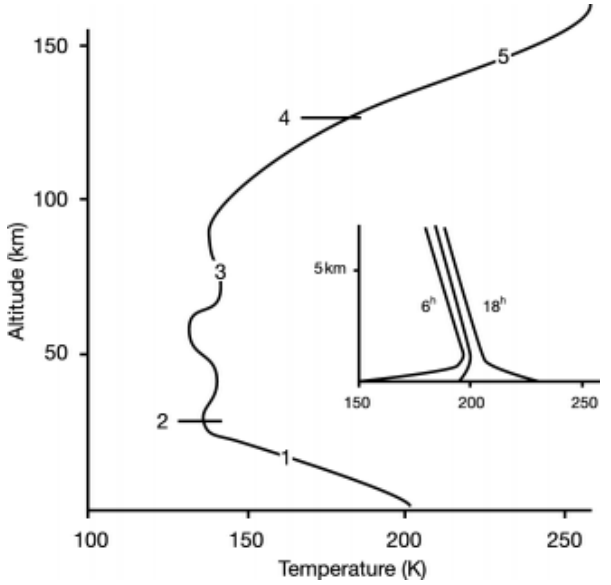

Figure 4. Schematic presentation of the vertical temperature profile in the Martian atmosphere, based mainly on *in situ* measurements during descent of Mars 6, Viking 1, Viking 2 and Pathfinder landing probes. 1 is the troposphere, a lower part of the atmosphere with large negative temperature gradient, 2 is the tropopause, 3 is the mesosphere, 4 is the homopause and 5 is the upper atmosphere. The inset illustrates the character of daily variations of the temperature profile in the boundary layer (the lowest part of the atmosphere where its motions are influenced by interaction with the surface; the rest of the atmosphere above this layer is treated as the 'free atmosphere'), predicted theoretically.

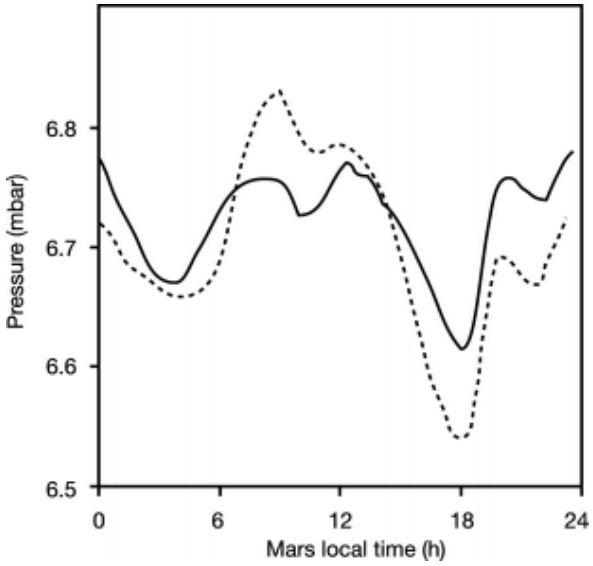

Figure 5. Example of surface pressure measurements by the Pathfinder lander (1997): diurnal pressure cycles for sols 9 and 19, illustrating the observed day-to-day changes in the diurnal pressure cycle and allowing for details of the daily pressure variation. The general shape of the curves is explained by superposition of diurnal and semidiurnal waves occurring due to atmospheric thermal tides.

In Hadley circulation lines of flow go around the whole planet almost along parallels with a much smaller meridional component, at least at low levels. Pure zonally symmetric circulation may transfer only a limited quantity of heat, and is replaced or added to by wave circulation if this limit is reached. Lines of flow in a wave regime oscillate a few times between high and low

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

latitudes going around the planet ('transient baroclinic waves'), wind speeds are higher and more variable and a large meridional component may appear. General circulation models (GCM) developed for Mars show that the observed wind pattern during most of the Martian year is more consistent with a zonally symmetric regime than is the terrestrial atmospheric circulation. (General circulation models are computational tools for the prediction of 3D wind patterns on the planet. Inputs are the thermal properties of the atmosphere and surface, incoming fluxes, surface topography, etc. Using hydrodynamic equations the model provides a time-dependent picture of atmospheric motion. Space and time resolution is restricted of course by computational possibilities.) However, travelling atmospheric waves are known to be prominent and regular in northern mid-latitudes during the fall and the winter. Variabilities in suspended dust content produce time variability (interannual, seasonal, local, diurnal) in atmospheric circulation and also in thermal structure.

Aerosols

There are two main types of Martian aerosol: dust and water ice particles. A mixed composition is also possible: a layer of a condensate around a mineral nucleus. Chemical composition of the dust particles should be the same as that of the surface regolith, although the size distribution can be different. At high altitudes and at high latitudes in winter solid CO_2 particles may appear due to local decreases of the atmospheric temperature to the condensation level.

Mineral aerosol (dust) formations can be divided into two main subclasses: (*a*) constant haze, (*b*) dust storm clouds. There is no sharp boundary between classes. Dust storms appear as a local rise of constant haze opacity and disappear leaving constant haze.

The average optical depth (=the natural logarithm of transmission) of the constant haze varies between 0.1 and 0.5 with a characteristic time scale of a few years. There is also a seasonal trend with the appearance of much denser cloud cover with an optical depth up to 6 during great dust storms (figure 6). The atmosphere is when it contains more dust and colder when the dust dissipates. The number density of the constant haze dust particles near the surface is about n = 1–2 cm^{-3}. Their single scattering ALBEDO (the ratio of omni-directional scattering flux to the incident flux of parallel rays (like the spherical albedo of a planet)) is ~0.86 at wavelengths between 0.55 and 0.6 μm and decreases to 0.63 near 0.32 μm. Corresponding values of the imaginary part of the refractive index m are ~0.005 and 0.015. They are compatible with the presence of a few per cent of materials like Fe_2O_3 in silicate particles. Typical values of mean particle radius in the constant haze are 1.5–2.5 μm. Observations of the vertical distribution of dust in the constant haze were made in experiments on the Phobos mission. They showed that the aerosol scale height is 10–11 km below 15–20 km, almost the same as the gaseous scale height, meaning that dust is well mixed in the lower atmosphere.

A few subclasses of condensate aerosol formations were observed: (*a*) ice haze near the surface, (*b*) high-altitude layers, (*c*) mountain clouds, (*d*) polar hood. Ice haze appears near the surface at night due to a significant decrease in temperature within a narrow (of the order of 1 km) layer near the surface. The typical optical thickness is of the order of 0.1 and depends on the local abundance of water vapor. In the morning the ice particles evaporate and their net effect is clearly visible as an a.m.–p.m. opacity difference. Several seasonal peaks of this difference were observed.

Condensation of water vapour at high altitudes results in the appearance of thin (few km) layers with an optical depth between 0.005 and 0.05. Such layers were observed at heights between 25 and 75 km in the visible, ultraviolet and thermal IR wavelengths. There are also a lot of TV observations of 'mountain' clouds, mainly around huge Tharsis volcanoes, but very few determinations of their optical depth.

Great dust storms

During the northern winter two different dynamic regimes have been observed in various years: in the first case great dust storms (GDS) cover nearly all the planet; in the second regime no great storm occurs, but strong winds produce dust lift in confined regions. Maximal wind speeds are observed during periods of GDS. A lot of dust fills the Martian atmosphere at low and moderate latitudes when a GDS happens. GDS arise when the planet is near perihelion (summer in the southern hemisphere) and consist of one, two or even three peaks covering up to 150 days. Sometimes local dust storms are observed on Mars. There is no terrestrial analogue of Martian GDS, but local dust storms occur on Earth also (in deserts). So, mechanisms of dust storm generation on both planets may have common details. Their study on Mars can be useful for understanding such events on Earth.

Mechanisms of development and decay of great dust storms are not well understood. However, on the qualitative level, the sequence of events may be described as follows. There is a threshold wind velocity that is necessary to lift up small particles from the surface. This threshold is reached only within some narrow limits of seasonal and local conditions. Laboratory experiments show that it is not the smallest but the relatively big (of the order of 100 μm) particles that are lifted first. However, they themselves fall very soon and disrupt the surface of much smaller particles. Soon the general number of lifted particles rises to a level sufficient to cause substantial obscuration, and to cool the

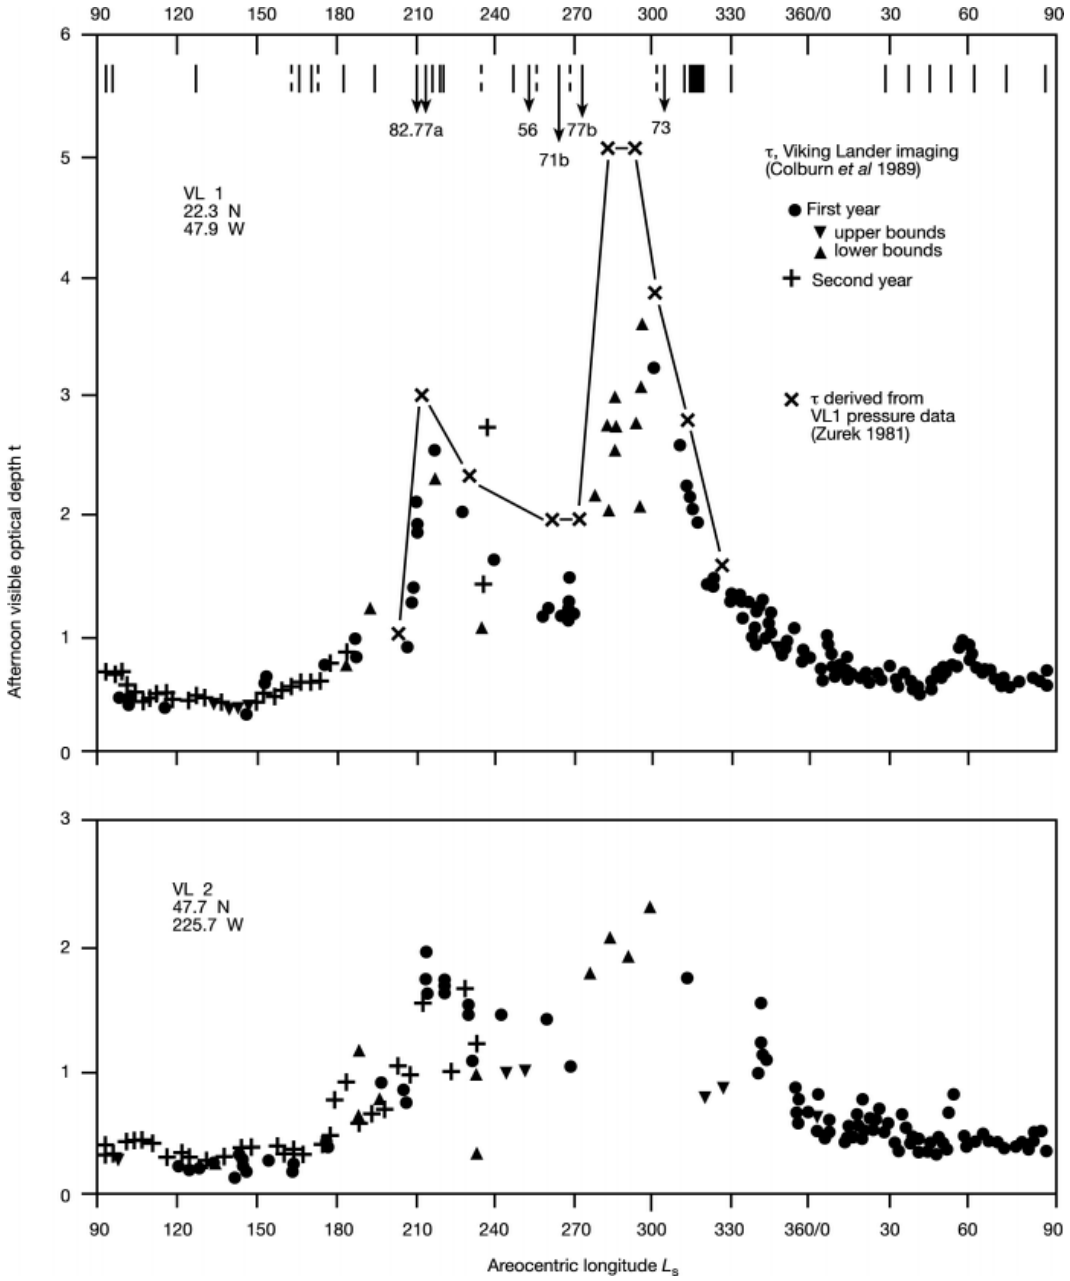

Figure 6. Seasonal trend of the optical depth of dust on Mars according to Viking 1 and 2 data. Two wide spikes correspond to great dust storms. The initial appearence or detection of observed regional dust clouds, hazes or obscurations (vertical lines) and of planet-encircling dust sorms (arrows) are indicated at the top of the upper panel.

atmosphere near the surface and heat it at some kilometers. Local wind speeds rise on the boundaries of this 'storm nucleus' and they expand rapidly. In a few days this originally small nucleus transforms to planetary encircling dust cloud cover. Then the temperature differences disappear and nothing supports higher wind speeds. The decay stage comes: particles lifted to a height of some tens of kilometers set down gradually, separating by sizes. Particles of 10 μm reach the surface in a few days and 1 μm particles in a few months.

Upper atmosphere and ionosphere

The temperature of the uppermost levels of the Martian atmosphere ('thermosphere', above 120 km) depends on the solar activity; its average value is about 210 K, minimum 135 K and maximum 310 K. The reason for this variability is that the thermosphere is heated by extreme solar UV radiation which is strong during solar maximum and much weaker near the minimum of the solar activity cycle. The chemical composition of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

upper atmosphere of Mars above a height of about 125 km (homopause) varies with height due to separation by molecular weight of its different components. However, CO_2 dominates up to a height of about 200 km at the average thermospheric temperature. Atomic oxygen (O) dominates between 200 and 400 km and atomic hydrogen (H) above 400 km. As a result the outer atmosphere of Mars consists of hydrogen, and sometimes even the name 'hydrogen corona' is used. It was observed in the Lα line up to 20 000 km from the planet. Earth and Venus have the same sort of H corona but less expanded due to the higher gravitational field (see VENUS: ATMOSPHERE).

The height of the exobase is about 200 km. Hydrogen atoms continuously leave the Martian atmosphere above these levels; a flux of about 3×10^{11} atoms/m^2 s^{-1} has been estimated. This corresponds to the loss of 1 m of water layer during 4 billion years of Martian geological history.

Ions appear in the upper atmosphere due to absorption of solar extreme UV radiation. Primary CO_2 ions are replaced by O_2 ions due to a set of reactions, and O_2 ions dominate in the Martian ionosphere. The daily peak electronic number density n_e is about 10^5 cm^{-3} at heights from 110 to 145 km, depending on the Sun zenith angle. At night time a peak $n_e = 5 \times 10^3$ cm^{-3} at a height of 110 km was found. The intrinsic magnetic field of Mars is very weak and does not protect the ionosphere from the impact of the solar wind. It influences the shape of the ionosphere profile and creates some induced magnetic field which overlaps the intrinsic one, and substantially masking it.

The long-term atmosphere/surface interaction; origin and evolution of the atmosphere

Mars is more depleted in volatiles than is Earth. However, the terrestrial atmosphere contains only a small part of the total inventory of volatiles. Almost all the water is in the liquid phase and carbon dioxide is hidden in carbonates. So, we may suppose that the full amount of volatiles appearing on Mars during its geological history is much more than in the recent gaseous atmosphere. There are no open reservoirs of liquid water on recent Mars, so POLAR CAPS and permafrost play the same role as the terrestrial oceans. Only rough estimates are possible. They lead to values of an equivalent water layer of the order of 100 m. Seasonal polar caps contain up to about one-third of the atmospheric carbon dioxide. However, much more may be buried in the residual permanent southern cap. Also Martian soil (working as a cryogenic pump) may adsorb a substantial amount of water and even carbon dioxide. Chemical weathering may also bound part some of the water in minerals. If open water reservoirs existed in the distant geological past, then the process of transformation of silicates to carbonates could be effective. So, the search of carbonates on Mars may give an important key to the history of the Martian volatiles.

The recent surface pressure on Mars is very close to the triple point of water. If carbon dioxide slowly enters the atmosphere due to volcanic outgassing, then this puzzling coincidence may be explained by the tempory appearance of liquid water, when the surface pressure exceeds the triple point value. It switches on the process of silicate to carbonate transformation, rapidly removing the excess of carbon dioxide.

In general, there are three types of processes that were (or can be) involved in the formation and the evolution of the Martian atmosphere: (A) supplying volatile (sources), (B) removing them (sinks), (C) reversible processes that work in both directions depending on conditions. Type A processes are: (1) trapping of gases bound in planetesimals from which Mars was composed during accretion; (2) fast release of these gases by impacts immediately during accretion (a catastrophic outgassing); (3) slow outgassing of planetary interiors over billions of years; (4) trapping of gases from the proto-planetary nebula directly; (5) cometary impacts; (6) solar wind implantation. Process (1) probably worked but the destiny of trapped gases is under question. They could be released by processes (2) or (3) predominantly. Some years ago experts preferred process (3), later process (2). Direct trapping from the nebula was never recognized as really important. But processes (1)–(4) all suppose that Martian volatiles came originally from the primary nebula. However, a very different scenario was also possible: the whole primordial atmosphere of Mars was removed by a huge single impact and then process (5) created a new atmosphere. Owen and Bar-Nun (1995) proposed some arguments for this based on the composition of SNC meteorites. The importance of process (6) is not clear, maybe it could be checked by measurements of Ne isotopic ratios.

Type B processes are: (1) impactory blow-off; (2) thermal escape (H and He) (Escape is process of the loss of lighter and faster atoms from the upper atmosphere. Such atoms may go out if their velocity is sufficient to enable them to leave the gravitational field of the planet and they are at a height where the probability of collision with other atoms is small (above the exobase, the height where free path length equals to the scale height); (3) non-thermal escape (oxygen); (4) solar wind blow-off; (5) chemical weathering. It is difficult to observe a flux of escaping materials directly. However, such a flux was measured for oxygen ions during the Phobos mission. An important example of chemical weathering is the binding of water in Martian minerals. Another may be silicate to carbonate transformation and formation of sedimentary rocks when and if open water existed on Mars.

Type C processes are: (1) polar cap formation; (2) permafrost formation; (3) atmosphere/soil exchange.

Water is involved in all three, carbon dioxide in (1). These processes are influenced by different sorts of insolation changes including seasonal and long-term (as solar constant trend) changes, effects of oscillations of equatorial inclination and orbital evolution. Atmosphere/soil exchange acts even within a daily cycle.

The Martian atmosphere is breathing even now, seasonally and from year to year. Much greater changes in the distant past may be anticipated. There are two sorts of evidence for this: (a) clear traces of liquid water activity on the surface and (b) isotopic ratios (N and Ar) showing that a significant part of the atmosphere was lost during evolution of the planet. At least two geological epochs of fluvial activity are supposed: earlier with the formation of valley systems and later with the formation of outflow channels. The first epoch was definitely warmer than now, the second maybe not. Carr (1996) estimates that the average thickness of the water layer may have been 500–1000 m on ancient Mars during the hypothetical 'Mars paradise' period.

Mars: Climate History

Unravelling the climate history of Mars is one of the main challenges in understanding the planet's evolution. There is substantial evidence for change in the climate and the inventory of volatiles through time. This evidence points to an early environment in which water was either more stable or more abundant at the surface than it is today and to processes of supply of volatiles to the atmosphere (see MARS: ATMOSPHERE) and their removal from it that are able to explain this shift in climate. Determining the forces behind the changing climate, particularly the relationship between the atmosphere, water at the surface and water in the crust, is important for understanding the planet as a whole. In addition, the potential for life to have existed in the past, or even today, is strongly governed by the occurrence of liquid water and its history over time.

The climate system of Mars is inherently complex, involving physical and chemical processes within the deep interior, the CRUST, the surface, the atmosphere and the upper atmosphere and interactions with the solar wind (figure 1). Our goal is to integrate observations and measurements pertinent to each of these areas into a coherent view of Martian climate and its evolution. We will focus on recent results from the MARS GLOBAL SURVEYOR mission and from ongoing analyses of the Martian meteorites and will emphasize observations that provide the strongest constraints rather than describing what is merely plausible.

The present-day atmosphere and climate

The Martian atmosphere consists predominantly of CO_2, with a total atmospheric pressure averaging about 6 mbar (6 hPa), about 0.6% of the Earth's atmospheric pressure. The atmosphere also contains N_2 and Ar at a level of 1–3%, lesser amounts of H_2O, CO and O_2 and additional gases in trace amounts (Owen 1992).

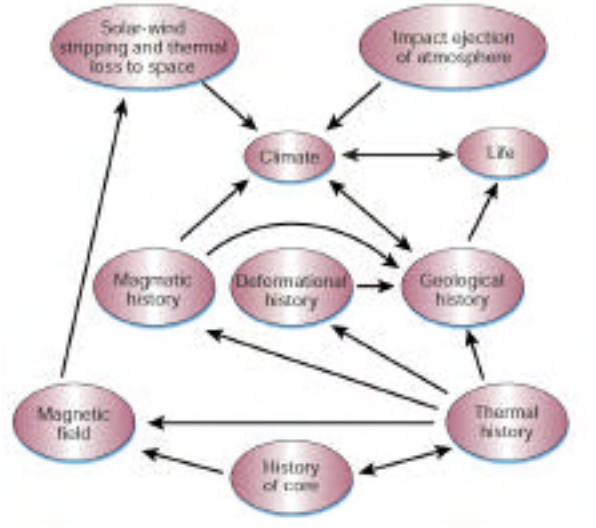

Figure 1. Schematic diagram showing the interconnected nature of the Martian climate system and the relationship between climate and various processes from the deep interior to the upper atmosphere. Arrows indicate how one region affects another, with the arrow pointing towards the processes or area being affected; two-headed arrows indicate mutual interactions.

Water vapour is present in the atmosphere, with a typical partial pressure of 10^{-3} mbar. This corresponds to about 10^{-3} g H_2O residing above each square centimetre, equivalent to a condensed layer about 10 m thick if it all precipitated onto the surface; the water content of the Earth's atmosphere, in contrast, is about 10^4 times greater. The atmospheric water content varies in a manner that is consistent with seasonal supply and removal from the polar caps, exchange with water adsorbed in the near-surface regolith and global transport by means of winds (Jakosky and Haberle 1992).

Temperatures average about 220 K globally, well below the melting temperature of ice and lower than the eutectic freezing temperature of most salt-rich brines. Even though surface temperatures rise above 273 K over large regions near the equator and near noon, liquid water still would not be stable. It could exist as a transient phase, but would quickly evaporate into the relatively dry atmosphere and eventually freeze out at the colder high latitudes (Jakosky and Haberle 1992).

Mars' north polar region is covered with CO_2 ice during winter, which sublimes away and leaves a residual summertime deposit of water ice. The south cap is covered year round by CO_2 frost but almost certainly has water ice mixed in or beneath it (Jakosky and Haberle 1992). The axial obliquity, the tilt of the polar axis with respect to the normal to the orbital plane (currently 25.2°), varies on timescales of 10^5–10^6 yr. On longer timescales, it is chaotic and may have been as low as 0° or as high as 60° in the past few million years. At high obliquity, polar summertime temperatures may increase markedly and substantial amounts of water ice may sublimate into the atmosphere. Exchange of this water between the north and south polar caps, modulated by the changing eccentricity and season of perihelion, is probably responsible for the formation and evolution of layered deposits in the polar regions (Jakosky and Haberle 1992).

Nature of the earliest atmosphere and climate

The observable surface record of Mars' geological history spans 4 billion years (Gyr). The oldest, most heavily cratered surfaces are thought to be about 4.0 Gyr old and the youngest are possibly less than 100 million years (Myr) old (Hartmann and Neukum in press; Hartmann *et al* 1981). Evidence pertaining to the ancient climate is inferred from processes that shaped the surface during the Noachian epoch, which ended when the cratering rate declined dramatically between 3.8 and 3.5 Gyr ago (Hartmann and Neukum in press). (Figure 2 summarizes the history and timing of processes involved in Martian

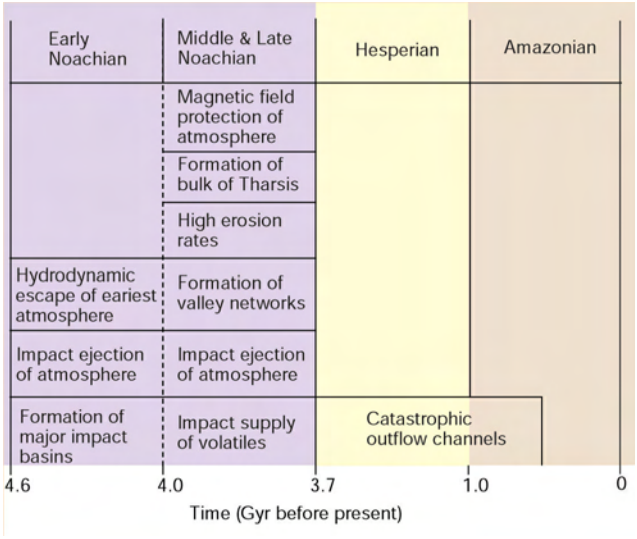

Figure 2. Schematic diagram showing the time history of the Martian volatile system. The 4.6 Gyr history of Mars is divided up into the major geological epochs that have been identified and processes that occur within each epoch are indicated. Note that the timeline is not a linear scale. Some climate-related processes are not shown (including recent polar-cap behaviour and the occurrence of possible crater lakes). Absolute ages marking the boundary between epochs are estimated based on the recent revision of cratering chronology (Hartmann and Neukum in press).

climate evolution.) Although atmospheric gas undoubtedly was present before 4.0 Gyr and was removed in part from the atmosphere by various processes, we focus here on processes that postdated the onset of the visible geological record.

The ancient Martian surfaces contain geological features that indicate that the early climate was different. Dendritic networks of valleys seem similar to those formed by run-off of surface water on the Earth, although the areal density of tributaries is typically lower. There is debate about the relative roles of surface run-off, sapping by release of subsurface water and discharge of water from hydrothermal systems in forming the valleys. However, there is general agreement that water must have flowed at the surface in order to form these features and that their dendritic character and typically V-shaped cross-section requires a gradual rather than catastrophic formation process (Carr 1996).

Erosion rates in general were substantially greater during the Noachian. This can be seen easily on ancient impact craters. The largest craters and basins are severely degraded; ejecta deposits, crater rims and central peaks have all been removed and a paucity of craters smaller than about 15 km diameter suggests that they have been removed in their entirety. Some partially degraded craters have fluting and scalloping along the interior rim that suggests erosion by flowing surface water. Estimated erosion rates were more than 1000 times larger than in subsequent epochs and approach values appropriate for drier regions on Earth (Carr 1996).

Additional evidence for a shift to a colder, drier climate at the end of the Noachian is provided by the initiation of U-shaped valley forms at the downstream ends of V-shaped valleys, suggesting an evolution of valley-forming erosional mechanisms from water related to ice related. This period of U-shaped valley formation and valley network evolution in general, ended rapidly at the end of the Noachian or early in the Hesperian.

Together, these features strongly suggest that liquid water was present during the Noachian and flowed over the surface and that the climate must have been such that water was either more stable or more abundant at the surface than it is at present. Such a climate is thought to have required warmer surface temperatures produced by substantial greenhouse warming (see GREENHOUSE EFFECT). Although the climate must have been 'warmer' and 'wetter', there is no consensus as to what temperatures would have been required, what the greenhouse gas would have been or how much water would have to have been at the surface or in the atmosphere (Squyres and Kasting 1994). If CO_2 were the greenhouse gas, up to several bars pressure would have been required to produce the necessary warming. A warmer climate is indicated even if valley network formation involved subsurface hydrothermal processes, as flow at the surface and gradual erosion require a warmer climate independent of the original source of the liquid water.

Connections between ancient climate and early geology

Other events also were taking place during the Noachian period that would have affected climate. The planet was being bombarded by impacting ASTEROIDS or PLANETESIMALS, it was creating its main division into a southern highlands and a northern lowlands (which is reflected today as the ancient and younger terrains respectively) and volcanism was forming the major Tharsis province on which sit many of the large volcanoes.

The formation of Tharsis was recognized only recently as occurring largely in the Noachian (Phillips *et al* 2001). The heavy loading of the lithosphere, due to the dominantly magmatic formation of the Tharsis rise, resulted in a global warping of the surface (Phillips *et al* 2001). Many of the ancient valley networks are seen to preferentially follow the slopes that resulted from the formation of Tharsis or, in at least one location (Margaritifer Sinus), are of the same age as those that do. This indicates that emplacement of Tharsis must have been nearly complete while the largely Noachian valley networks were still forming. Although much of the surface in Tharsis is sparsely cratered and therefore relatively young, indicating that resurfacing of Tharsis continued throughout Martian history, the bulk of the volume of Tharsis must be old (Phillips *et al* 2001).

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

The volcanic magma from which Tharsis formed probably contained substantial quantities of both water and CO_2 that would have been released, providing input of gases to the atmosphere and possibly contributing to an early, thicker atmosphere. Geochemical analysis of the Martian METEORITES, for example, suggests a water content of as much as 1.8% by weight. Thus, the timing of valley network formation may be more than coincidental. Tharsis volcanism may have supplied gases that helped maintain a climate conducive to weathering and erosion and the cessation of volcanism may have allowed other processes to begin removal of much of the atmosphere (see below) (Phillips *et al* 2001).

There is another compelling connection between Tharsis and the history of water. The lithospheric deformation due to the weight of Tharsis created a depression or trough encircling it at a radius of about 5000 km (figure 3(*a*)). Most of the large-scale geological features related to surface water are concentrated in this trough (Phillips *et al* 2001). This includes the large-scale drainages that flow northward from the Argyre basin (at 50° S latitude) and the catastrophic flood channels that emanate from the eastern end of Valles Marineris and flow north into the Chryse basin and into the northern lowlands. Argyre, for example, seems to have been filled with water, which subsequently overflowed the rim and flowed northward. Although the catastrophic flooding occurred episodically throughout Martian history, the source and flow regions concentrate in the Tharsis trough. This relationship suggests a long-lasting connection between the geological and geophysical history of Mars and the release, availability and geological effects of liquid water. However, some anomalies exist, such as the paucity of similar features in the western branch of the circum-Tharsis trough and the ill-defined nature of processes, other than simple structural control of water pathways, that would provide a causal connection between the trough and the release of crustal water.

Finally, we note an apparent correlation between the regions on which crustal remanent magnetic fields are imprinted and areas on which valley networks are identified (figure 4). The magnetic anomalies presumably retain an imprint of a global-scale intrinsic magnetic field from an early time in Martian history (Acuña *et al* 1999). Exceptions to the correlation include the large-scale magnetic anomalies occurring in discrete bands in the high southern latitudes, where valley networks may have never formed because of climate constraints and Margaritifer Sinus, where stripping of the surface may have removed the valleys without removing enough material to eliminate the magnetic anomalies. If genuine, this correlation may reflect a coincidence in timing of the formation of both the valleys and the magnetic anomalies or in the geographic location of subsequent

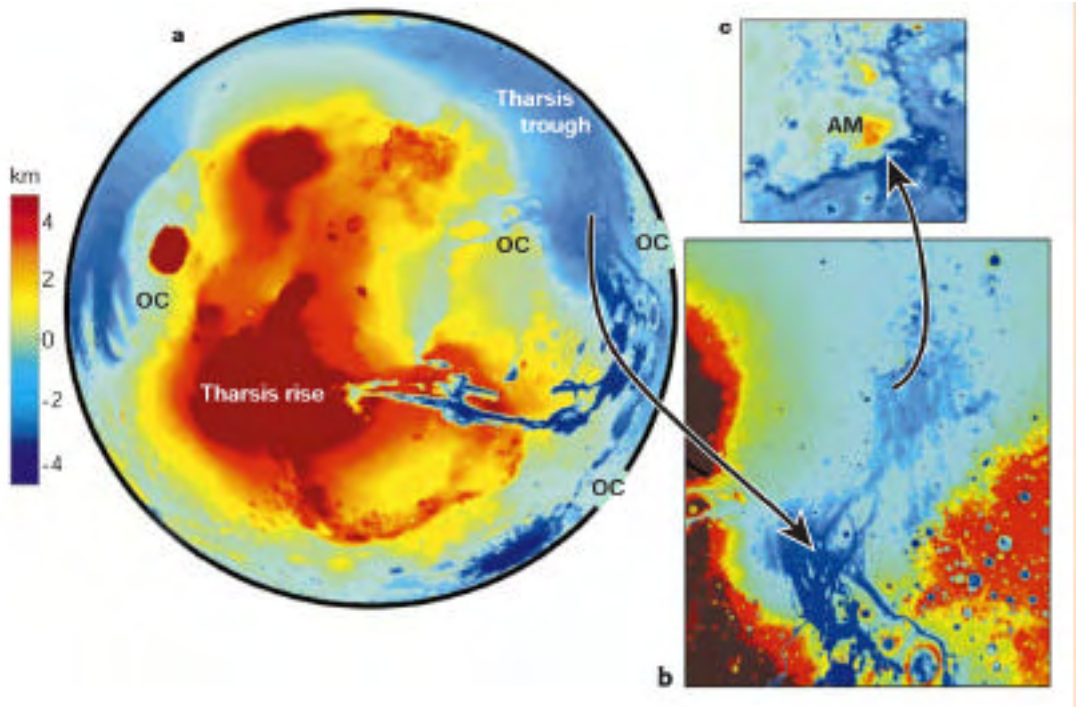

Figure 3. Topography (Smith *et al* 1999) of Tharsis rise and Tharsis trough (Phillips *et al* 2001). (*a*) Topography, which has been saturated at 5 km, with pole-to-pole slope (Smith *et al* 1999) removed. Image is centred on 260° E longitude and view is from 10° north of equator. Outflow channel locations are marked by 'OC'. (*b*) Channel detail in Chryse and Acidalia Planitiae (0°–60° N, 300°–0° E, Mercator projection; elevation range is –3.9 to 0 km). Dirac House, Temple Back, Bristol, BS21 6BE, UK

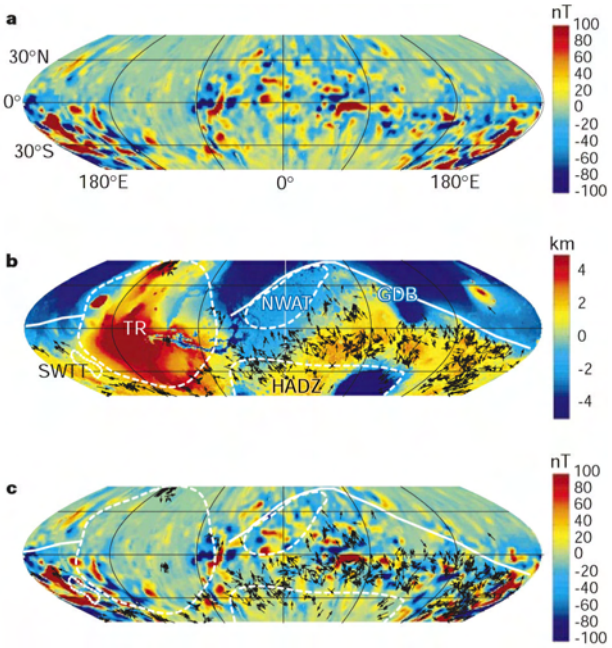

Figure 4. Comparison of Martian magnetic field, topography and valley network locations. (*a*) Radial component of the Martian magnetic field at an altitude of 200 km (after Purucker *et al* 2000). Values saturated at 100 nT. Sinusoidal projection to 47.5° latitude. (*b*) Topographic map of Mars (after Smith *et al* 1999), saturated at 5 km elevation and locations of valley network systems. Database is limited to latitudes less than 47.5°, which is the approximate limit of valley network distribution. Features indicated are the Tharsis rise (TR), global dichotomy boundary (GDB), northwestern Arabia Terra (NWAT), southwestern Tharsis trough (SWTT) and Hellas–Argyre disruption zone (HADZ). TR, NWAT, SWTT and the area north of GDB are regions of valley network exclusion by erosion and/or deposition and cannot be judged for the level of correlation of valley networks with anomalies in the remanent magnetic field. Likewise, TR, HADZ and the area north of GDB are regions of magnetic field exclusion by the presence of post-main-field crustal ages or crustal disruption (Acuña *et al* 1999). (*c*) Valley networks and features in (*b*) superposed on magnetic anomaly map.

alteration processes. Alternatively, it may involve a cause-and-effect relationship, in which valleys could represent the surface manifestation of hydrothermal systems driven by subsurface volcanism that thermally induced the creation of the localized remanent fields. However, as neither the mechanism of formation of the magnetic anomalies nor that of their removal (if they ever were distributed globally) is understood, such connections are speculative at best.

Evolution of the Noachian atmosphere

What processes might have caused the inferred changes in Noachian climate, what sinks were available for atmospheric gases during this epoch and can we infer the degree to which each process acted? These are especially important issues, as the output of the Sun was some 30% less 4 Gyr ago than it is today, making the maintenance of an early warmer climate more difficult.

Impact of large asteroids through the Noachian epoch would have ejected gas in the atmosphere to space. Although inherently capable of removing large amounts of atmosphere, only those impacts occurring since the time of the onset of the geological record would have resulted in climate change that can be inferred from that record (Brain and Jakosky 1998). We know how many impacts occurred, based on the number of large craters and impact basins seen on the ancient terrain and can readily extrapolate to impacts on areas subsequently buried. Combined, impacts are likely to have ejected about 50–90% of the atmosphere present in the early epoch (Brain and Jakosky 1998). This fraction probably is an upper limit, as some volatiles (such as water) might not have resided exclusively in the atmosphere at this time or might have been outgassed late in the epoch.

Recent measurements of surface elevation have allowed identification of previously unknown impact basins buried below a relatively thin veneer in both the southern highlands and the northern plains. The buried craters in the northern plains have similar abundance to the craters in the southern highlands and justify the extrapolation of southern-hemisphere craters to a global inventory. The buried southern-highlands craters predate the geological evidence pertaining to the early climate, so those impacts would not have contributed to the changes in climate and should not be counted in summing up atmospheric loss.

Impacts of volatile-rich objects can supply new volatiles to Mars as well as remove them from the atmosphere. In particular, the analysis of isotope ratios of heavy noble gases in the atmospheres of Earth and Mars suggests that much of the planets' volatiles could have been supplied by comets. However, the relative roles of supply and removal of volatiles by impacts are unknown.

The impingement of the solar wind can strip gases directly from the upper atmosphere. Both atom-on-atom collisions that eject individual molecules (pick-up-ion sputtering) and hydrodynamic collisions that could strip off large volumes of gas en masse would have been important. However, theoretical models of these processes are exceedingly uncertain even at the present epoch and extrapolating to past epochs when the solar wind and solar ultraviolet radiation were more intense compounds the uncertainties. However, two observations of the present-day atmosphere indicate that these processes were significant. First, *in situ* measurements of the energy spectrum of ionospheric electrons distinguish between ionization of gases in the upper atmosphere and those from the incoming solar wind. The morphology of discrete regions of solar-wind versus planetary electrons requires that large masses of upper atmosphere are being

stripped off en masse. Second, isotopic measurements indicate that such stripping has occurred and has been significant. The lighter isotopes of each atom are enriched relative to the heavier ones at the top of the atmosphere by diffusive separation (for example, ^{12}C relative to ^{13}C, ^{14}N to ^{15}N or ^{36}Ar to ^{38}Ar) and will be preferentially removed to space. Consequently, the gas remaining in the atmosphere becomes enriched in the heavier isotope. This enrichment pattern is observed consistently in the modern atmosphere. For example, the ratio $^{38}Ar/^{36}Ar$ is 30% greater on Mars than elsewhere in the solar system and nitrogen and carbon also show enrichments (table 1). This enrichment indicates loss of between about 50% and 90% of the atmospheric species to space, with the actual loss probably tending towards the higher values (Jakosky *et al* 1994).

In addition, compared with terrestrial values, Martian water shows a five-fold enrichment of D relative to H (see Table 1). The lighter H atom can escape thermally to space more readily than D, so the considerable enrichment of observed D requires the loss of substantial quantities of hydrogen to space. The hydrogen comes from water, with the oxygen from water probably also being lost to space. The inferred water loss depends on the relative supply rates of H and D to the upper atmosphere, their relative escape rates and the initial D / H ratio on Mars. Recent analysis of Martian meteorites suggests that the initial D / H value on Mars was twice the terrestrial value (Leshin 2000); in addition, there has been a spectroscopic detection of upper-atmospheric D and a revision of atmospheric reaction rates. Although the initial interpretation was that about 90% of Martian water had been lost to space, the current understanding suggests loss of about two-thirds of the water.

The observed isotopic enrichments indicate the fraction of each species that has been lost but not the total amount lost. Atmospheric gases exchange with the regolith and polar caps, so the fraction lost actually represents that lost from the combined atmospheric plus non-atmospheric reservoir. In addition, different portions of the polar ice, for example, may exchange with the atmosphere on different timescales and outgassing of juvenile gas at later times will affect the isotope ratios. The absolute loss rates to space are uncertain today and may have varied through time, so although we can be confident that loss of substantial volatiles to space has occurred, we are uncertain as to how much has been lost, where it came from or exactly how much has been left behind. (Although the losses of H and O are related and one would expect the isotopic fractionation of D / H to be related to that of $^{18}O/^{16}O$, oxygen has an additional reservoir with which it can exchange — minerals in the crust — so that the connection is likely to be complex.)

Whereas stripping by the solar wind of upper-atmospheric gases will change the isotope ratios, removal by impact will not. Impacts remove the gas from the entire atmospheric column and thereby remove all isotopes with equal efficiency. Thus, the fractions of gas lost by these two processes add together. For example, if each indicates loss of 90%, these represent a different 90% and they sum up to a net loss of 99% of the atmospheric gas. In addition, the two loss processes probably operated at different times, with impact erosion probably being most important early in the Noachian when impact rates were highest and solar-wind stripping occurring late in the Noachian or into the Hesperian.

CO_2 can be removed from the atmosphere in the presence of liquid water to form carbonate minerals on the surface or in the subsurface. This process occurs on Earth, where gaseous CO_2 dissolves in the oceans, combines with calcium ions weathered from the continents and forms deposits of calcite in limestone. If SO_2 was an early greenhouse gas, it might have formed crustal sulphate minerals. Carbonates have been found in the Martian meteorites and have been shown to be indigenous to Mars. However, carbonate and sulphate minerals have not been detected in sufficient quantities that, if released in gaseous form, they could provide enough greenhouse warming to explain the early environment (Christensen *et al* in press). The CO_2 from a several-bar atmosphere would form a global equivalent layer of carbonates perhaps a hundred metres thick; were this distributed throughout the entire volume of the crust, perhaps carried there by circulating groundwater, it might not be detectable at the surface. Thus, the extent to which carbonate minerals could be a sink for gases from an early atmosphere remains uncertain.

However, processes do exist that together can account for loss of an early thicker atmosphere. Theoretical models of the timing of volatile loss suggest that these processes can account quantitatively for the inferred change in climate, but they are not unique (Brain and Jakosky 1998). Two measurements, however, provide supporting evidence.

First, gas trapped in the Martian meteorite ALH84001 may represent a direct sample of the ancient

Dirac House, Temple Back, Bristol, BS21 6BE, UK

atmosphere. Measurements of nitrogen and argon isotopes indicate that this gas is essentially unfractionated, meaning that most of the isotope-fractionating loss to space through solar-wind stripping had not yet occurred (Mathew and Marti 2001). Isotopic measurements of the gas Xe indicate that it was trapped into the rock 3.9 Gyr ago. If the Xe and lighter gases were incorporated into the rock at the same time and represent a sample of the Martian atmosphere from that epoch, they provide a key time constraint on atmospheric loss (the bulk of the loss to space must have postdated 3.9 Gyr). However, although the gases most plausibly came from the atmosphere and were incorporated into the rock at that time, there are concerns related to their uncertain carrier within the meteorite and to the presumed non-juvenile nature of the gases, such that the interpretation is not unique.

Second, measurements of localized remanent magnetic anomalies detected on Mars today (Acuña *et al* 1999) provide information on the timing of the shut-off of an intrinsic magnetic field. A substantial global magnetic field would cause the solar wind to stand off from the planet, limiting its ability to strip off the atmosphere. In addition, local magnetic anomalies each have the ability to protect the local atmosphere, such that the atmosphere of a planet covered entirely by such anomalies also would be relatively well protected. Thus, the shut-off of an intrinsic magnetic field and the 'erasure' of local remanent magnetic anomalies in the crust, if they ever were distributed globally, would have allowed the turn-on of the stripping of the atmosphere by the solar wind.

The history of the magnetic field and the timing of its shut-off is extremely uncertain (see MARS: CORE AND MAGNETISM). Most of the remanent magnetic anomalies occur in the ancient terrain, indicating that Mars had a substantial intrinsic magnetic field and that it turned off relatively early in Martian history (Acuña *et al* 1999). Suggestion of a late turn-on of the global magnetic field is at odds with magnetization found in carbonate globules in ALH84001, which indicates that a Martian geodynamo was active 4 Gyr ago or earlier. A few younger areas also have remanent fields, although there is a general absence of magnetic anomalies associated with Hesperian and Amazonian volcanics, adding to the confusion. It is clear, however, that an intrinsic magnetic field was most strongly connected to the Noachian epoch and very much less so to later epochs. It may not be possible to resolve the timing issues more clearly, as it is uncertain what the carrier of the remanent magnetic fields is, whether remanent anomalies were originally distributed globally and, if they were, what process would have erased them.

If the turn-off of the magnetic field and the erasure of localized magnetic anomalies allowed the solar wind to begin to strip species out of the atmosphere, then this atmospheric loss would have begun during the Noachian or early Hesperian. The turn-on of atmospheric loss would have been complete only when a substantial fraction of local anomalies had been destroyed. This may not have happened prior to the substantial volcanism associated with Tharsis and the subsequent Hesperian era.

Together, the isotopic and magnetic-field evidence indicates, but does not prove, that the bulk of solar-wind stripping to space occurred subsequent to 3.9 Gyr and that the turn-on of loss occurred sometime between the Middle Noachian and the Early Hesperian. Loss by solar-wind stripping seems to have been roughly contemporaneous with the change in climate inferred from geology, with the main changes in climate coinciding with the end of the Noachian.

Evidence for liquid water in later epochs

There is substantial evidence that liquid water has been present within the Martian crust up to the present. Evidence comes from geological features seen on the surface as well as from geochemical analyses.

Catastrophic outflow channels provide compelling evidence that liquid water was released from within the crust, flowed over the surface and drained into the northern lowlands (see Carr 1996). As these floods involved large quantities of water released catastrophically, with water able to flow substantial distances before freezing, they could occur even in the present cold climate (Carr 1996). They do indicate, however, that liquid water must have been present within the crust. Other eroding agents have been suggested, including liquid CO_2, SO_2, volcanic lava, ice, debris flows and the wind. In particular, the similarity of some of the Martian channels to volcanic channels and the ability of the wind to weather and erode substantial amounts of material, have recently been highlighted, along with the difficulty of reaching unique conclusions about the eroding fluid from morphology alone. However, water or water-filled debris flows remain the most plausible candidates and require the fewest extrapolations. Although the observed floods seem to have drained only about 10% of the surface, connected largely to the Tharsis trough, there is no reason to think that crustal water was not distributed globally.

The Martian meteorites contain weathering products, produced when liquid water was present, filling cracks and voids in the rock. These include carbonate deposits at levels of several per cent in ALH84001, as well as trace amounts of carbonates and the mineral iddingsite (which forms from weathering of basalt in the presence of liquid water) in several of the other meteorites. Detailed microstratigraphy shows that the deposits were present before the rocks were ejected from the Martian subsurface, providing direct evidence that liquid water circulated through the Martian crust.

Indirect geochemical evidence for liquid water in the crust comes from measurements of various isotope ratios within these weathering products. They contain enhanced D / H, $^{13}C/^{12}C$, $^{15}N/^{14}N$ and $^{38}Ar/^{36}Ar$ ratios. Enhancement of each of these ratios is best explained as having resulted from atmospheric processes involving preferential escape of the lighter isotopes to space (as discussed earlier). This requires that these gases once resided in the atmosphere, were left behind as a residuum of loss to space and were subsequently incorporated into the crust. Circulation of groundwater between the surface and the crust provides the best means for exchange of these gases, again suggesting the presence of liquid water (Jakosky and Jones 1997; Watson *et al* 1994).

While the carbonates in ALH84001 were probably precipitated from liquid water about 3.9 Gyr ago, water also must have been present much more recently. The other Martian meteorites are all much younger rocks, having crystallized between about 170 Myr and 1.3 Gyr and also contain weathering deposits (McSween 1994). Thus, crustal water must have been present within the past billion years. Radiogenic dates for the weathering products in the Lafayette meteorite indicate deposition around 650 Myr ago or even more recently.

Several locations on the surface show spectroscopic evidence for the presence of coarse-grained haematite, probably formed in association with liquid water (Christensen *et al* 2000). The haematite may have been deposited from water released from volcanic intrusions or driven by subsurface hydrothermal or aqueous systems (Christensen *et al* 2000), although some could have formed by volcanic processes not requiring water. One of the occurrences is in Aram Chaos, a feature attributed to the release of subsurface water and not connected to volcanism. A second, larger location is in Western Terra Meridiani, located at about 0° latitude and 0° longitude thought to have formed at depth and been exposed subsequently by erosion (Christensen *et al* 2000).

Liquid water also may have been present within the near-surface crust very recently, based on the presence of pristine gullies on the exposed walls of impact craters and valleys (Malin and Edgett 2000). These are identical in size, shape and appearance to gullies on Earth carved by liquid water seeping from aquifers on exposed scarps. Liquid CO_2 has been suggested as a possible eroding agent, based on the similarity of the depth of seeping to that at which the overburden pressure equals the CO_2 liquefaction pressure. However, the absence of a viable charge or recharge mechanism for liquid CO_2 and the inability of CO_2 to discharge as a liquid under Martian conditions preclude its role as a significant erosive agent. Rather, liquid water is much more plausible geologically (see Malin and Edgett 2000). Recent calculations of the stability of liquid water in the crust and of the ability of cyclical oscillations in temperature to freeze and release water, suggest that this is a viable mechanism (Mellon and Phillips in press). There is no means to uniquely determine the age of the features, but they are unweathered and gully debris overlies features such as sand dunes that are themselves thought to be extremely young. If these interpretations are correct, liquid water has been present within a few hundred metres of the surface within the past few million years and may reside there today (Malin and Edgett 2000).

There also is geological evidence for liquid water at the surface, possibly during the later epochs of Martian history. Most intriguing is the evidence for standing lakes within impact craters and the Valles Marineris canyon system (Carr 1996). Potential crater lakes are identified by the presence of channels flowing into and / or out of the craters, providing a source or sink for water. Some deposits within craters have an appearance similar to deltas, sedimentary terraces and shorelines, as might be formed by flowing water. Although most of the craters themselves are relatively old, the age of the lakebed deposits is uncertain. There are few craters on the lakebed deposits, which indicates either that they are very young or that they were buried for long periods and were exhumed very recently (Malin and Edgett 2001); stratigraphic relationships of layered sedimentary deposits within Valles Marineris suggest an old age despite the absence of craters (Malin and Edgett 2001). Well-defined layering within these deposits supports the idea of standing water, although layered lakebed deposits cannot be distinguished uniquely from windblown sediments (Malin and Edgett 2001). However, even if these sediments were windblown, they would have required either liquid water at least in trace amounts or water ice that might be stable at other epochs in order to cement the grains together to form coherent layers.

The catastrophic outflow channels all drain into the northern lowlands (Carr 1996). Possible shoreline features have been identified, suggesting that the water may have accumulated in the lowlands to form a large, long-lived body of water (that is, an ocean). The crudely constant elevation of the innermost of the two main proposed shorelines and the extreme smoothness of the lowlands are held to be consistent with the presence of an ocean. However, the proposed shoreline features are not visible in recent high-resolution images and thus cannot be ascribed with certainty to wave action at an ocean boundary. Features described originally as 'high stands' or shorelines created by a retreating ocean are now recognized as being wrinkle ridges of tectonic derivation. These ridges underlie the Vastitas Borealis formation, a deposit that may in part be sedimentary in origin.

The smoothness of the lowlands (Smith *et al* 1999) may have resulted from fluvially transported sediments associated with channel emplacement during the Hesperian; such a process allows but does not

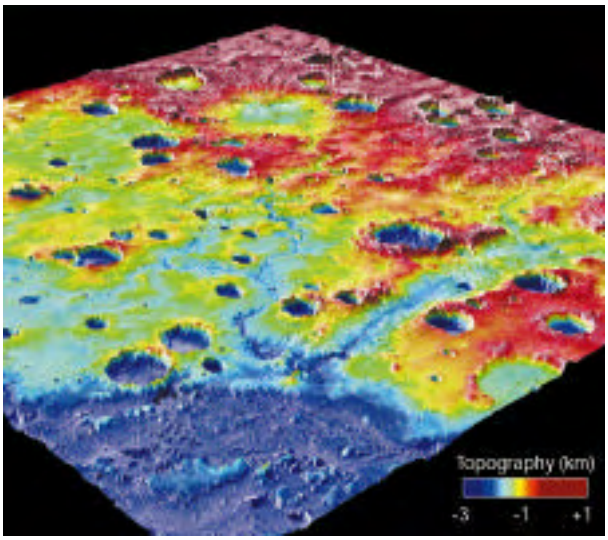

Figure 5. View of topography (from Smith *et al* 1999) looking towards the southeast in Margaritifer Sinus region. Area is 30° x 30° in size and there is 12 vertical exaggeration in topography. Pole-to-pole slope has been removed in topography to emphasize regional variations. The prominent depression in the centre of the image is Parana basin, a possible site of lake sediments; it is drained by a prominent channel (Loire Vallis) that descends northwesterly into the Tharsis trough (foreground). Higher elevations (red shades) are Early- and Middle-Noachian plateau materials. Yellow, green and blue/grey shades of lower elevations represent widespread erosion events in the Late Noachian that removed 1.5 x 10^6 km^3 of Early/Middle-Noachian material from this region. Erosional remnants of older material occur in isolated mesas. (Image courtesy of B Hynek.)

require the presence of an ocean. Erosion of material in the Margaritifer Sinus region and an adjacent area in northwestern Arabia Terra may have provided a significant source of sediments. About a kilometre of material seems to have been stripped away during the Late Noachian and geological evidence points to erosion by liquid water (figure 5). The resulting debris could have filled the northern plains to a depth of about 100 m north of 30° N. The corresponding equivalent depth of water necessary to transport this sediment would have been several times the sediment volume. Whether or not this resulted in a Late Noachian ocean would have depended on the relative rates of erosion and of water removal by ground infiltration, evaporation and so on. Linear gravity anomalies trending northward from Chryse Planitia may be indicative of early channels buried in the northern plains, analogous to the main catastrophic flood channels seen to the east of Valles Marineris (Zuber *et al* 2000). These could be Noachian-era pathways that moved water and sediment from the southern highlands to the northern lowlands.

In addition, the Hesperian outflow flood channels can be traced northward into Acidalia Planitia. There, they converge into a basin (not presently closed) with an area 6 x 10^5 km^2, south of the high-standing Noachian inlier Acidalia Mensa at 45° N latitude (figure 3(*b*)). Acidalia Mensa itself has erosional boundaries on the south and east that are channels (figure 3(c)) and may at one time have formed a natural barrier to water flow. This region of channel convergence coincides closely with one of two main occurrences of kilometre-scale polygonally fractured terrain. The origin of polygonally fractured terrain is controversial, but many of the processes proposed involve water. Thus, it is likely that water (and thus sediments) were carried far into the northern lowlands during the Hesperian, perhaps forming lakes. The region of channel convergence in Acidalia Planitia may mark the largest possible extent of any standing bodies of surface water. If there ever was a Hesperian northern 'ocean', it may have been more of a large lake about the size of the Caspian Sea (4 x 10^5 km^2).

Synthesis of the observations and interpretations

It is clear that there are a number of strong constraints on the history of water on Mars. They tell us that water was present at the surface early in the planet's history and within the crust throughout time. They also allow us to construct a self-consistent scenario of the history of Martian volatiles and climate, although such a scenario is not unique.

The history of Martian volatiles involved the following (see figure 2).

Most of the earliest atmosphere of Mars was lost during the Early Noachian by impact erosion and hydrodynamic escape. A secondary atmosphere was created by water and CO_2 released to the atmosphere as a direct result of Tharsis volcanism and this may have had a strong influence on climate. It is likely that volatiles were also released by non-Tharsis Noachian volcanism presumed to have been responsible for forming the ancient highland crust. Water and CO_2 were lost from the surface and atmosphere system to space, to the polar caps and to carbonate deposits within the crust. There is compelling evidence for the existence of each of these sinks, as described above, although it is not possible at this time to determine uniquely the relative or absolute importance of each. There is a coincidence in the timing of major events in Martian history. The decrease in the impact rate at the end of heavy bombardment, the formation of the bulk of the Tharsis construct by magmatism, the decline in the intensity or existence of an intrinsic magnetic field, the change in climate inferred from the morphological characteristics of the surface and the loss of substantial volatiles to space all occurred at nearly the same time and marked the end of the Noachian epoch about 3.7 Gyr ago. Many of these events are likely to have been causally connected to each other, although some of the similarity in timing may be coincidental. However, the loss of atmos-

pheric protection by the shutdown of the global magnetic field and the decline in the rate of Tharsis volcanism at the end of the Noachian probably both were instrumental in the major shift in climate as inferred from the geological record. There has been a reservoir of crustal liquid water throughout Martian history, continuing possibly to the present. This reservoir has exchanged, at various times and to various degrees, with water at the surface and in the atmosphere. We have little information as to how much water is contained in this reservoir today, but it is likely to be substantial, globally distributed and readily accessible to the surface in some places.

New measurements from both planned and potential missions will allow us both to test the above hypotheses and to further constrain the processes that have taken place. Although the list of relevant observations is long, some measurements will be key to improving our understanding. These include determining the present-day isotope ratios of the climate-related species (H, C, O and N) and the noble gases, sampling rocks over a broad age spectrum and determining the abundance of weathering products and the isotope ratios of gases contained within them, continuing the search for evidence for trapped carbonate or sulphate minerals within the crust, especially in rocks previously underground and now exposed at the surface, and continuing to explore the morphology of the surface for evidence of climate-related processes.

Discoveries made in the past decade have had a tremendous impact on our understanding of the history of Martian water, volatiles and climate. Analysis of the Martian meteorites and the measurements made from the Mars Global Surveyor spacecraft in particular have been key to progress in this area. Unravelling the history of Martian volatiles and climate will be central to addressing in a meaningful way the potential for Martian life and to interpreting results obtained specifically to look for evidence of present or past life.

Mars: Core and Magnetism

The existence of the MARTIAN CORE, which has been accepted for many decades, is interesting for several reasons. First, its size and composition tell us about Mars as a whole — its constituents and provenance. Second, its antiquity tells us about early conditions on Mars; we believe that the core formed early, and this requires that Mars had a hot beginning. Third, this core is the likely source of a magnetic field for some part of Mars' history, probably the earliest part, just as Earth's core is the source of the current geomagnetic field. Fourth, the field may have influenced the early climate through its influence on atmospheric escape. It could also have affected the environment for early life on Mars. Fifth, the heat flow from the core may have fed mantle plumes and influenced volcanic activity, much as hot spots such as Hawaii are thought to be fed by core heat flow on Earth. Sixth, a core, if partly or entirely liquid, influences rotational dynamics, just as (for example) changes in length of day are influenced by Earth's liquid core.

Mars is built from roughly the same ingredients as Earth: silicates and oxides of magnesium and iron, as well as metallic iron (alloyed with various constituents). When we refer to a core for the terrestrial planets Mercury, Venus, Earth and Mars, we mean a central region that is rich in metallic iron. Because this material is about twice as dense as the silicates and oxides making up the CRUST and MANTLE, its presence as a core is revealed through its influence on the mean density of the planet and through its effect on the moment of inertia. Old measurements of gravity and more recent geodetic data from Pathfinder (Folkner *et al* 1997) reveal that the mean moment of inertia for Mars is $0.365MR^2$, where M is the mass of Mars and R is its mean radius. Together with the Martian mean density of 3.93 g cm^{-3}, this suggests a model of Mars that is not too different from a scale model of Earth (that is, similar ingredients, distributed similarly). The Martian core is proportionately a little smaller than Earth's core, and proportionately more iron is found in the mantle (in oxides or silicates). As we do not know the composition of the core we cannot be certain about core size, but a core radius of around 1 300–1500 km (depth to core of 1900–2100 km) is indicated. Figure 1 shows a simple interior structure of Mars. Bertka and Fei (Bertka and Fei 1998) suggest a composition for Mars that is different from partly devolatilized primitive METEORITES.

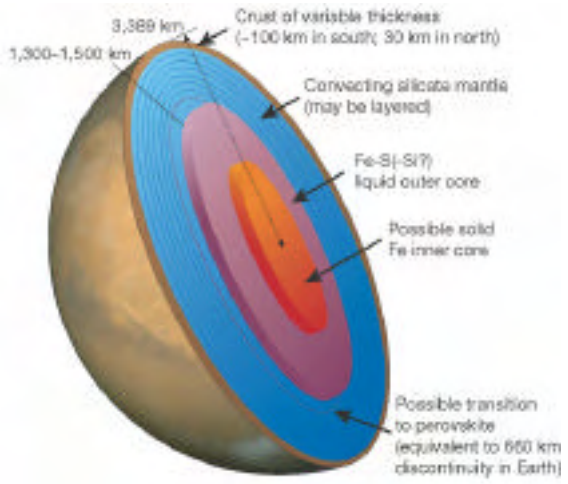

Figure 1. Cutaway view of the Martian interior

Far less is known about the Martian core than Earth's core because we lack seismological evidence or geodetic data of sufficient precision. In particular, we do not know whether the core is entirely liquid, partly liquid (like Earth) or entirely solid, although there are indirect arguments against an entirely solid core. Fortunately, because Mars is at lower pressures than Earth, and so is more accessible to high-pressure experiment, it is possible to assess the likely phase composition for the core.

Core formation

It is widely accepted that terrestrial planetary cores owe their existence to a process of gravitational separation of mostly liquid, immiscible iron from the (partly) solid silicates. The supporting arguments are partly physical (Stevenson 1990), but increasingly geochemical. Although we have no samples of either the core of Earth or the core of Mars, we do have rocks that are probably indicative of mantle composition. For Mars, these are the very limited yet highly important SNC METEORITES (for shergottites, nakhilites and chassignites). As on Earth, these igneous rocks show a striking depletion of 'iron-loving elements' (called siderophiles) whose extraction testifies to the conditions of core formation (Righter, Hervig and Kring 1998). Isotopic data (Chen and Wasserburg 1986, Lee and Halliday 1997) also suggest that this core-forming event was early in Mars' history.

These data, together with physical modelling, suggest a scenario similar to the following. Mars accumulated from smaller bodies over a period of perhaps as long as 100 million yr (Myr), but possibly much shorter, around 4.5–4.6 billion yr (Gyr) ago (Wetherill 1994, Chambers and Wetherill 1998). Isotopic evidence is compatible with a very short accretion time, suggesting that Mars might even have been a runaway, isolated embryo rather than a slowly accumulated body like Earth. In this accretional process, the impacting bodies may have already had iron cores, but the energetics of the impact events would have caused extensive melting and mixing of the immiscible metallic iron and silicate / oxide components, allowing chemical re-equilibration on a small scale (centimetres to metres) (Stevenson 1990). A substantial

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

mass of the impacting bodies may have been in the form of giant impacts (bodies of the order of the mass of Earth's Moon), but even much smaller bodies can bury a great deal of heat at depth. The energy of gravitational formation of Mars is roughly $0.6GM/R$ per unit mass, where G is the gravitational constant. If all this were converted into heat it would be sufficient to heat the Mars-forming material to several thousand degrees Celsius above the melting point and, even with the loss of heat by radiation, a magma ocean is likely. This ocean might be transient (surviving for a brief period after each giant impact) or it might be sustained by a dense steam atmosphere, but in either case it will define the conditions of most of the core formation.

Although not as hot or at such high pressure as the likely conditions that formed Earth's core (Righter, Hervig and Kring 1998), the lower gravity on Mars would still permit a thick magma ocean. Metallic iron can settle as droplets in a convecting magma ocean, to accumulate as large blobs ('diapirs') that then ascend by Stokes flow through the possibly more viscous and high-pressure deep mantle. In this scenario, the core might initially be either a few hundred degrees Celsius hotter than the mantle (if the energy of core formation is retained substantially within the iron) or the same temperature as the deep mantle (if efficient thermal equilibration takes place). Much of the Martian crust (particularly that preserved in the south) may have formed in this very earliest epoch.

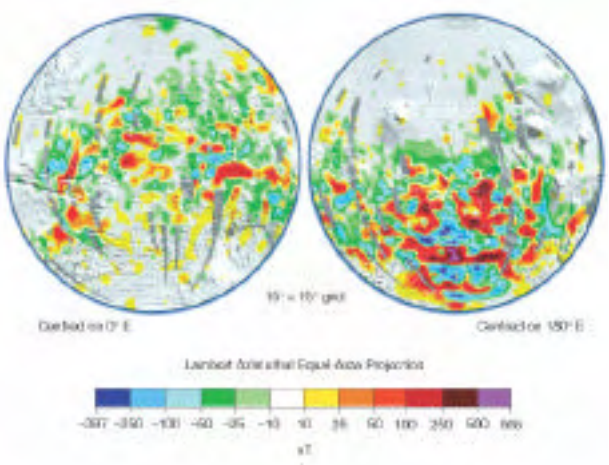

Figure 2. Radial magnetic field at 200 km altitude, based on data collected by the Mars Global Surveyor spacecraft. The southern hemisphere exhibits the largest field anomalies. Notice that the opposite hemisphere has field anomalies that are typically an order of magnitude smaller and exhibit less coherent spatial structure. These maps were prepared by M. Purucker, Goddard Space Flight Center. They are in Lambert azimuthal equidistant projection and were published (in a different projection) in Purucker *et al* 2000.

Martian magnetism

Mars, unlike Earth, has no global dipole magnetic field. The Mars Global Surveyor spacecraft confirmed this but also found strong, spatially variable magnetic fields at altitudes of 200 km down to closest approach of 110 km (Acuña *et al* 1999, Connerny 1999). Figure 2 shows hemispherical maps of the radial field normalized to a constant 200 km altitude. The fields are measured below much of the Martian ionosphere and much of the power in their spatial variability is at length scales comparable with the distance from the surface. 'Inversion' of these data is non-unique, but the source of the field must be confined to the outermost several tens of kilometres of the crust (and possibly confined to an even thinner layer). A deeper layer or source of currents could not provide the observed spatial structure, except with physically implausible assumptions. The inferred crustal magnetizations are up to 10–30 A m^{-1}, an order of magnitude higher than the strongest magnetizations typically encountered in Earth rocks, and even these values are underestimates if one were to require thinner magnetized layers or incoherent magnetization directions. Given the large amounts of magnetized crust required, it seems very likely that the magnetization is thermal remanence acquired during the last time the rocks cooled through the blocking temperature, for example following dike injection. Most of these cooling events took place at a time when a large global field was present. ('Most' rather than 'all' is appropriate here, because the surface magnetizations are so large that it is possible for crustal rock to be substantially magnetized through cooling in the presence of other crustal fields, rather than a global field.) Other origins of the magnetization (for example, due to impact, as suggested for the Moon) are conceivable in principle, but seem insufficient given the magnitude of the requirements.

There is great interest in the meaning of the spatial pattern of magnetization, including possible lineations that suggest an analogy to plate tectonically (see TECTONICS) derived lineations of magnetization on Earth's ocean floor, but the current constant-altitude (that is, constant-resolution) maps do not provide strong support for these speculations. Models of the crustal magnetization suggest that the Martian field may have undergone reversals.

It seems likely that Mars requires at least one (and preferably several) of the following: high abundance of appropriate magnetic materials (for example, magnetite), a particularly favourable magnetic mineralization (for example, single domains), large volumes of crust that are coherently magnetized and/or an unusually large field in which the magnetization was acquired.

The fact that Mars did have a global magnetic field for one or more periods in its early history suggests that it once had an active core dynamo, the process responsible for Earth's current field. The

strongest magnetizations are observed in the ancient southern highlands of Mars, which pre-date 4 Gyr. The antiquity of these regions is inferred by the (imprecise) method of crater counts. However, not all ancient crust on Mars produces large magnetic fields at the spacecraft altitude, and not all younger crust is devoid of magnetization. This prevents firm conclusions being made about the timing of acquisition of magnetization and hence the timing of a postulated Martian core dynamo.

Schubert *et al* (Schubert, Russell and Moore 2000) have suggested a later (post 4.0 Gyr) period of magnetization, which would indicate a later period of dynamo activity. However, some arguments point towards ancient (4.2 Gyr or earlier) acquisition. First, as noted by Acuña *et al* (Acuña, 1999), the ancient impact structure Hellas (believed to be at least 4 Gyr old) lacks any magnetic signature and seems to be surrounded by a region with very little coherent magnetization. This is a plausible outcome were the impact to have occurred when Mars possessed no global magnetic field. It is not a plausible outcome if the southern crust were subsequently reheated and then cooled to acquire magnetization during a later epoch in which a global field was active. Second, it is difficult to imagine any physically plausible scenario in which large provinces of the southern crust were extensively heated later in Mars' history without producing some surficial difference in appearance from those regions that were not so treated. This argument is supported by the recognition that huge volumes of crust are required to explain the observed magnetization, rather than some thin layer of possibly remagnetized material. In particular, revived igneous activity generating new crust would certainly disrupt these terrains because of the large amounts required. Third, evidence from the ancient Martian meteorite ALH84001 suggests that its magnetization was acquired at 4.0 Gyr or even earlier.

A region that lacks large magnetic fields at the spacecraft altitude might still consist of crust that formed in the presence of a global magnetic field. For example, the magnetization may be spatially incoherent, the cooling history may have favoured multidomain magnetite or less favourable mineralization, or the field may have been reversing more rapidly. Moreover, the early rapid pace of planetary evolution means that regions in the south that seem to be of the same age may nonetheless differ in age by 100 Myr and thus cooled in a different magnetic field, even though their surface appearance and crater density seem to be identical. Last but not least, ancient crust may underlay younger crust in some northern localities, thereby allowing preservation of a (relatively weak and patchy) magnetization, even when the surface age postdates any global field.

A Martian dynamo?

The dynamo mechanism is much studied but still imperfectly understood, despite recent advances in numerical simulation. In particular, we do not know the conditions sufficient for the existence of a planetary dynamo. Because we can only speculate about early conditions on Mars, the problem of inferring or predicting the history of a Martian dynamo is indeed formidable. Earth's dynamo is also imperfectly understood, although it is thought that it arises from convection driven largely by inner-core growth (Stevenson, Spohn and Schubert 1983).

If a dynamo exists, then it is likely that the expected field magnitude B inside the region of field generation is given by the Elsasser number of order unity. This implies $B \sim (2\rho\Omega/\sigma)^{1/2}$, where ρ is the fluid density, Ω is the planetary rotation rate and σ is the electrical conductivity. For the Martian core, this yields $\sim 10^{-3}$ tesla, but because this is the same prediction as for present Earth, the predicted palaeofield at the surface of Mars is indistinguishable (at the level of this crude argument) from the present field at Earth's surface. Dynamo theory admits weaker fields as possible solutions, but it does not admit fields substantially larger than $B \sim (2\rho\Omega/\sigma)^{1/2}$. Despite suggestions to the contrary (Stevenson, Spohn and Schubert 1983), there is no theoretical basis at present for the idea that the field scales in some direct way with the energy source, so that it might undergo slow decline over geological time or large changes arising from inner-core nucleation.

One speculative explanation for the origin of magnetization on Mars is that the field was generated in a magma ocean. Plausible numbers are a characteristic fluid velocity v of 10^{-1} m s^{-1} (because of very high heat flows at that time), a characteristic length scale L of 10^6 m and a magnetic diffusivity of 10^4 m^2 s^{-1} (possibly appropriate to high-temperature and high-pressure silicate melts), which together give a magnetic Reynolds number R_m of 10. This is marginal at best, but would be attractive because large fields are predicted (0.01–0.1 T at the Martian surface). The extremely high observed magnetizations might then be explained, although a core dynamo is more plausible.

Thermal or compositional convection?

If one accepts that core convection is needed, then a probable necessary condition for a dynamo is the presence of convection. In terrestrial planets (including Earth), the criterion for core convection is difficult to satisfy. The reason for this is that the natural scale for core heat flows is such that this heat can probably be carried by conduction at a temperature gradient that is stably stratified (that is, it inhibits convection). To obtain core convection, one must appeal to unusually large heat flows or the development of an inner core. In either case, the core must be cooling. To appreciate this argument,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

consider first the simple case of no inner core. Convection will occur provided that the heat flux within the core exceeds that which is carried by conduction along an adiabat:

$$F_{\text{total}} > F_{\text{cond.ad}} \equiv k\alpha Tg / C_{\text{p}} \Leftrightarrow \text{thermal convection}$$

where k is the thermal conductivity, α is the coefficient of thermal expansion, T is the temperature, g is the gravitational acceleration and C_{p} is the specific heat at constant pressure. These parameters are all slowly varying within a core (if T is close to being adiabatically distributed), except for g, which is approximately linear in radius r, the distance from the planet centre. If the core is simply cooling and releasing the stored sensible heat (provided by gravity during planetary accretion), then the total heat flux is also linear in r: $F_{\text{total}}(\text{r}) = -\rho C_{\text{p}} r(\text{d}T_{\text{c}}/\text{d}t)/3$, where T_{c} is the mean core temperature and t is time. It is unlikely that the core contains significant radioactive heat sources (even less likely than Earth, where one can always appeal to unknown, very high pressure effects). Consequently, if thermal convection ceases to operate in the outer part of the core, then it will also cease to operate at about the same time elsewhere in the core.

If the core is cooling and the central temperature drops below the liquidus for the core alloy, then an inner core will nucleate. In Earth, we know from seismic evidence that the core is ~10% less dense than pure iron, and many suggestions have been offered for the identity of the light elements that are mixed with the iron. At the lower pressures relevant to Mars, the dominant light element may be sulphur (Bertka and Fei 1998). For sulphur abundances that are less than cosmic relative to iron, as cosmochemical arguments suggest, the inner core will be nearly pure iron (with some nickel) and the sulphur will be entirely in the outer core. The introduction of this light element into the fluid of the lowermost core will tend to promote convection and cause mixing throughout all or most of the outer core, provided that the cooling is sufficiently fast. Latent heat release at the inner-core–outer-core boundary will also contribute to the likelihood of convection. However, inner-core growth permits outer-core convection even when the heat flow through the core–mantle boundary is less (perhaps much less) than the heat carried by conduction along an adiabat. In this regime (possibly that occupied by Earth), the temperature gradient is very slightly less steep than adiabatic and the compositional convection carries heat downwards. The total heat flux is still outwards, of course, as the heat carried by conduction is large. This state is possible because the buoyancy release associated with the compositional change exceeds the work done against the unfavourable thermal stratification. Unlike thermal convection, compositional convection may not cease everywhere throughout the core at a single epoch. This argument is modified in detail but not in general outline, should the core include a light element that does not exhibit eutectic behaviour (for example, silicon) as well as the (universally expected) complement of sulphur.

Required cooling rates

For plausible choices of parameters, the cooling rate of the core must exceed about 80 K Gyr^{-1} to obtain thermal convection. However, this estimate is uncertain by perhaps as much as a factor of 2. The required cooling rate in the presence of a growing inner core is much smaller, by a factor of several (Stevenson 1983), but has not been studied in detail for Mars. As a consequence, models with an inner core will tend to sustain a dynamo for a long time, perhaps even to the present day, unless there is something unusual about the thermal history (as suggested below). The overlying mantle determines the cooling rate. Indeed, it is the mantle that determines whether a terrestrial planet has core convection and whether it can have a dynamo.

It is also possible that the sufficient condition for a dynamo is not far removed from the necessary condition for the presence of any convection (Stevenson 1983). Simple scaling laws for convection (compatible with the philosophy of Kolmogorov turbulence and known to astrophysicists as mixing length theory) suggest that $v \sim 0.1(F_{\text{conv}}/\rho)^{1/3}$, where ρ is the fluid density and F_{conv} is the convective heat flux (or its compositional equivalent when the convection is driven by compositional density differences). I define

$$\varepsilon = F_{\text{conv}} / F_{\text{cond.ad}} = (F_{\text{total}} - F_{\text{cond.ad}}) / F_{\text{cond.ad}}$$

Substitution above shows immediately that for plausible parameters in the Martian core ($L \sim 10^6$ m, $\lambda \sim 1$ m^2 s^{-1}, $\rho \sim 10^4$ kg m^{-3}), R_{m} may be large even if $\varepsilon \ll 1$. That is, the heat flow has to only slightly exceed that for any convection in order to reach that for convection of sufficient vigour to sustain a dynamo. This claim must be tested by further numerical work. It is conceivable, but difficult energetically, for a dynamo to function for $\varepsilon < 0$ (for example, because of baroclinic instabilities and thermal winds arising from horizontal temperature gradients that are caused by lateral differences in heat flow through the core–mantle boundary). Even in this case, one would expect that a dynamo requires $|\varepsilon| \ll 1$, as the vertical motions would otherwise be strongly suppressed and this inhibits dynamo activity. Alternatives to convective driving (for example precession) still require the core to be close to adiabatic and thus do not escape the constraints discussed above.

In conclusion, if the mantle cools fast enough (or is cool enough to allow inner-core nucleation) then a dynamo occurs, but if the mantle is too hot or fails to cool then there is no dynamo.

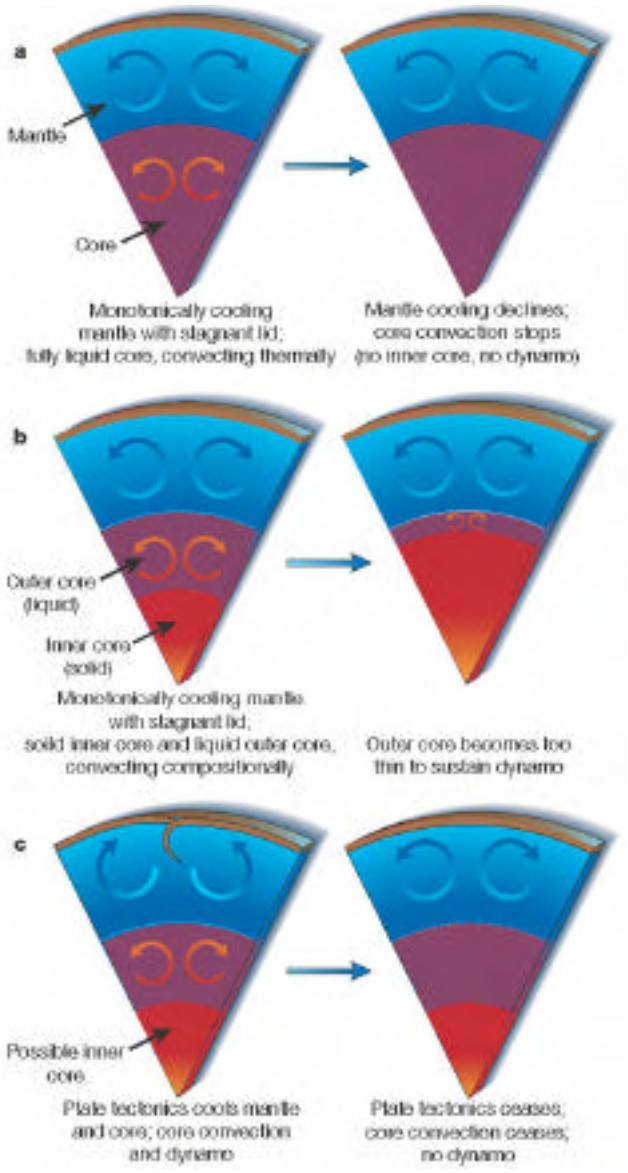

Figure 3. Possible scenarios of Martian core evolution: (a) high-sulphur model; (b) low-sulphur model; (c) plate-tectonic model (works for all sulphur contents).

Possible histories of the Martian core

Three possible scenarios for the history of the Martian dynamo are presented in figure 3. The first is the simplest: the planet starts out very hot and cools quickly at first. The core remains completely liquid throughout. As the cooling rate declines, a point is reached at which the heat flow out of the core can be accommodated by conduction alone. At that epoch, the dynamo turns off (in a very short time geologically, perhaps as little as a few thousand years) and no further field generation is possible, provided that an inner core never develops. This model requires that the core of Mars is sulphur rich, perhaps 10% or more by mass. It also requires tuning of the parameters so that the dynamo turns off as early in Mars' history as some arguments suggest. Most published models are of this kind.

The second scenario is almost the antithesis of the first. It has not been modelled in detail, although it is implicit in the early work of Young and Schubert (Young and Schubert 1974), who considered the possibility of complete core freezing. In this model, the sulphur content for the core is sufficiently low that an inner core develops early and grows rapidly. The liquid outer core becomes progressively more sulphur rich and evolves towards the eutectic composition. The experimental data (Fei, Bertka and Finger 1997) yield a eutectic of around 1400 K at the top of the core. For realistic models of Mars' mantle convection (Nimmo and Stevenson 2000), the expected present-day core–mantle boundary temperature is at least 1850 K, so there is no prospect that the outer core will completely freeze. However, it is conceivable that the outer core will become sufficiently thin that dynamo activity can no longer be sustained. This would seem implausible based on simple scaling arguments, but it might be the state that Mercury currently occupies. It probably requires a lower sulphur content of the Martian core than most would consider plausible, perhaps no more than a few per cent (even less than typical estimates for Earth). Further dynamo simulations are needed to test this hypothesis.

The third scenario invokes a change in mantle convection to trigger the death of the Martian dynamo (Nimmo and Stevenson 2000). It is assumed that early Mars had mobile lid convection in which the lithosphere could be recycled. On Earth, this is accomplished by plate tectonics, and this could also be the case on Mars (Sleep 1994). (It is, however, the recycling of the lithosphere that matters, not the form of the recycling; so there is no need to assume that Mars did exactly what Earth does.) At some time, perhaps after only a few hundred million years, this process ceased and Mars evolved slowly into the stagnant lid regime that it (and all terrestrial bodies except Earth) currently occupies. If this regime follows one of lithospheric recycling, then the mantle must heat up, because the elimination of heat is less efficient. In other words, the coldest time for the Martian mantle was early in Mars' history, despite the inexorable monotonic decline of radioactive heat sources in the mantle and the crust. This scenario has the advantage that it may work for all possible sulphur contents in the core, as the presence of an inner core will not drive a dynamo if the mantle minimum temperature was reached early in Mars' history. An inner core drives a dynamo only while it is growing, and it can grow only if the core is cooling. One problem with this scenario is that it invokes an *ad*

hoc timing for the cessation of 'plate tectonics'; it also implies the ability for Mars to be volcanically active throughout geological time.

In all these scenarios, the beginning of dynamo activity may be delayed after Mars' accretion until a thermal boundary layer builds up in the lowermost mantle, depending on the uncertainty in the initial temperature difference between the core and mantle. However, this is unlikely to produce a delay of more than 100 Myr.

There may be other scenarios not yet considered. Unfortunately, none of these scenarios can be tested with great confidence because the parameters that define their chronologies are not known with sufficient accuracy. However, the presence or absence or size of the inner core is clearly a crucial variable and may eventually be determined by a combination of geodesy and seismology. Numerical dynamo modelling will also be important in the coming years.

Consequences of the Martian core and dynamo

Core cooling dictates the presence of a thermal boundary layer at the base of the overlying mantle. Plumes can detach from this layer and may be a cause of hot-spot volcanism. Harder and Christensen (Harder and Christensen 1996) have proposed that Mars may be in a regime where a single plume dominates because of the effect of a major endothermic phase transition near the base of the Martian mantle (the same phase transition that defines the upper-mantle–lower-mantle boundary on Earth). This plume might be stable for a long period of time, perhaps billions of years, and may be responsible for the Tharsis volcanic province. This hypothesis provides the exciting prospect of linking core thermal history with Martian volcanic history. However, it leaves unanswered several questions. If the core heat flow is so low (as required by the absence of a dynamo throughout much of Mars' history), then is it reasonable to suppose that it is responsible for the dominant volcanic activity on Mars? Why would a deep-seated plume happen to produce volcanism at a location just northward of the principal geological feature (the crustal dichotomy)? Why is the plume so stable? Perhaps the answer to Tharsis lies nearer the surface of Mars rather than in the core history.

The history of the atmosphere (Brain and Jakosky 1998) (see MARS: ATMOSPHERE) may also be influenced by the magnetic field history through the effect of the field on atmospheric sputtering. The history of Martian magnetism might even be linked to the history of life on Mars. Perhaps the strongest argument for a biological effect in ALH84001 lies in the single-domain magnetite grains, whose presence in biological organisms is useful only while Mars has a field. This might also push Martian magnetism back to the earliest epoch.

The future

Although Martian core studies can benefit from work in all areas of planetary science (including geochemistry), the greatest contribution is likely to arise from seismological and geodetic efforts. In particular, the Mars Netlander mission and subsequent follow-ups are likely to have the greatest role. It may also be essential to better characterize the surface magnetization, something that no currently funded mission can do. We can also look forward to exciting developments in our understanding of dynamos. Mars' core is at least as interesting as Earth's core for our general understanding of planet evolution.

Mars: Surface

Like all bodies of the solar system, Mars initially experienced a period of heavy meteoritic bombardment that ended about 3.8 Gyr ago. The planet has remained geologically active much longer than Mercury or the Moon, and volcanism and tectonics have continued into a relatively recent past. However, activity was never efficient enough to conceal completely the previous stages of evolution; because of the small amount of energy available to reshape the surface, a large part of the ancient surface is preserved that dates back to the period of heavy bombardment, and the Martian surface presents a sort of catalog of the successive steps in planetary evolution. In the framework of comparative planetology, Mars represents the intermediate situation between the Moon and Mercury on the one hand and Venus and the Earth on the other hand. It is therefore a key element to understand the evolution of telluric bodies. In addition, Mars is probably the most favorable location in the solar system for the development of a prebiotic chemistry, or even for the development of life. These two elements explain why Mars has always been a favored target for space exploration. It is also the most accessible body in the solar system after the Moon, requiring only a 9 month journey with a new launch opportunity every 26 months. As we will see, the study of the surface leads to the inventory of volatile elements, so it is closely related to that of the atmosphere, and gives fascinating hindsight into the past climatic environments.

Historical perspective

Detailed observations of the surface became possible only half a century after GALILEO GALILEI first observed Mars around the year 1610, thanks to the progress of optical instruments. By the end of the 17th century Christiaan HUYGENS and G D CASSINI had produced the first drawings of Mars, determined the rotation period (24 h 40 min) from permanent markings on the surface and identified the polar caps. The most important subsequent observations were performed by Filippo Maraldi (from 1672 to 1719), W HERSCHEL (1777–1783) and J E Schroeter (from 1785 to 1802). By the mid-19th century, the main characteristics of the planet were known; the occurrence of atmospheric phenomena was recognized, together with the presence of dark and bright markings at the surface, and polar caps with large seasonal variations. The first attempt to compile a complete map was made by W BEER and J H MÄDLER in 1840. At this time, the dark areas were generally thought to be seas, following an assumption of W Herschel. Emmanuel Liais made the suggestion, in 1860, that they could be large patches of vegetation, thus explaining the changes in hue and brightness; this idea was widely accepted by the end of the century.

The modern era began with the close opposition of 1877, when G SCHIAPARELLI drew the first map based on precise measurements of surface features. The resulting map was much more detailed than any previous one, with old 'continents' resolved as intricated series of 'islands' and 'bays', so Schiaparelli had to abandon the feature names in use and introduced the foundation of modern nomenclature. This map was also the first one to report numerous 'canals'. Canals, previously mentioned by SECCHI and DAWES, were the first features reported on Mars with no terrestrial equivalent. They remained at the center of discussions about the Martian surface and habitability for several decades, mainly because of their interpretation by Percival LOWELL as artificial constructions. Although this interpretation was always debated, a majority of Mars observers (including C FLAMMARION, O von STRUVE, W Holden, W PICKERING, …) were convinced of the reality of the canals. It was only after E ANTONIADI's observations in 1909 that canals were largely recognized as an interpretation of a very subtle surface structure through the constantly moving terrestrial atmosphere; however, the matter was definitively settled only with the first spacecraft observations in the 1960s.

Planetary astronomy was relatively neglected in the US after the First World War, partly because of the long and sterile controversy about the Martian canals, but it remained vivid in Europe. Along with continuing detailed observations (mainly by Antoniadi, Focas, Maggini, SLIPHER, …), this period saw the first conclusive physical studies of the planet. The classical assumption that Mars was covered with seas did not survive the first atmospheric studies (1920–1950): both pressure and temperature are too low to permit the existence of liquid water. Concerning the surface, polarimetric studies in the 1940s (B LYOT, A Dolffus) suggested that the bright areas are covered by mineral dust with composition dominated by iron oxides; hydrated oxides were actually observed in 1964 by infrared spectroscopy (V Moroz). The assumption that dark areas are covered with vegetation was severely challenged by spectroscopic measurements in the 1950s (Sharonov, Sinton, Vaucouleurs, Kuiper, …) and more so by radar observations in the early 1960s (Goldstein and Gilmore, Kotelnikov) that yielded the first topographic measurements.

The emerging picture of Mars at the eve of the space era was very different from the conceptions of Lowell and Flammarion and resembled the modern view. However, the first close-up images, returned by Mariner 4 in 1965, surprised all Mars observers: the surface appeared much more Moon-like than Earth-like. Craters were never observed from the ground and seldom considered, and they appeared to be the most prominent surface features. Although Mariners 6 and 7 in 1969 confirmed this new view of Mars, they also evidenced more evolved processes in chaotic terrains and uncratered

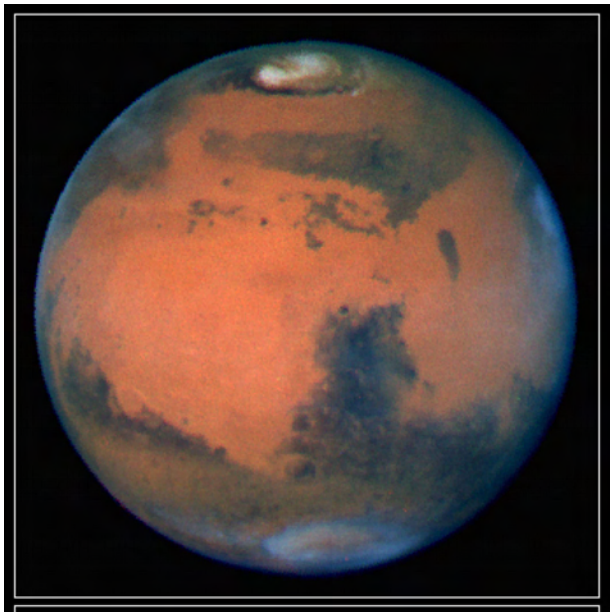

Figure 1. This view of Mars was taken with HST's Wide Field Planetary Camera-2 (WFPC2) on 10 March 1997, just before opposition, when Mars was about 100 million km from the Earth. The resolution is 22 km at the disk center. The image shows the planet during the transition between spring and summer in the northern hemisphere. The annual north polar carbon dioxide ice cap is rapidly sublimating, revealing the much smaller permanent water ice cap, along with a few nearby detached regions of surface frost. Bright water ice clouds can be seen in the giant impact basin, Hellas (near bottom of the image). The largest impact craters can be seen on such images (e.g. Schiaparelli on the left). The dark region at the center is Syrtis Major, a low volcanic shield. (David Crisp and the WFPC2 Science Team (Jet Propulsion Laboratory/California Institute of Technology).)

plains, but missed the more characteristic areas of the planet (see MARINER MISSIONS). The whole complexity of Mars became apparent only in 1971 with the first fully successful orbital spacecraft, Mariner 9. The VIKING MISSION, which consisted of two orbiters and two landers, was then operated for 6 yr (1976–1982). Limited but important additional information was provided by Mars 4 and 5 (1973–1974), PHOBOS-2 (1989) and MARS PATHFINDER (1997).

The main body of our current knowledge of the Martian surface still derives from Viking observations. Most of this information is related to surface morphology however, not directly to composition; even the geological maps are actually based on photointerpretation, while the nature of the soils is still poorly known. In this respect, two other sources of information are particularly important: SNC METEORITES, thought to come from Mars, and telescopic spectral observations in the near-infrared (pioneered in the 1960s by Moroz, Adams, and McCord). SNC meteorites provide direct compositional information but are not as useful as collected samples, since their source areas are unknown. High spatial resolution spectroscopy is less conclusive but provides the opportunity to understand the relationship between morphology and mineralogical composition over large areas, thus hinting at the processes that shaped the surface and at their succession in time.

Major features and main processes

Physiography

The most striking features on Mars, as seen from the ground, are the opposition between bright and dark

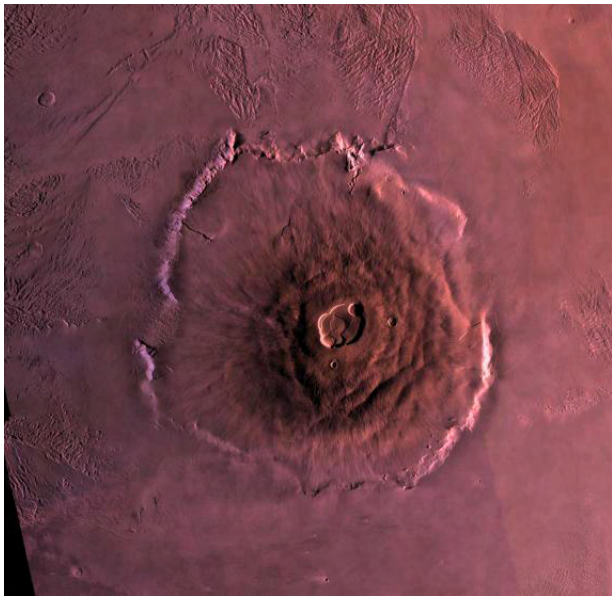

Figure 3. Five giant volcanoes are present on the surface of Mars, including Olympus Mons, the largest known volcano in the solar system. It is 27 km high and 550 km at its base, and the caldera is 90 km across and ~3 km deep. The volcano is surrounded by an outward-facing cliff up to 6 km high, recovered in places by lava flows. The plains surrounding the volcano are covered by the ridged and grooved 'aureole' of the volcano, extending 700 km to the northwest. The origin of the aureole is controversial: it may be related to gravitation-induced sliding of material from the flanks of an ancestral volcano or to a pyroclastic phase in the volcano's history. The small density of craters implies that the last periods of activity are relatively recent. (Mosaic of Viking images, NASA.)

areas, and variations in colors (figure 1). The orbital view is rather different, because local contrast is dominated by shadows, so that relief becomes apparent. The major morphological features consist of the following.

- There is a topographic and physiognomic asymmetry between hemispheres, often referred to as the Martian 'dichotomy' (figure 2). Old, densely cratered highlands are concentrated in the south, and younger low volcanic plains in the north. The difference in altitude is on the order of 3 km in general.
- A broad topographic bulge, Tharsis, is centered at the equator. This region is 8000 km wide and 10 km high and is covered by both old and young terrains. This structure has no equivalent in the solar system. It is surmounted by three huge volcanoes rising another 15 km or so in altitude.
- There are five enormous volcanoes, three of which are aligned on top of Tharsis and another one (Elysium Mons) is on a smaller bulge. The fifth one, Olympus Mons (figure 3), is the largest volcano in the solar system and rests in a low plain. It reaches 27 km at its highest point. The five giant volcanoes are built from fluid basaltic lavas and are similar in type to the Hawaii volcanoes.
- A huge canyon system, Valles Marineris, extends eastward from Tharsis along the equator (figure 4). The complex is 4000 km long, and reaches 600 km wide and 7 km deep in its central part. The canyons appear to be related to faulting and constraints that followed Tharsis formation.
- Channels tens of kilometers wide and hundreds long exist, similar to those produced on Earth by catastrophic flooding (figure 5). Most of them originate in the chaotic terrains east of Valles Marineris, cross the old terrains and merge with the low plains at 45° N.

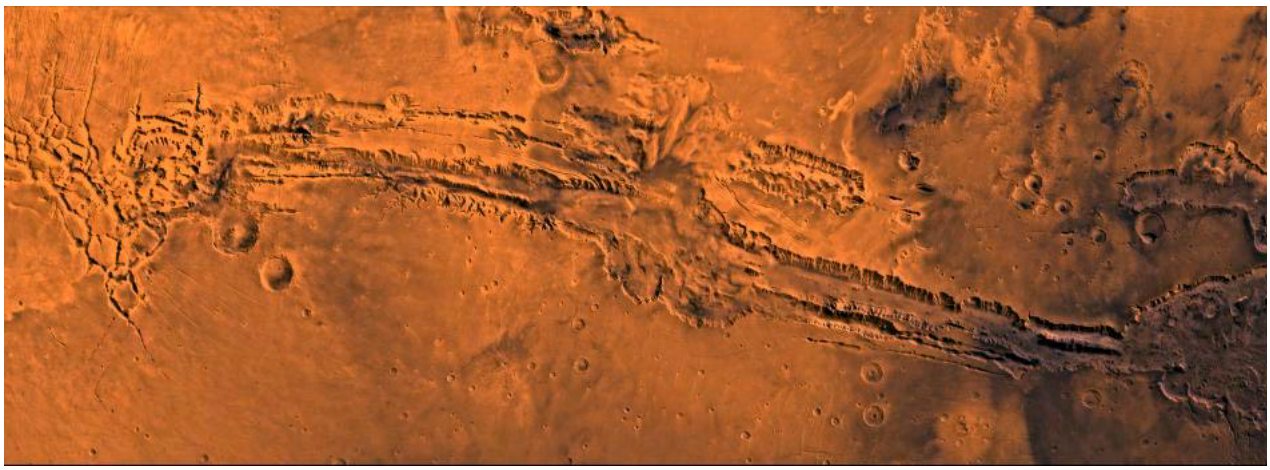

Figure 4. Synoptic view of Valles Marineris, the great canyon of Mars. The scene shows the entire canyon system, over 3000 km long and averaging 8 km deep, extending from Noctis Labyrinthus, the arcuate system of graben on top of the Tharsis bulge, to the chaotic terrains to the east. The connected chasmata of Valles Marineris originated as tectonic structures, and have later been modified by other processes, most notably mass wasting. The central and eastern parts contain layered materials and evidences of erosion by liquid water. Huge channels began from Valles Marineris and from adjacent canyons and ran north. Many of the channels flowed north into Chryse Basin, which contains the Viking Lander 1 and Mars Pathfinder sites. (Mosaic of Viking medium-resolution images in black and white and low-resolution images in color, Mercator projection.)

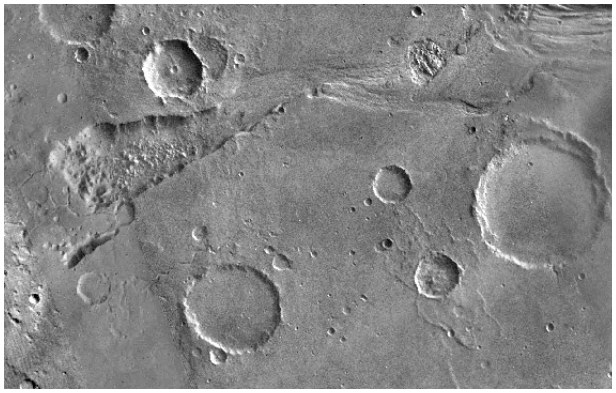

Figure 5. Chaotic terrains and outflow channels are concentrated east of Valles Marineris. This image shows a 300 km long portion of Ravi Vallis. Like many other channels, Ravi Vallis orginates in a closed depression with no apparent tributaries, suggesting that the water was released under great pressure from beneath a confining layer of frozen ground. As the water was released and flowed away the overlying surface collapsed; three such regions of collapsed material (chaotic terrains) are seen in this image, connected by a channel whose floor was scoured by the flowing water. Structures in these channels indicate that they were carved by liquid water moving at high flow rates. Ravi Vallis connects with a system of channels that ultimately flowed northward into the Chryse Basin. A small crater (~10 km diameter) with fluidized ejecta can be seen at the bottom of the image. (Viking mosaic from the Mars Digital Image Map, image processing by Brian Fessler, Lunar and Planetary Institute.)

- Polar deposits are 2–3 km thick with very thin layering (<20 m), cut by spiraling valleys. In the north they are surrounded by a vast, uncratered, dune field.

Although most of these constructs have their equivalent on Earth, they reach enormous dimensions on Mars. Conversely, some of the major terrestrial features do not have their counterpart on Mars, in particular folded mountains and mid-ocean ridges; sedimentary deposits are rare compared with the Earth, while 60% of the present surface is made of volcanic materials. These characteristics derive directly from the largest two differences between Mars and the Earth: their size (Mars' radius is only about half the Earth's, and its mass is one-tenth) and their distance to the Sun (Mars is 1.52 times further).

Main processes

Because of the smaller size the internal temperature of Mars never reached that of the Earth, and cooling was also more effective. In these conditions, the crust thickened and stabilized early in the history of the planet so that plate tectonics, the most effective resurfacing process on Earth, never developed on Mars. Therefore, very old terrains still compose a large part of the present Martian surface: the cratered highlands formed 3.8 Gyr ago, when impacts were the dominant process in the solar system, and are globally well preserved. The enormous size of the Martian volcanoes is another consequence of the absence of plate tectonics: all the material accumulates on the same spot, instead of building series of constructs as the plate shifts above the magma source, like in the Hawaii islands. There is evidence that the volcanoes have accumulated during a long part of Mars history but their surfaces exhibit very few craters, implying that the last eruptive events are relatively recent (~100 Myr?). Other types of volcanoes exist on Mars, in particular small domes and wide low-relief shields (paterae) composed mostly of ash deposits; most plains were also formed by successive deposits of lava flows all along the history of the planet. Although the period of volcanic activity was much longer than on the Moon, volcanism is probably exhausted today. Overall, it was the most widespread and effective process that contributed to the formation of the surface after the period of heavy bombardment.

The small size of Mars has resulted in a short period of geological activity and gas recycling, and the large Sun distance has not permitted a runaway greenhouse effect like that on Venus (see GREENHOUSE EFFECT). The combination of these has resulted in an atmosphere thinner than the Earth's and indirectly in a lower surface temperature and hence in different evolution processes. In particular, liquid water is unstable at the present time, so the most active surface processes on Earth (weathering, aqueous erosion and sedimentation) are only marginal on Mars. For this reason relief created by volcanism, tectonics or impacts remains largely unmodified, and considerable relief exists on Mars despite the small size of the planet: the overall altitude dynamic reaches 37 km, twice the Earth value. The only regulation is provided by the capacity of the crust to sustain the corresponding load, which explains the importance of fracture systems (in particular around Tharsis). On the other hand, the lack of liquid water also has resulted in limited sedimentary processes. Instead, the surface currently evolves mainly under the influence of winds and, to a lesser extent, landslides. Winds related to seasonal sublimation and condensation of atmospheric CO_2 on the polar caps are strong enough to cut the spiraling valleys in the polar deposits and form dunes fields at high latitudes. The polar deposits are successions of layers of ice and dust with proportions related to climatic variations; the absence of craters in these terrains implies that they are constantly modified at the present time. Other wind-related features include erosional and depositional streaks behind craters and erosional forms at lower latitudes (yardangs). Active dust deposition occurs in the northern hemisphere, with net south-to-north transport; this pattern is probably reversed on various time scales because of periodic changes in obliquity and eccentricity (see SOLAR–TERRESTRIAL CONNECTION: SHORT-TERM AND LONG-TERM CLIMATE VARIABILITY). The dust currently seems to be remobilized from southern areas rather than

Dirac House, Temple Back, Bristol, BS21 6BE, UK

formed from erosion of fresh surfaces, so that the fine materials are generally thought to be homogenized on a global scale and decoupled from the bedrock. Variations of surfaces markings observed from the ground are mostly due to aeolian transport of fines.

Aeolian processes appear to have been significant all along the history of Mars. However, there are numerous indications that other processes were active in a more or less distant past, in particular those related to liquid water and water ice, providing important clues about former climatic conditions and the degree of chemical and perhaps biological evolution.

In 2001, high-resolution pictures taken by the Mars Orbiter Camera on NASA's Mars Global Surveyor spacecraft show distinct, thick layers of rock within craters and other depressions, suggesting that they may have formed in lakes or shallow seas. Such layered rock structures where there were once lakes are common on Earth. The pancake-like layers of sediment have compressed and cemented to form a rock record of the planet's history. The regions of sedimentary layers on Mars are spread out and scattered around the planet. They are most common within impact craters of Western Arabia Terra, the inter-crater plains of northern Terra Meridiani, the chasms of the Valles Marineris, and parts of the northeastern Hellas Basin rim.

Although Martian highlands are very similar to lunar ones, these areas are significantly more evolved on Mars: they are dissected by valley networks and include smooth areas and craters with smoothed shapes. These differences reflect later evolution under the action of erosive processes and highland volcanism in the early stages of the planet's history. Valleys (figure 6) are particularly interesting since they imply the presence of running water at the surface in early times, and consequently a very different climate with higher temperature and pressure. At latitudes higher than 40°, highland craters are more rounded and degraded, and all escarpments are surrounded by lobate debris aprons, suggesting relaxation of soils with a large water ice content (permafrost). This is consistent with present climatic conditions, where underground water ice is potentially stable at high latitudes but not near the equator; accordingly, this process could still be active nowadays. Initial data from NASA's Mars Odyssey gamma ray spectrometer instrument suite has been used to detect hydrogen, which indicates the

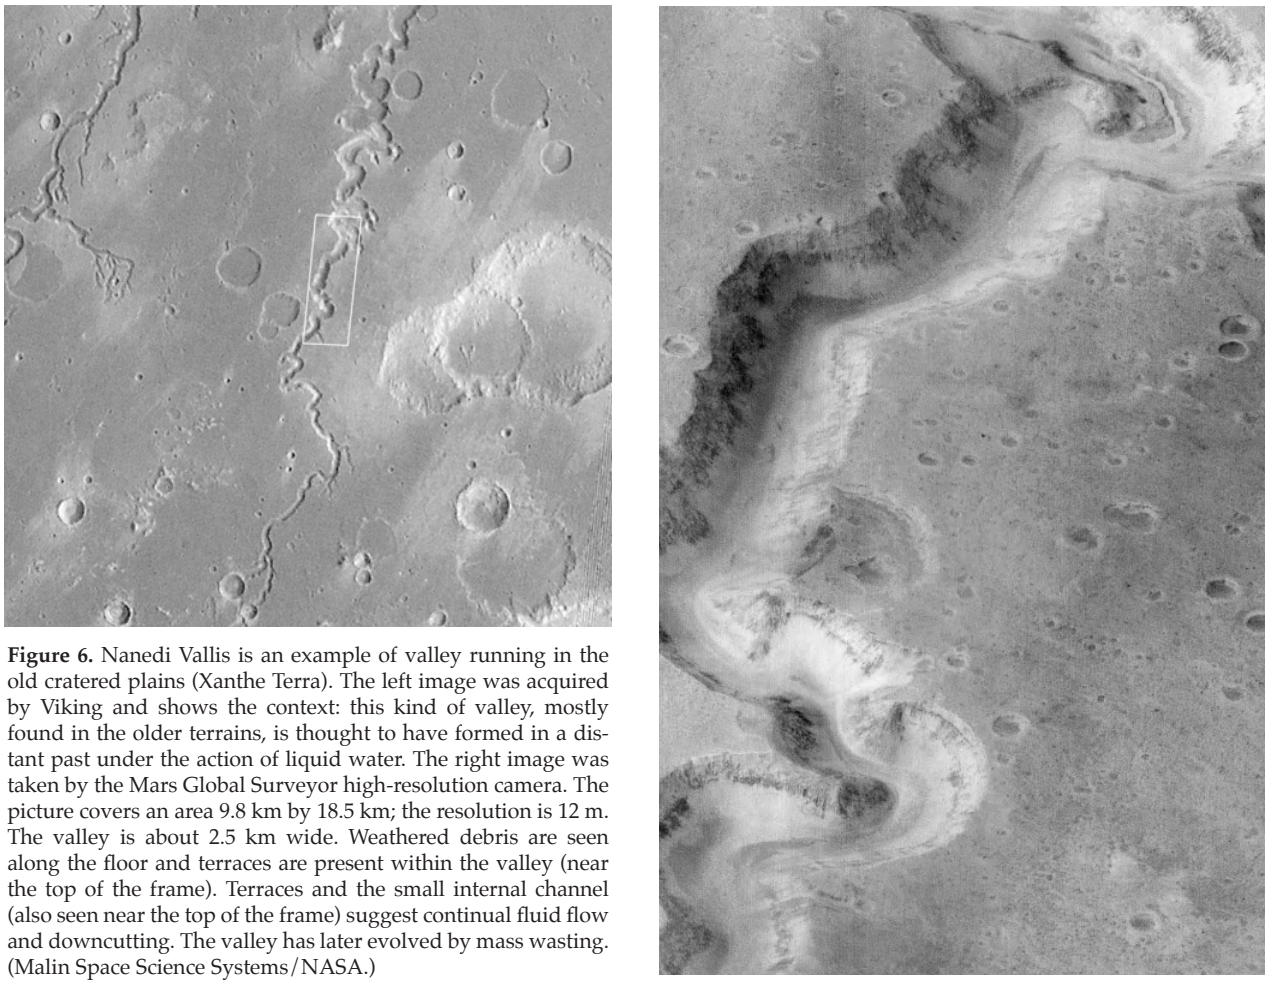

Figure 6. Nanedi Vallis is an example of valley running in the old cratered plains (Xanthe Terra). The left image was acquired by Viking and shows the context: this kind of valley, mostly found in the older terrains, is thought to have formed in a distant past under the action of liquid water. The right image was taken by the Mars Global Surveyor high-resolution camera. The picture covers an area 9.8 km by 18.5 km; the resolution is 12 m. The valley is about 2.5 km wide. Weathered debris are seen along the floor and terraces are present within the valley (near the top of the frame). Terraces and the small internal channel (also seen near the top of the frame) suggest continual fluid flow and downcutting. The valley has later evolved by mass wasting. Figure 7. Rampart craters represent a special cratering style found only on Mars: the ejecta deposits consist of one or several sheets with either rounded or lobate contours, sometimes ending with a pedestal escarpment. The 18 km crater Yuty in this figure exhibits overlapping ejecta sheets with complex lobate forms. This type of ejecta morphology is found mostly equatorward of 40°, whereas circular ejecta sheets are frequent poleward of 30°. Rampart craters are believed to form when the impacting object rapidly melts subsurface ice. The presence of liquid water in the ejected material allows it to flow along the surface, giving the ejecta blanket its characteristic, fluidized appearance. The spatial distribution of rampart craters of a given size permits to map the depth of the permafrost. (Viking Orbiter image 3A07.)

presence of water ice in the upper meter (three feet) of soil in a large region surrounding the planet's south pole. The amount of hydrogen detected indicates 20 to 50% ice by mass in the lower layer. Because rock has a greater density than ice, this amount is more than 50% water ice by volume.

Martian craters have another unique particularity: many of them have ejecta blankets lobate in form, clearly due to fluidized materials (figure 7). Although they may result from interactions with the atmosphere during ballistic emplacement, these shapes are better explained by impacts in soils with high water content, with ejecta emplaced as radially directed surface flows. Other glacial forms exist in particular at high latitudes, including thermokarst, patterned grounds, pingos and ridges similar to glacial moraines. These forms suggest that ice has played an important role in the evolution of the surface; they also put constraints on the distribution of ground ice along the planet's history.

Other major landforms related to water are found in the canyons, chaotic terrains and outflow channels. Outflow channels are morphologically different from highland valleys and much younger. Some of them originate in closed collapse zones, which suggests that they are related to sudden discharges of underground water under pressure. Typical forms are present in the channels, in particular streamlined islands and scour marks, that are reminiscent of catastrophic flood features on Earth such as the Channeled Scablands, Washington state, although on a much larger scale. The eastern and central parts of Valles Marineris contain thick layered terrains that were extensively eroded after deposition (figure 8). There is evidence that the layered terrains formed under ice-covered lakes filling the canyons; the water could have been released to the eastern chaotic terrains and channels during catastrophic events (landslides, impacts, …). Several episodes of filling and release of such lakes may have occurred in the canyons. However, various hypotheses have been proposed to explain the evolution of Valles Marineris on the basis of orbital images, and a knowledge of rock composition (volcanic versus sedimentary origin) is required to choose among them. The presence of lakes at low latitudes, even under a frozen surface, could imply an important change in climatic conditions in a relatively recent past. A much more speculative topic concerns the existence of an ocean in the distant past: it has been suggested on the basis of Viking images that the contact between highlands and plains in the northern hemisphere is an ancient shoreline contemporaneous with the layered deposits and outflow

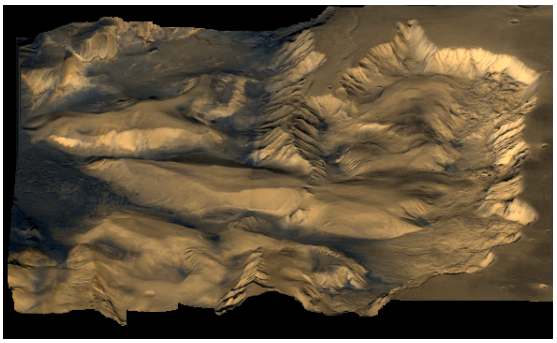

Figure 8. Oblique view of Candor and Ophir Chasmata in central Valles Marineris, from the east. The divide between the two canyons is a remnant of the plateau in which the canyons are cut. This part of the canyon was filled with materials that were later deeply eroded. Two different kinds of layering are visible in the image: in the canyon walls (successive episods of volcanism that formed the plains) and in the mesa-like formations inside the canyon (possible lacustrine deposits). The north–south direction and the gap between the two canyons may indicate drainage of material by catastrophic release of water. A variety of processes have contributed to the present landscape, including tectonics (the canyon itself), mass wasting (canyon walls, top right), wind (the fluted slopes of the layered terrains) and perhaps water and volcanism (layered terrains and canyon floors). (Composite of high-resolution black-and-white images from Viking 1 and color images from Viking 2. Image processing by Jody Swann, Tammy Becker and Alfred McEwen, USGS Flagstaff.)

channels. Radar observations from MARS GLOBAL SURVEYOR show that the possible contact line is close to an equipotential surface (as expected from a sea level) and that the terrains are very smooth below this level, thus supporting the idea of an ancient ocean.

Volatiles inventory and past climates

There is a striking paradox in the extent of water-related landscapes and the present amount of water in the atmosphere, which is equivalent to a layer of ~15 μm precipitated on the surface. In contrast, a layer about 500 m thick seems to be required to form the valley networks observed in the highlands (versus 3000 m present on the Earth). This estimate conflicts with much smaller quantities derived from planetary formation models and noble-gas measurements (10–100 m) but seems more reliable. Hence, most of the water has been stored in surface reservoirs for several billion years or has escaped the planet at the end of the heavy bombardment period. The residual polar caps and the regolith can store only a small amount of water. Conversely, the permafrost could retain up to several hundred meters of water, although no realistic estimates can be made of the actual amount tied up this way. At present, the water stored in the reservoirs can be released in the atmosphere only if the temperature is high enough, which is possible only if a sufficient amount of greenhouse gases, namely CO_2, is present.

Accordingly, periods of large water erosion indicate high temperature and high atmospheric pressure. The CO_2 pressure necessary to maintain liquid water on Mars is consistent with estimates of outgassing and is on the order of 1–5 bar. In such a situation, similar to the present Earth's, atmospheric CO_2 is continually depleted by formation of carbonate minerals in liquid water and refurbished by recycling of buried rocks through volcanic and tectonic processes. This process is ultimately controlled by the planetary heat flow. In the absence

Table 1. Tentative chronology of surface evolution.

Epoch	*Absolute age range (Gyr)*		*Events*	*Main processes*	*Proportion of present surface (%)*
	Hartmann–Tanaka	*Neukum–Wide*			
Late Amazonian	0.25–0.0	0.7–0.0	Aeolian resurfacing Final activity of Tharsis volcanoes Final evolution of Valles Marineris	Aeolian	7
Middle Amazonian	0.7–0.25	2.5–0.7	Polar layered deposits Outflow channels are still active	Volcanic Aeolian Periglacial	8
Early Amazonian	1.8–0.7	3.55–2.5	Late volcanic plains Erosion of layered terrains in Valles Marineris	Volcanic	11
Late Hesperian	3.1–1.8	3.7–3.55	Giant volcanoes Relatively hot climate? Liquid water may be stable or metastable Layered terrains in Valles Marineris Outflow channels and chaotic terrains	Volcanic Fluvial Periglacial	19
Early Hesperian	3.5–3.1	3.8–3.7	Important development of Tharsis and Elysium Earliest central-vent volcanism (highland paterae) First volcanic plains Development of Valles Marineris	Volcanic	16
Late Noachian	3.85–3.5	4.3–3.8	Hot and humid climate? Then dissipation of early atmosphere and cooling Highland valleys, fluvial resurfacing Highland volcanism	Volcanic (flood) Fluvial	12
Middle Noachian	3.92–3.85	4.5–4.3	Early development of Tharsis Highland formation and large basins Formation of megaregolith and sediments	Impact Volcanic (flood)	24
Early Noachian	4.6–3.92	4.6–4.5	Planetary formation First mantle differentiation Outgassing of early atmosphere	Impact Volcanic (flood)	4

Absolute ages are given according to the two time scale models indicated (Hartmann–Tanaka, Neukum-Wise). Adapted from Tanaka *et al* 1993 in Kieffer *et al* (1993).

of plate tectonics CO_2 recycling was never very effective on Mars, but the early warm and wet period could have lasted hundreds of millions of years, and could have favored rapid chemical reactions, possibly leading to biological evolution. With the secular reduction of the heat flow, this mechanism slowed down: recycling of CO_2 became less efficient, pressure and temperature decreased to the freezing point of water, water was stored mainly as ice under the surface, the remaining CO_2 was trapped in surface carbonates by slower processes, and to a lesser extent adsorbed in the regolith and frozen in the polar caps. The above model is largely theoretical, however; an alternate model states that the dense CO_2 atmosphere was dissipated during large-impact events, in which case carbonates would not have formed in large quantities (see MARS: ATMOSPHERE and PLANETARY ATMOSPHERES). For this reason an estimate of the abundance of carbonates, which have not been positively identified either on the surface or in the airborne dust so far, would give important constraints on the evolution of the primitive atmosphere.

Geological history

Ages of planetary surfaces are estimated through crater counts by comparison with lunar terrains, whose ages are known precisely from the Apollo samples (see CRATERS). Transposing this kind of dating to Mars involves making a hypothesis on the meteoritic flux, so that absolute ages will remain very uncertain until samples are returned from Mars. However, the relative age of the terrains can be estimated from photointerpretation alone. The time scale is divided in three main systems, Noachian, Hesperian and Amazonian, and eight subsystems. Table 1 summarizes the chronology of surface evolution.

Close view

The view from the surface is currently known only by images returned by the three American landers, Viking Landers 1 and 2 and Mars Pathfinder (figure 9). The two Viking landing sites were selected on the basis of minimal surface roughness inferred from the orbital images and are very similar to one another. They mostly consist of rocks standing in a layer of fine debris; VL1 site is less monotonous, with large patches of fines accumulating in dunes from place to place. Rocks range from centimeters to meters in size and are in general angular; they are thought to be ejectas excavated by nearby impacts. Dust particles are less than 10 μm in size but often aggregate in clods looking like rocks. The two Viking landers observed slow movements of the dust layer during their two Martian years of functioning, but little evidence for evolution of the rocks although climatic variations are large. In contrast, the Mars Pathfinder landing site was selected for its geological interest: it is located in an outflow channel east of Valles Marineris, and hence it was hoped to contain materials coming from different source regions. Although it is very similar to the previous two sites the landscape shows some possible evidences of flood but mainly demonstrates again that wind has been the major process at least in these areas for a huge period of time. Most of the rocks are volcanic in origin, but some rocks at the Pathfinder landing site show faint evidence of layering, consistent with a sedimentary origin.

All three landers performed basic chemical analyses of the surface materials. Viking landers analyzed the dust and the duricrust, while Pathfinder's robot, Sojourner, also analyzed rocks. Martian soils are consistent with weathering products of basalts, although they are richer in Fe and Mg, and poorer in K, than most terrestrial basalts; the most probable mineralogical compositions are mixtures of clays and ferric oxides. Duricrust samples have higher S content than the loose fines, suggesting formation by evaporation of salt-rich solutions, with sulfates as the cementing agent. All soils are very similar at the three landing sites, with high degrees of oxidation and high magnetic properties. Pathfinder rocks have composition similar to terrestrial andesites, with relatively high silicon contents. These rocks are obviously not representative of the diversity of Martian rocks, since

Figure 9. Enhanced image from Mars Pathfinder. The image is a mosaic of 300 camera images covering 360° of azimuth and elevations from approximately 4° above the horizon to 45° below it. Dark and bright rocks and bright soils are visible in the image. Dark rocks have elemental composition indicating more silica-rich basaltic andesite. These rocks are typically the small boulders and intermediate-sized cobbles at the Pathfinder site. Bright rocks have elemental spectra indicating basaltic compositions. These rocks are typically larger than 1 m in diameter and many display morphologies suggestive of flood deposition. Bright soils have a strongly reddened spectrum indicative of oxidized ferric minerals. Other materials are also apparent, including pink rocks with morphology indicating a cemented or rock-like structure. This material may be a chemically cemented hardpan that underlies much of the Pathfinder site. (Local solar time increases nearly continuously from about 10:00 at the right-hand edge to about 12:00 at the left.)

they are compositionally different from the dust, and have a much higher Al content.

Mineralogical and chemical compositions are distinct: for a given chemical composition, mineral formation depends strongly on the thermodynamical conditions, and minerals are therefore very useful indicators of past environments and formation processes. No mineralogical analysis has been performed at the surface so far, so the most direct source of information in this regard is provided by the SNC meteorites. These meteorites are believed to be igneous Martian rocks ejected during impacts, based on their young crystallization ages and close match between their gaseous inclusions and the Martian atmosphere. SNCs are not as informative as samples collected *in situ* would be, since there is no precise knowledge of their origin and thus little understanding of how representative they are of Martian crustal materials. These meteorites can be grouped in three large families, a younger one composed of basaltic rocks dominated by two pyroxene mixtures (Shergotty, Zagami, … formed ~180 Myr ago) and an older one dominated by Ca-rich pyroxenes and olivine, with very low concentrations of Al (Chassigny, Nakhla, …formed ~1.3 Gyr ago); ALH84001 is much older (~4.5 Gyr) and has a different origin. These three groups apparently have been ejected during three different impact events, possibly from the Tharsis region. Like materials analyzed *in situ*, all SNCs are richer in Fe than the terrestrial crust, probably reflecting a higher FeO content of the Martian mantle. In contrast with the rocks analyzed by Pathfinder, the SNCs are all poor in Al; hence they derive from an Al-depleted source region and probably formed later, but at least 1.3 Gyr ago. Compositionally, the global dust could derive from a mixture of Mg-poor SNCs (Nakhla, Shergotty, …) and rocks observed at the Pathfinder site. The occurrence of carbonates in SNC meteorites, together with a few ground-based observations at high spectral resolution, suggests that these minerals are indeed the major crustal sink for primitive CO_2. Alternatively, carbonates and other salts could have formed in restricted areas where volcanic activity resulted in a temperature high enough to maintain liquid water at the surface (hydrothermal springs). Globules of carbonates contained in ALH84001 were also presented as a possible byproduct of ancient life on Mars: microscopic shapes included in these globules were tentatively interpreted as fossil bacteria that lived on Mars 1.4–3.6 Gyr ago.

Global surface units

The surface exhibits marked contrast with respect to many observational parameters. Morphological units are commonly interpreted as geological provinces. Surface units defined by other measurements do not necessarily correlate with them, owing to the thickness of the layer scanned by different methods: visible and near-infrared spectroscopy analyzes the first few microns only and gives information on mobile materials, crusts, veneers. Mid-infrared and radar measurements penetrate to a deeper layer, from which rock abundance can be estimated. Multiple observations at different wavelengths help us in understanding the composition and physical state of the materials present on the surface.

As viewed from the ground, the major opposition is between bright and dark regions, with the polar caps constituting a third type. In violet to green light, these soils are equally dark (geometric albedo ~5%) and the surface is almost completely featureless. At longer wavelength, the contrast increases very rapidly and reaches a factor of 4 in the near-infrared (from 0.7 to 2.7 μm). All soils are actually very red in color, the greenish hue reported by 19th century observers being mostly a contrast effect. Seasonal color variations are largely due to scattering by airborne dust and are related to dust storms. At higher spatial resolution, another type of unit with intermediate reflectance and color can be recognized on Viking and HUBBLE SPACE TELESCOPE images. This unit includes bright crater rims and dark patches, so it was first interpreted as a mixture of dark and bright materials; it is currently interpreted as bright materials indurated by local processes. The Viking cameras have also shown a small-scale variability within dark areas, while bright regions are more uniform.

Other important information is provided by mid-infrared radiometry and radar observations, from which thermal inertia and rock abundances can be derived. Rock abundances estimated this way have been confirmed at the Pathfinder site. Four main units have been identified on the basis of all these physical properties at latitudes lower than 60°.

- Bright, fine materials are interpreted as loose dust. The corresponding areas are regions of active dust accumulation several meters thick (e.g. Amazonis, Arabia).
- Dark, coarse materials are interpreted as exposed rocks with constant deposition and removal of a thin dust layer (e.g. Acidalia, SYRTIS MAJOR). In some areas, however, this unit seems to correspond to accumulation of dark sands.
- Intermediate materials with high thermal inertia are interpreted as indurated surfaces (cemented dust).
- Bright materials with high thermal inertia are interpreted as areas of limited dust accumulation. Both Viking landing sites are located in such regions, which are rather uncommon (e.g. Chryse Planitia, Elysium Planitia).

Most units appear relatively young and active, indicating that the upper surface is continually being reworked, in particular by aeolian processes and duricrust formation.

Concerning composition, the most effective method to retrieve information on a global scale is by infrared imaging spectroscopy in the 0.6–20 μm range. Minerals, and therefore rocks, can be identified from their infrared spectra even at modest spectral resolution. Conversely, high spatial resolution is critical to detect materials of limited exposures, e.g. produced by local processes; on Mars, mineralogical interpretation is also complicated by atmospheric absorption and scattering and by mixing of surface features in absorption and emission above 4 μm. Overall, the spectra of every region can be matched by more or less oxidized basalts, so that spectral characteristics are dominated by ferromagnesian ('mafic') volcanic materials and their alteration products. Bright regions are spectrally very homogeneous and are dominated by subtle features of hydrated ferric oxides, while dark areas have spectra typical of ferrous absorptions in mafic minerals such as pyroxenes and exhibit a greater variability. This is consistent with the interpretation that bright regions are covered by a thick layer of weathered dust mixed at the planetary scale, while dark areas have large bedrock exposures and are contaminated at various levels by bright materials.

The freshest dark equatorial regions have spectral characteristics indicating a volcanic mineralogy dominated by two pyroxenes with high and low calcium content (perhaps augite and pigeonite), similar to the basaltic SNC meteorites (e.g. Shergotty, Zagami). The range of ages for these regions indicates that the SNC analyses are relevant to large regions of Mars and to a large lapse of time (3.0–0.13 Gyr). Such materials are not common on the Earth's surface and are probably derived from a source region depleted in Al relative to the hypothesized original mantle composition. An interpretation of these observations is that a primary planetary differentiation occurred very early in the history of Mars (4.5 Gyr) and that the mantle reservoirs have not been remixed since. The depletion in Al could be explained by the presence of a crust enriched in Al, perhaps similar to the lunar highlands; such rocks were actually observed at the Pathfinder site, but their source area is unknown. The occurrence of significant amounts of olivine in dark areas would be inconsistent with the idea of an early differentiation. Although detection of olivine-rich materials was claimed in the past, these observations are not confirmed by recent data. Instead, most of the second-order variations are explained by small amounts of dust and perhaps thin alteration coatings of ferric materials on the rocks themselves.

In bright areas, the only mineral phase that has been positively identified so far is hematite, an iron oxide. Spectral features are subdued and indicate a low degree of crystallization in most areas, so that hematite is thought to occur mainly as extremely fine-grained, or nanophase, particles; furthermore, all bright regions have deep hydration bands, corresponding to an adsorbed- or bound-water abundance of ~1% with local and temporal variations. These materials are clearly alteration products of mafic minerals exposed in the dark areas; the present rate of weathering and dust formation is unknown but is certainly small, and hence most bright materials were probably formed in a distant past. The 'classical' rock analogs for bright regions are palagonites, which are formed by alteration of mafic volcanic glasses under low temperature, often by interaction with water ice. Spectral properties of palagonites are dominated in the near-infrared by nanophase hematite, although it is only a minor component dispersed in a silicate-clay matrix that can include other salts, such as sulfates. Overall, large amounts of palagonites are consistent with spectral observations, *in situ* analyses, thermodynamical considerations and composition of SNC meteorites. Most of this material could have formed during volcanic eruptions through a thick permafrost. The unusual magnetic properties measured by the landers may indicate significant amounts of maghemite, an iron oxide. Airborne dust, which should be compositionally similar to the bright surface materials, has been observed chiefly in the mid-infrared; its spectrum in this domain is more consistent with iron-rich clays.

Subtle local variations are observed in bright regions, indicating that some bright materials are not remobilized and mixed. Most of these variations are ascribed to differences in particle size or degree of crystallization, but some small areas could have high concentrations of other alteration materials: smectite clays, oxyhydroxides, iron sulfates, chlorides, hydrous carbonates, …. These minerals are potentially very helpful indicators of past climates, since they are the major sinks for H_2O, CO_2 and other volatile components such as nitrogen. Some of them have been tentatively detected in the airborne dust, but their spatial distributions and properties must be known to improve our knowledge of the surface evolution. Similarly, 'anomalous' dark materials provide important hints about the major puzzles concerning the surface. In particular, an unusual material observed in the layered deposits of Valles Marineris, with both mafic and hydration characteristics, suggests that hydrovolcanism was an important factor in the development of these areas.

Conclusion

Our present perception of Mars results mostly from the Viking mission, analyses of the SNC meteorites and ground-based spectral observations. Large gaps remain in our current understanding of the planet, however, while Mars is a key factor in the study of the solar system's evolution; in addition, the Martian origin of the SNCs is not definitely demonstrated although a large part of the present ideas concerning Mars derive from

their study. Some of the most important open questions are related to chronology, composition and volatiles inventory: there is no absolute dating of the terrains; the amount of volatiles outgassed and the current reservoirs are unknown; the present rate of alteration and the main period of dust production are unknown. All these questions would be best addressed by collecting samples in well-characterized locations on the surface and by high-resolution orbital observations of particular areas such as hydrothermal deposits. The canyon walls also provide a natural traverse in the successive volcanic materials accumulated in the plains and a unique opportunity to probe the sequence of event leading to surface formation.

Other questions relevant to the geological evolution include the following. What are the current and past heat flows? How and when did the Tharsis bulge form? What is the history of Valles Marineris (its relations with Tharsis, nature of the layered deposits, extent of volcanic processes, fate of the materials evacuated)? Were there lakes or even oceans on Mars (when, and what is their relation to the channels)? How long did the warm and wet period last? What was the extent of prebiotic evolution, if at all? In this regard, the study of Mars could help understand the first stages of life's evolution on Earth.

NASA's Global Surveyor has revealed images which suggests the Martian climate is changing significantly, even today. The observations were made during a full Martian year, 687 Earth days and show that pits—often referred to as the 'Swiss cheese' terrain—at the southern polar ice cap of Mars have dramatically increased in diameter, indicating the material has evaporated rapidly compared to last year. Images of the south polar cap taken in 1999 were compared with images of the same locations taken in 2001, and it was discovered that pits had enlarged, mesas had shrunk, and small buttes had vanished. In all, the scarps that enclose the pits and bound the mesas and buttes retreated about 3 m in one Martian year. This rapid retreat of polar scarps can only occur if the ice is frozen carbon dioxide (dry ice). Retreat of scarps made of water ice is much slower and would not have been measurable from one Martian year to the next.

Some of these issues will be addressed by the ongoing Mars Surveyor program (NASA), the MARS EXPRESS mission (ESA), and the future Mars sample return program (NASA–CNES (see SOLAR SYSTEM: EXPLORATION)). *In situ* analyses and sample return should be performed in different geological settings, and their results extended to the whole surface by means of orbital remote sensing. Even in the space era, however, ground-based observations remain important. Large orbital observatories like HST and ISO, or the NGST project, have not changed this situation radically, since they are limited by observational schedules and solar pointing constraints. In a threefold approach where spacecraft yield exceptionally detailed but exceptionally rare data, and spaceborne observatories provide high resolution at limited viewing geometry on a year-to-year basis, ground- based observation is still the only method to monitor quick processes on Mars and to clarify the context for future spaceborne observations.

Mars: Water and the Martian Landscape

Over the past 30 yr, the water-generated landforms and landscapes of Mars have been revealed in increasing detail by a succession of spacecraft missions. Recent data from the Mars Global Surveyor (MGS) mission confirm the view that brief episodes of water-related activity, including glaciation, punctuated the geological history of Mars. The most recent of these episodes seems to have occurred within the past 10 million years. These new results are anomalous with regard to the prevailing view that the Martian surface has been continuously extremely cold and dry, much as it is today, for the past 3.9 billion years. Interpretations of the new data are controversial, but explaining the anomalies in a consistent manner leads to potentially fruitful hypotheses for understanding the evolution of Mars in relation to Earth.

When the Mariner 9 spacecraft (see MARINER MISSIONS) went into orbit on 14 November 1971, the surface of Mars was shrouded in a global dust storm. Fortunately, by March of 1972, the atmosphere cleared and the true complexity of the Mars landscape was finally revealed to the spacecraft's vidicon cameras. In addition to the immense volcanoes of Tharsis, there was a great equatorial canyon system, Valles Marineris, named for the discovery spacecraft. Most remarkable, however, were sinuous channels and valleys, from whose morphology it was inferred that water had once flowed on the surface of this now dry, unearthly cold planet. The late Harold Masursky, science team leader for the vidicon imaging experiment, wrote in 1973 (Masursky 1973):

> The possible fluviatile channels may record episodes when water was much more abundant in the atmosphere than it is at present. Planet-wide warmer interglacial periods would release not only the water locked in the polar caps but also that frozen in the subsurface as permafrost. Similar warmer and colder periods also are characteristic of terrestrial history.

Although intended primarily as support to landers seeking evidence of Martian life, the Viking orbiters (see VIKING MISSION) of the late 1970s returned 52603 images of Mars, most of them at much higher resolution than the 7329 images returned by Mariner 9. The pictures with the highest resolution have a pixel spacing of 7.5 m, although most frames resolve to several tens of metres. Viking orbiter images (figure 1) provided the basis for an understanding of water and landscape that prevailed until the past few years.

In 1997, MGS spacecraft was inserted into Mars' orbit, but a variety of problems prevented it from achieving a circular mapping orbit until 19 February 1999. Two instruments are particularly relevant to the scientific study of the Mars landscape. The Mars Orbiter Camera (MOC) achieves a resolution of 1.4 m per pixel, but the required high data volume limits scenes to a kilometre or so in width at the highest resolutions. The Mars Orbiter Laser Altimeter (MOLA) maps the topography of Mars with a precision better than 10 m (Smith *et al* 1999). Together these instruments provide new data for studying Mars' landforms (figure 2), although human reasoning about those landforms remains a matter of long-standing scientific experience.

The study of Earth-like planetary surfaces—geomorphology—is not a disjointed collection of observational facts solely with which to test, or against which to constrain, theoretical models. Rather, such scientific inquiry proceeds from the informed colligation of landform observations to the discovery of consistency and coherence and, ultimately, to consilience in the theoretical accounting (explanation) of those observations. The key element of this inquiry is the formulation of one or more working hypotheses, which are most often suggested (but not proved) by analogies of form and context among landscapes of known origin and those under scrutiny. In the retroductive inferences of geomorphology, analogy

serves merely to suggest fruitful working hypotheses, thereby leading to completely new theories that bind together any newly discovered facts. Mars' landscape provides particularly stimulating opportunities to practise geomorphological reasoning, generating hypotheses that may initially strike some researchers as outrageous. Nevertheless, it is the productive pursuit of such hypotheses that leads ultimately to new understanding, not only of Mars, but also of Earth itself.

The surface of Mars is today extremely cold and dry. The atmosphere at the land surface is over 100 times less dense than that of Earth and it holds only minuscule amounts of water vapour. For the present obliquity (tilt of the planet's rotational axis with respect to the orbital plane) of 25°, the residual north polar ice cap sublimates water in the northern spring–summer and the vapour moves to and condenses at south polar areas, a pattern that may reverse in northern autumn–winter (Kieffer, Jakosky, Snyder and Matthews 1992). Given its minor role in comparison with that on Earth, it is not surprising that on present-day Mars, water is replaced by wind as the most continuously active surface-modifying process.

In stark contrast to the current environment, however, numerous landforms provide signs, or indicators, of extensive past activity of water and ice on the Martian surface (see MARS: CLIMATE HISTORY). From the densities of impact craters on the various terrains it is possible to work out a chronology for this activity, such that Mars is divided stratigraphically into ancient heavily cratered uplands that formed prior to about 3.5 billion years ago (the Noachian epoch), intermediate cratered plains (the Hesperian epoch) and more lightly cratered areas (the Amazonian epoch). Water and ice were active on the surface during all these periods. The mode, timing and long-term cycling of water in surficial processes are the phenomena to be considered from the various signs of activity.

Signs of subsurface water and ice

Landforms indicative of ground ice in permafrost (perennially frozen ground) on Mars have been known since the early flyby missions of the 1960s. Images from Viking orbiters provided an overwhelming list of permafrost and ground-ice indicators, including various kinds of patterned ground, thermokarst, hillslope features and mass-movement phenomena. Although originally attributed to permafrost processes, the immense polygons, 3–20 km across, of the northern Mars plains are much larger than the contraction-crack polygons typical of terrestrial permafrost terrains. These features are now explained variously as the tectonic uplift of basin floors, perhaps following removal of load from an overlying standing body of water, or as the result of Rayleigh convection driven by unstable density or temperature gradients in a catastrophic flood deposit positioned over frozen ground (Lane and Christensen 2000). Recently acquired very high-resolution MOC imagery reveals extensive areas of the northern plains and southern highlands of Mars, notably on crater floors (figure 3), where small-scale contraction-crack polygons, tens or hundreds of metres across, cover the landscape (Seibert and Kargel 2001). This polygonal terrain, which closely mimics the ice-wedge polygonal terrains of terrestrial permafrost areas, is essentially uncratered, indicating a surprisingly youthful phase of water-related activity on Mars.

Viking pictures revealed that many Martian craters have a unique morphology, different from that observed elsewhere in the solar system. Ejecta surrounding these craters are layered and each layer has an outer edge terminating in a low ridge or escarpment. Named 'rampart craters', the flow-ejecta morphology most likely represents the incorporation of groundwater and ground ice, although atmospheric effects on ejecta emplacement may also be important. Thus, layered ejecta morphologies can

be used to characterize the past presence of water in various Martian terrains.

First revealed by Mariner 9, the long and complex volcanic history of Mars contains a wealth of examples of interactions among volcanism, ice and water. Much as in the Pleistocene landscapes of Iceland, Martian volcanism has produced features interpreted as table mountains built up on products of subice eruptions, outburst flood channels and extensive pyroclastic landscapes. Some of the youngest volcanic landscapes occur in the Cerberus Rupes and Marte Vallis region (Hartmann and Berman 2000), where cataclysmic flood channels and volcanic lava flows occur in close spatial and temporal association. Even Olympus Mons, one of the largest known volcano constructs, has a morphology interpreted by some to be indicative of water/ice volcanic interactions. Its huge aureole deposits, extending 1000 km, may represent immense submarine landslides, similar to those of Earth's Hawaiian Islands.

Initial data from NASA's Mars Odyssey spacecraft suggests possible identification of significant amounts of frozen water in the upper meter (three feet) of soil in a large region surrounding the planet's south pole. The gamma ray spectrometer instrument suite has been used to detect hydrogen, which indicates the presence of water ice. The amount of hydrogen detected indicates 20 to 50 percent ice by mass in the lower layer. Because rock has a greater density than ice, this amount is more than 50 percent water ice by volume.

Signs of surface water

The heavily cratered Martian highlands are locally dissected by integrated networks of tributaries with widths of about 10 km or less and lengths from <5 km to nearly 1000 km. Drainage densities are generally much lower than for terrestrial valley networks, although an interesting set of valleys on Martian volcanoes is more similar to terrestrial valleys in their general morphology and degree of terrain dissection. Among the other important morphological attributes of Martian valley networks are the following: theatre-like valley heads, prominent structural control, low junction angles, quasi-parallel patterns, hanging valleys, irregular widening and narrowing and indistinct terminal areas. In general, this assemblage of features seems best explained by groundwater sapping processes (Gulick 2001), excellent examples of which occur in the sandstone terrains of the Colorado plateau and in parts of the Hawaiian Islands.

Although most of the networks occur in the heavily cratered terrains of Mars, as many as 25–35% of the valleys may be Hesperian or Amazonian in age. Moreover, MOC images show that some valleys, which formed early in Mars' history, were later reactivated by smaller flows—a discovery that had been expected from Viking data. Another observation, the localized development and incomplete dissection of upland areas by valleys, is reinforced by the lack of fine-scale tributaries to valleys observed at MOC resolution. Explanations for such relationships remain contentious, with lack of precipitation as only one of several alternatives, others of which include the probable high infiltration capacities of the Martian surfaces, the burial of small-scale features beneath mantling deposits and the local hydrothermal and/or snowmelt processes (Gulick 2001).

Many valley networks have orientations consistent with the effects of surface deformation by extensive volcanic loading at Tharsis, inferred to have occurred by late Noachian time (Phillips *et al* 2001). These networks occur in heavily cratered terrains that show evidence of extensive erosion during the Noachian. The average rates for this presumed water erosion are estimated at 10^2–10^4 mm per 10^6 yr, which are comparable with the lower range of terrestrial values. However, post-Noachian rates are estimated at only 10^{-1}–10^{-2} mm per 10^6 years (Golombek and Bridges 2000). This discrepancy led some researchers to postulate an epoch of late Noachian climate conducive to water erosion, followed by post-Noachian conditions that precluded such erosion (Carr 1999). However, if post-Noachian aqueous erosion episodes are limited to very short episodes, then the average post-Noachian erosion will yield the same rate as calculated.

The term 'channel' is properly restricted to one class of Martian trough-like landforms that display at least some evidence for large-scale fluid flow on their floors. The principal landform of interest here is the outflow channel, which shows evidence of flows emanating from zones of regional collapse known as 'chaotic terrain'. The

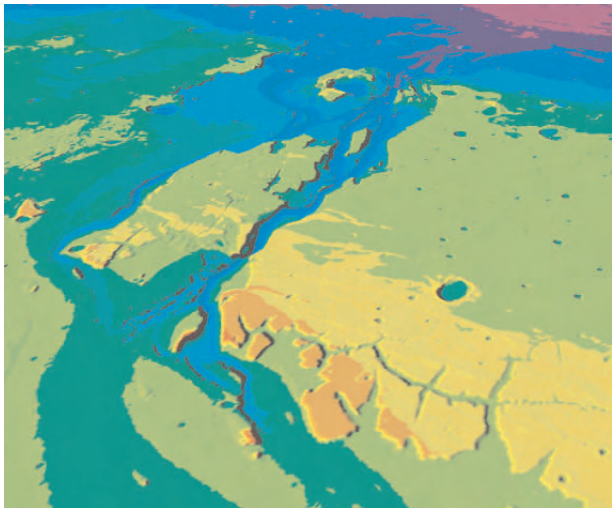

Figure 4. Oblique view of topographic data from the MOLA showing downstream portions of the outflow channel Kasei Vallis.

Martian outflow channels are immense (figure 4), as much as 150 km wide and 2000 km in length. It was recognized shortly after their discovery that they possessed a suite of bedforms and morphological relationships similar to what is exhibited in the 'Channeled Scabland', a terrestrial landscape created by Pleistocene glacially related cataclysmic flooding in the northwestern coterminous United States.

At their largest scale, the outflow channels are broadly anastomosing and split by residual uplands, or 'islands', of pre-flood-modified terrain (figure 2). The channels have low sinuosity and high width–depth ratios. Pronounced flow expansions and constrictions occur, as do prominent divide crossings, hanging valleys and structural control of erosion. At a finer scale, streamlining of the residual uplands is very well developed, as are longitudinal grooves, inner channels, cataract complexes, scabland and bar complexes. Although a variety of other fluid-flow systems have been invoked to explain these features, the whole assemblage of these landforms is best explained by cataclysmic flood processes, with particular analogy to the origin of the Channeled Scabland. Nevertheless, it is also recognized that some important differences derive from the peculiar Martian environment, notably its lower gravitational acceleration, its much lower atmospheric pressure and its prevailing subfreezing temperature in comparison with Earth. These special conditions on Mars would influence such factors as sediment transport mechanics, cavitation and ice formation, debris flow and possible large-scale ice processes in the channels (Lucchitta 2001).

The sizes of Martian outflow channels imply immense discharges of water, exceeding any known flood flows on Earth (figure 5). The calculated peak-flow magnitudes are comparable with those of the high-discharge western boundary currents of Earth's world ocean, such as the Gulf Stream, the Kuroshio and the Agulhas (Baker in press). These currents are integral to Earth's climate system, distributing heat poleward from equatorial latitudes. Major disruption of Earth's circulation pattern provides an endogenetic model for large-scale terrestrial climate change. By analogy, Mars' climate could have been impacted by the megaflood discharges transferring water and heat from the equatorial Tharsis volcanic province to the northern plains of the planet. Outflow activity was probably initiated in the Noachian and outflow events occurred during the early Hesperian, the late Hesperian/early Amazonian (Ivanov and Head 2001) and, surprisingly, during the past 10 million years (Hartmann and Berman 2000). The latter floods occurred in the Marte Vallis–Cerberus Rupes region and the Tharsis area. Thus, principal fluvial events (and possibly associated climate change) occurred right up to most recent Martian history. Alternatively, however, outflow channel events are considered to be random outbursts from a progressively thickening cryo-sphere.

Integral to the controversy over post-Noachian water-related climate change on Mars is the lack of understanding of how such immense discharges can be released from the Martian subsurface. The role of the cryosphere seems important, perhaps for generating pressurized aquifer confinement (Carr 2000). Dike emplacement and penetration of the ice-rich cryosphere (Head and Wilson 2001), pressurized volcanic influences on fracture systems and decompression of gas hydrates deep in the crust (Komatsu *et al* 2000) are other possible factors in the cataclysmic release of outburst floods.

The largest outflow channels delivered their immense discharges to the northern plains of Mars.

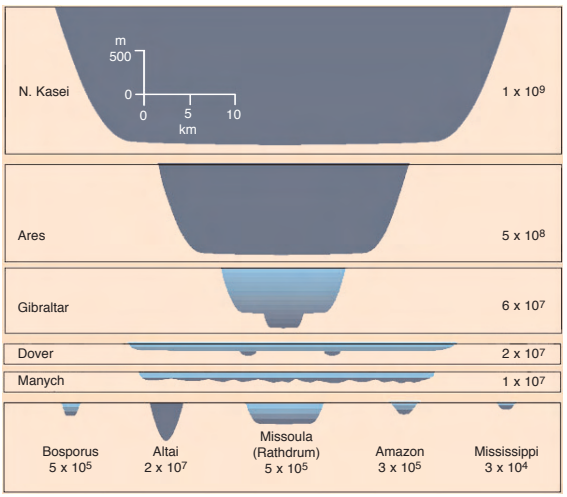

Figure 5. Comparison of simplified channel cross-sections for cataclysmic flood channels on Mars (upper two channels) and Earth (lower channels).

Evidence of temporary inundation of the northern plains was recognized on the basis of Viking data and some aspects of the inundation hypothesis are consistent with new results from the MOLA instrument (Head *et al* 1999). These include the extreme topographic smoothness of the northern plains, the apparent burial of wrinkle ridges, correlation of basin topography with landforms of likely aqueous origin, gradation of outflow-channel floors to ancient inundation levels, consistency of inundation volumes with possible Mars water balances and some correspondence of one of the possible shoreline levels to a deformed ancient equipotential surface (Head *et al* 1999). However, landforms interpreted as diagnostic of shoreline processes are not confirmed by detailed study of MOC imagery. Named 'Oceanus Borealis', the northern-plains inundation remains controversial as to its size, age (or ages), persistence and episodic formation. Other interpretations of the northern-plains inundation include the emplacement of massive debris flows, effects of glaciation and a complex layering of both ice- and water-laid deposits (Clifford and Parker in press).

Evidence for past lakes abounds in numerous impact craters on Mars. Most of the lakes formed in the Upper Hesperian and Lower Amazonian. Lacustrine terraces and Gilbert-type deltas indicate that the lakes must have persisted for 103 to 104 yr (Ori, Marinangeli and Baliva 2000). Standing water in lakes for such timescales requires a major change in climate from present-day conditions, although ice-covered lakes could persist for considerable time at current conditions or for those associated with the range of variation in Mars' orbital parameters. The relationships at the Gale Crater palaeolake are particularly interesting because of extensive work indicating a relatively young age. However, the first interpretation of MOC images claimed that the Gale Crater deposits and all Martian lake deposits were Noachian in age. This ancient age designation was even applied to extensive sedimentary deposits in the Valles Marineris, an interpretation that has been strongly challenged following public release of the images (Weitz 2001). Ironically, the claim of a Noachian age for the deposits requires their extensive exhumation late in Martian history in order to account for the lack of impact craters on the exposed surfaces. Such a presumed erosion event would require even more extreme Martian climate change than would the aqueous emplacement of the deposits that many investigators originally associated with post-Noachian lacustrine activity (Ori, Marinangeli and Baliva 2000). This important scientific controversy continues.

Perhaps the most striking discoveries made from MOC images are the very young, relatively small-scale debris-flow gullies (figure 6), initially explained as the result of groundwater seepage and subsequent surface run-off (Malin and Edgett 2000). The gullies have morphologies essentially identical to those that are common on terrestrial hillslopes in periglacial environments (Costard *et al* 2001), such as coastal Greenland, Iceland, Svalbad and arctic Canada. On Earth, initiation of debris flow occurs when soil water saturation follows surface melting of snow cover or ground ice. Remarkably, the Mars gullies generated debris-flow deposits that are superimposed on aeolian bedforms and on small-scale contraction-crack polygons (Malin and Edgett 2000), all of which are uncratered. Thus, the various age indicators show the gullies and debris flows to be extremely young, probably active within the past several million years of Mars' history.

The profound implications of a recent Earth-like origin for the young gullies led some researchers to seek

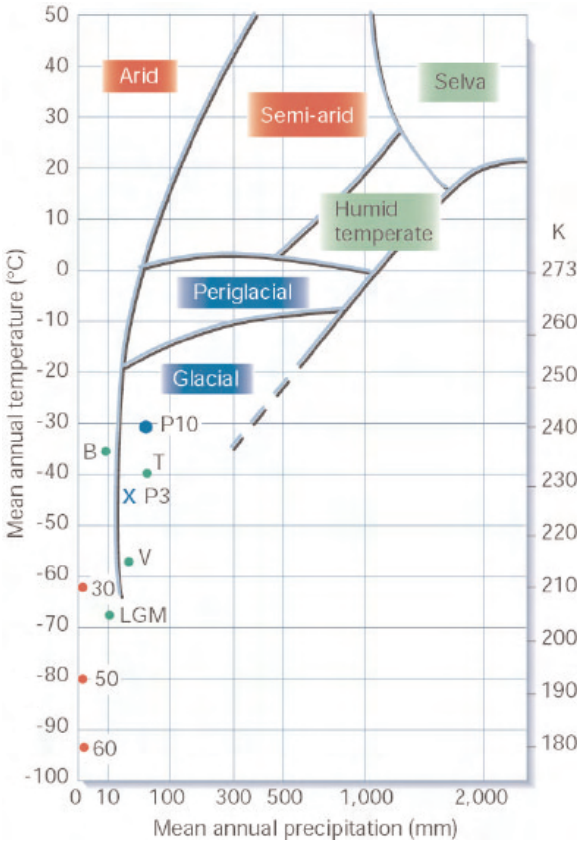

Figure 7. Morphogenetic regions for climate-related landforms on Earth.

alternative mechanisms that might generate debris flows on Mars. Ideally, the modelled processes should be able to occur in the current cold, dry environment. For example, the existence of CO_2-vapour-supported debris flows might, in theory, permit build-up of a liquid-CO_2 aquifer behind a near-surface dry-ice barrier that is subsequently breached by heating. In one extreme scenario, Mars is hypothesized as both currently being and always having been an extreme cryogenic world in which water behaves largely as a solid mineral and nearly all manifestations of fluid-flow phenomena involve CO_2 gas or liquid (Hoffman 2000). This 'white Mars' model postulates a history of mean temperatures continuously lower than those prevailing today.

Signs of glacial ice

Given that periglacial landscapes on Earth involve warmer climatic conditions than do glacial landscapes (figure 7), it is interesting that glacial interpretations of Martian landforms have generally been more controversial than have periglacial interpretations. A strong case was made for the contribution of glacial processes to the origin of landforms associated with certain outflow channels and both glacial and flood outflow processes can operate together or sequentially in large-scale channel morphogenesis (Costard and Baker 2001). Nevertheless, the scale of the presumed climate changes occurring late in Mars' history that would have been necessary to account for glaciation led many researchers to express extreme scepticism with regard to any glacial interpretation.

The most intricate assemblages of glacial landforms are hypothesized to explain landscapes in the mountainous uplands adjacent to the Argyre and Hellas impact basins. Local alpine glacial sculpture in the Charítum Montes, south of Argyre at latitude 57° S, includes cirques, horns, aretes, grooves and V-shaped valley troughs. Many of the cirques and troughs seem to be occupied by extant or relict rock glaciers or debris-covered glaciers (see discussion below). The adjacent floor of Argyre Planitia has landforms that can be interpreted as moraines, drumlins, esker-like ridges, kettles, outwash plains and glaciolacustrine plains.

The esker-like ridges (figure 8), which are 10–200 km long, have proven to be a source of lively controversy at professional meetings. Taken as individual landforms, these sinuous ridges have been variously explained as sand dunes, inverted stream valley fills, igneous or clastic dikes, lake beach ridges, mudflow levees and the wrinkle ridges generated by deep-seated faults. MOC images of the Argyre Planitia sinuous ridges (figure 9) reveal apparent sedimentary strata, boulders and discontinuous ridges, with heights of

Figure 8. Esker-like ridges in southern Argyre Planitia (latitude 56° S, longitude 40° W).

Dirac House, Temple Back, Bristol, BS21 6BE, UK

10–100 m and widths of 200–2000 m. Together with the associated glacial landforms, the esker interpretation seems to provide a consistent hypothesis explaining all relevant observations.

Even more prominent esker-like ridges are associated with the Hesperian-aged Dorsa Argentea Formation at latitudes 75–80° S. Numerous morphological similarities show these ridges to be similar to terrestrial eskers (Head and Hallet 2001). The eskers seem to have been produced by the meltback of ice-rich deposits, perhaps deriving from an extensive south polar ice cap in the middle (Hesperian) portion of Mars' history (Head and Pratt in press). The drainage from this ice cap was carried through prominent valleys to the Argyre impact basin, where it constituted a temporary lake.

MOC images of lineated valley fills in the northern fretted terrain and valleys draining to Hellas, plus images of the lobate debris aprons in uplands near Hellas (figure 1) and Argyre, show features interpreted to represent very recent glacial flow. These include crevasse-like fracture concentrations and medial moraines displaying glacier-like patterns of tributary convergence and down-valley flow. The surfaces of the lineated valley fills and lobate debris aprons are uncratered, indicating likely emplacement within the past several million years. MOLA profiles of lobate debris aprons in Deuteronilus Mensae (latitude 40° N) and Protonilus Mensae (latitude 46° N) reveal shapes best explained by solid-state deformation of ice hundreds of metres thick (Mangold and Allemand 2001). However, at current Mars surface temperatures and very low accumulation rates (<1 cm yr^{-1}), flow rates for these large ice masses would be so slow that they could not be produced on the timescale of 10^6–10^7 yr implied by their uncratered surfaces. Because the hypothesized glaciers are associated with outwash and other water-drainage landforms, higher past temperatures are implied and these could achieve Earth-like strain rates in the deforming ice.

One school of glacial geomorphological thought holds that a continuum exists on Earth from true glaciers to debris-covered glaciers and then to remobilized talus or till. The last phenomena would certainly be classed as rock glaciers, which another geomorphological school holds strictly to be permafrost phenomena. The prevailing hypothesis for the Mars lineated valley fills and lobate debris aprons follows the permafrost theory in its claim that deformation is achieved in ground ice that cements slope-derived debris. In contrast, following the continuum theory, one can hypothesize that recently active, true Martian glaciers carved the V-shaped troughs, cirques, aretes and other landforms of local highland terrains. These ancient glaciers would have had large accumulation areas, requiring atmospheric transport of water to the site and a net surplus of input from snow to offset losses by sublimation and meltwater runoff.

When climate shifted to more adverse conditions, such that input of snow no longer exceeded losses, the glaciers wasted back. However, debris accumulating on the now extensive ablation zone would have greatly reduced sublimation loss. Moreover, if temperatures also fell, meltwater loss would cease. The resulting debris-covered glacier might still have had a very small accumulation zone at its head and this could sustain continued flow of ice at very low rates, as observed in rock glaciers on Earth.

For the extremely cold conditions that currently prevail on Mars, debris-covered ice would have sublimation

Cyclic and episodic change on Mars

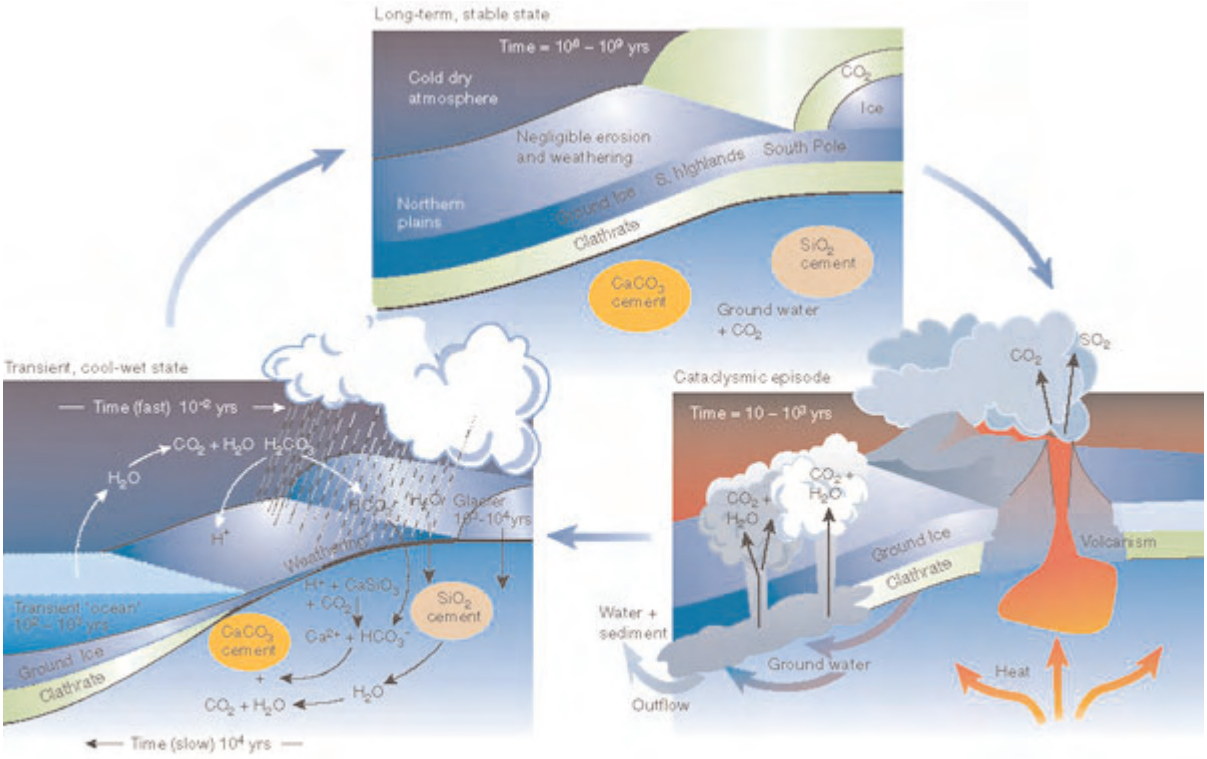

Figure 10. A genetic model, presented in an early form in 1991, predicts both long-term (108–109 yr) and short-term (103–104 yr) aspects of a global Martian hydrological cycle. The episodic inundation of the northern plains of Mars is one component of the short-term portion of the cycle. The hypothesis explains the phenomenally long epochs of post-heavy-bombardment time during which the Mars surface clearly had extremely cold and dry conditions similar to those prevailing today. The alteration of this prevailing condition with quasi-, stable, short-duration warmer (cool) and wetter conditions explains many young landforms that require such conditions, including glaciated terrain, crater lakes, melting of permafrost and other water-related landforms that occur throughout Mars' history. Internal planetary heat could have provided the trigger for the massive outflows that transformed Martian climate during the geologically short epochs of climatic change. Superimposed on the long-term monotonic decline in mantle heat flux for Mars, one can predict short episodes of higher heat flux to the surface. These episodes of higher heat flow seem consistent with the magmatic and tectonic (see TECTONICS) history of Mars (Anderson *et al* 2001). The huge floods would have acted to initiate climate change through release of CO_2, leading to greenhouse warming. During the short-duration thermal episodes of cataclysmic outflow, a temporary cool–wet climate would prevail. Water that evaporated off a transient 'ocean' would be transferred to uplands, including the Tharsis volcanoes and portions of the southern highlands, where precipitation as snow would promote the growth of glaciers. However, such a cool–wet climate is inherently unstable for Mars. Water from the evaporating ocean would be lost to storage in highland glaciers and through infiltration into the porous lithologies of the Martian surface. This would lead to the demise of warm conditions owing to the progressive loss of CO_2 through dissolved gas in infiltrating acidic water and through silicate weathering carrying bicarbonate into the subsurface by infiltration. Subsequent underground carbonate deposition would then release CO_2 to the groundwater, which would become trapped beneath an ice-cemented permafrost zone. The latter develops as the greenhouse effect declines, because of atmospheric loss of water and CO_2 over a timescale of 10^3–10^5 yr. A concurrent decline in planetary heat flow following the triggering peak episode, would lead to a downward-extending permafrost zone that would progressively incorporate the recharging water and groundwater. As the permafrost extended downward into the stability field for CO_2 clathrate, this gas hydrate would accumulate above the gas-charged groundwater. Thus, the underground sequestering of clathrate, gas-charged groundwater and carbonate cements constitute the long-term reservoir for carbon on Mars. Only occasionally, and for relatively short duration, is carbon transferred to the atmosphere, as greenhouse-promoting CO_2, during cataclysmic ocean-forming episodes triggered by pulses of high heat flow. The whole process would be cyclic as illustrated in the diagrams.

rates as low as 10^{-5} cm yr^{-1} (Carr 1990). Thus, even very small accumulation rates over small areas might sustain a positive net mass balance, although flow rates would be extremely low in a glacier at a mean annual temperature of –75 °C (the current condition on Mars at about 45° latitude). Of course, present water precipitation at this latitude is effectively zero and water condensation occurs today primarily at near-polar latitudes.

The current mean annual temperature at Vostok on the East Antarctic Ice Sheet is –57 °C and the accumulation rate is only 2 cm yr^{-1}. During the Last Glacial Maximum, ice-core data indicate that mean annual temperatures may have been as much as 20 °C colder and accumulation rates may have been less than 1 cm yr^{-1} (Mulvaney *et al* 2000). These conditions are very close to those on Mars today (figure 7), although Earth atmospheric pressures are, of course, much higher. In Beacon Valley, part of the Dry Valley region of Antarctica, precipitation is currently less than 1 cm yr^{-1} water equivalent and the mean annual temperature is -35 °C. The area is icefree, but relict glacial ice occurs beneath a 0.5 m debris cover that is dated at 8.1 million years (Myr) old. The indicated sublimation rate is 10^{-5} cm yr^{-1}, the same rate noted above for debris-covered ice on Mars. With present-day conditions on Mars so close to those in parts of Antarctica (figure 7), it is reasonable to invoke a climate-change scenario to explain the observed glacial phenomena.

Temperatures achieved during the Last Glacial Maximum are representative only of Earth's most recent glacial epoch, the Late Cenozoic. Earlier periods of prolonged, extensive glaciations (megaglaciations) of Earth occurred in the Late Palaeozoic (260–340 Myr ago), Late Devonian/Early Carboniferous (350–360 Myr ago), Ordovician/Silurian (430–450 Myr ago), Late Proterozoic (500–900 Myr ago), Early Proterozoic (about 2200–2400 Myr ago) and Archaean (2910–2990 Myr ago). The Late Proterozoic glaciation is particularly enigmatic, as there is evidence that Earth may have switched into Mars-like ice-house conditions by freezing the surface of the global ocean. The extreme glaciation is explained alternatively as a result of a huge change in planetary obliquity or as a runaway cooling that terminates cataclysmically with a super-greenhouse build-up caused by volcanism (Hoffman and Schrag in press). The rapid melting of ice and weathering of the land surface lead to carbonate precipitation in the ocean, thereby terminating the super-greenhouse.

The glacial epochs of Earth are explained by two classes of theoretical models: external and internal. External causes include the orbital parameters, axial tilt (obliquity), precession and eccentricity, all of which acted as the 'pacemaker' of Pleistocene glaciations. Internal causes include the role of conveyor-belt oceanic circulation and the arrangement of continental relief on the planet. For Mars, it is possible to imagine an internal scenario capable of explaining the diverse observations summarized in this paper (see figure 10), although there have been many objections raised to an earlier version of this model. Alternatively, the complex variability of Mars' obliquity over long timescales may be able to mobilize water in ways that will explain relatively recent manifestations of glacial action, lakes and fluvial gullies and the melting of near-surface ground ice.

Is it possible, as a theoretical matter of pure physics, that the numerous Martian landscapes, temporal associations of landforms and proximal-to-distal relationships—all analogous to water-generated process–form relationships on Earth—could have been produced by a fluid that mimics the behaviour of water? For appropriate relationships with temperature and pressure, CO_2 is a possible candidate for achieving the necessary physical behaviour (Hoffman, 2000). Moreover, the CO_2 hypothesis is parsimonious in the sense of being capable of generating flow phenomena for the current near-surface environment of Mars. If Mars, unlike Earth, were not perturbed over geological time by major epochs of climate change, then a perpetual 'white Mars' might well occur. Nevertheless, it would be remarkable that this white Mars landscape evolved locally to generate surprisingly detailed copies of what on Earth is readily produced by the long-term action of water and ice. It is also a measure of simplicity in a hypothesis that the most natural explanation, in this case an aqueous origin, tends to accord with greater consistency with the observed phenomena.

In choosing to explore the consequences of a water-based explanation for Mars' geomorphology and the associated implications for both ancient and very recent climate change, one is not assured of easily testable hypotheses. The extensive hydrosphere implied by past aqueous activity on Mars may only be extant as ground ice in the thick permafrost zone and as underlying groundwater. Yet, this is the type of environment in which the extremophile progenitors of Earth's biosphere probably evolved. Indeed, early Mars provided an arguably better habitat for the inception and incubation of early life than did early Earth. Episodic, brief episodes of aqueous activity on the Martian surface may have exposed this biosphere to produce possible fossil indicators of its existence. More speculatively, a deep subsurface biosphere containing methanogenic archaea could have produced methane that accumulated beneath a growing Martian cryosphere. The result could destabilize the Martian cryosphere (see figure 10) and perhaps change the climate on short timescales.

Ultimately in geomorphological investigation, one chooses the working hypothesis that is most fruitful with regard to connection to other lines of scientific inquiry, while still providing consistency and coherence in

explaining the whole complex of available observations. The water-generated landforms and landscapes of Mars have proven especially difficult to unite under a single working hypothesis. Nevertheless, whatever explanation one chooses as a working hypothesis, its roots in the complex detail of Mars' landscape features ensure that it will provide a highly probable basis for further productive inquiry.

Marshall Space Flight Center

NASA's George C Marshall Space Flight Center is located in Huntsville, Alabama. It is the agency's leading center for space transportation and propulsion development. The Saturn launch vehicles used in the Apollo Moon program were designed and developed here. Today, it provides the solid rocket boosters, main engines and external tank for the Space Shuttle. Apart from upgrades to these systems, Marshall engineers are designing future concepts for reusable, low-cost space transportation.

The Marshall Space Flight Center is also an important center for research into microgravity, space physics and astrophysics. One of its most important recent programs is the Chandra X-ray Observatory (formerly known as AXAF).

Maskelyne, Nevil (1732–1811)

Astronomer Royal, born in London, England, his interest in astronomy had begun after seeing the eclipse of 1748. After a mathematics education at Cambridge, he was sent by the Royal Society in 1761 to St Helena to observe the transit of Venus. In 1764 he traveled to Barbados, testing JOHN HARRISON's chronometer, and was appointed Astronomer Royal on his return. He initiated publication of the *Nautical Almanac* in 1766. Following BOUGUER and LA CONDAMINE, he proposed an experiment for determining the Earth's density with the use of a plumb line, whose plumb-bob was attracted sideways by the gravitational pull of a mountain. He carried out the experiment in 1774 on Schiehallion, a mountain in Perthshire, Scotland, chosen because it was a regular conical shape and its volume could be calculated accurately. He determined that the Earth's density is approximately 4.5 times that of water.

Mason, Charles (1730–87)

English astronomer, an assistant at the Royal Observatory, Greenwich, he went with JEREMIAH DIXON to the Cape of Good Hope to observe the transit of Venus in 1761. Dixon and Mason were engaged to survey the boundary between Maryland and Pennsylvania, and reached a point 224 miles west of the Delaware River, but stopped work due to hostile Indians. The boundary was given the name *Mason–Dixon line*.

Mass

A measure of the amount of matter in a body or of its inertia (the extent to which it resists acceleration when a force is applied to it).

The mass of a body, when regarded as a measure of the amount of matter contained within it, is one of the factors that determines the strength of its gravitational field. In Newtonian gravitation, the magnitude of the mutual gravitational attraction (F_g) between two bodies, of masses m and M respectively, separated by distance r, is given by $F_g = GmM/r^2$, where G is the gravitational constant. Mass, in this context, is called 'gravitational mass'.

Mass also appears as a constant of proportionality in Newton's third law of motion (the law of inertia), which describes the acceleration (a) experienced by a body when acted on by a force (F). This law is commonly written as $F = ma$, or $a = F/m$, where m, in this context, is called 'inertial mass' (the acceleration produced by a given force is inversely proportional to the mass of the body to which that force is applied). Inertial and gravitational mass are assumed to be identical. Although this assumption has been confirmed experimentally to a very high degree of precision, it remains a theoretical assumption.

The mass of a body when measured in a frame of reference in which that body is stationary is its 'rest-mass'. According to the special theory of relativity, the mass of a moving object is greater than its rest-mass and tends towards an infinite value as the velocity approaches very close to the speed of light. This theory also asserts that mass and energy are equivalent and interchangeable, the relationship between mass (m) and energy (E) being $E = mc^2$, where c denotes the speed of light. The total mass-energy of an isolated system (i.e. the sum of the total mass and total energy in that system) is a constant.

The unit of mass in the SI (International) system is the kilogram (kg). Particle physicists tend to use the term 'mass' to describe the quantity of energy (E) that is equivalent to a subatomic particle of mass m ($E = mc^2$), and quote 'masses' in terms of energy units (electronvolts). Strictly speaking, however, the mass of an elementary particle is its equivalent energy divided by the square of the speed of light (E/c^2). For example, the 'mass' of a proton is often quoted as 938.3 MeV. In conventional units, the mass of a proton (=938.3 MeV/c^2) is 1.6725×10^{-27} kg.

See also: electronvolt, energy, gravitation, inertia, matter, proton, special relativity, subatomic particles.

Matter

Physical substance that occupies finite volumes of space and which has mass. Bulk quantities of matter can exist in any of the following states: solid, liquid, gas or plasma. On the microscopic scale, matter exists as molecules, atoms, ions, subatomic particles or elementary particles. Because of the equivalence of mass and energy, which is a consequence of the special theory of relativity, matter may be considered as a particular form of energy.

All but a tiny fraction of each atom's mass is contained within its central nucleus, which is composed of protons and neutrons (the nucleus is surrounded by a cloud of much lighter electrons). Because protons and neutrons belong to a class of particles called baryons, normal matter is often referred to as 'baryonic matter'. In addition to luminous matter (the stuff of which stars are composed), which is detectable by the radiation that it emits, the universe appears to contain substantial quantities of dark matter that emits no discernible radiation and which is detectable only through its gravitational influence. There are theoretical grounds to suggest that part of the dark matter may be 'non-baryonic' (composed of hypothesized particles that are not baryons).

Maunder, E W (1851–1928) and Maunder, Mrs A S D

Solar astronomers. Maunder became assistant for spectroscopic and solar observations at the Royal Observatory, Greenwich under GEORGE AIRY, aided by his wife. In 1890, while studying the numbers of sunspots over a 300 year time-span he noticed the scarcity of spots in the period 1645–1715. This so-called *Maunder minimum* was confirmed by Jack Eddy (1976) to be a real effect rather than simply a scarcity of observations, by a reduction of carbon-14 in old tree rings at the same time (carbon-14 production in the Earth's atmosphere is modulated by solar activity). In 1904 invented the 'butterfly diagram' of sunspots, showing the solar latitude at which sunspots appear as a function of time. The spots show a progressive drift with the phase of the solar cycle (Spörer law). At the beginning of the solar cycle, spots tend to appear at latitudes 35 degrees N and S. Their number increases and their latitude tends to decrease as the cycle moves on, so that at solar maximum the many spots appear at intermediate latitudes (15 degrees north and south). At the next solar minimum, spots of the old cycle are equatorial, while spots of the new cycle are starting to appear at latitudes 35 degrees again. The plot of this phenomenon has the shape of a butterfly's wings. Maunder also researched into the history of the constellations, for example he calculated the date of origin of the classical constellations at 2700 BC by considerations of the effects of precession on the constellation figures. As an evaluation of the reality of the 'canals of Mars', he carried out experiments on how random unresolved spots tended to be subjectively viewed as linear features.

Maupertuis, Pierre Louis Moreau de (1698–1759)

Mathematician, born in Saint Malo, France, published on mathematics, geography, and astronomy, introduced NEWTON's theory of gravitation in France. He developed his theory of dynamics with the principle of least action, a way to determine the orbit of a body by a minimization technique. As a unifying principle, he though that it could be a proof of the existence of God. He went to Lapland in 1736 to determine the flattening of the Earth at the poles into an oblate spheroid, as predicted by Newton.

Max-Planck-Institut für Astronomie

Founded by the Senate of the Max Planck Society in 1967, it is one of 68 Max-Planck-Institutes in Germany. The Max-Planck-Institut für Astronomie has its headquarters in Heidelberg, where new buildings were erected between 1971 and 1975 on a 5.2 hectare site alongside the State Observatory.

The staff of approximately 150 includes engineers and other technicians as well as about 30 astronomers. They cover a broad spectrum of expertise including laboratory physics, informatics, electronics, instrument-making and photography. It is also an institute of higher education for students of astronomy and physics, and for apprentices in instrument-making and information electronics.

The Institute also operates the CALAR ALTO OBSERVATORY in southern Spain as well as conducting research in astronomy and astrophysics. Studies include star formation, extragalactic objects, astrophysical theory and instrumentation development.

A small station with a 50 cm telescope is also operated on the 2350 m high Gamsberg, a table mountain on the western edge of the Kalahari desert in Namibia. Thousands of photometric measurements on stars of the southern Milky Way have been carried out from this site.

Since 1984, the Institute has also loaned a 2.2 m telescope to the EUROPEAN SOUTHERN OBSERVATORY at La Silla. Under the 25 year agreement, astronomers of the Max Planck Society are permitted sole use of the telescope for 25 per cent of the observing time.

Max-Planck-Institut für Astrophysik

The Max-Planck-Institut für Astrophysik, now located in the town of Garching north of Munich in Germany, is one of the more than 70 autonomous research institutes of the Max-Planck-Gesellschaft. It was founded in 1958 under the direction of Ludwig Biermann as part of the Max-Planck-Institut für Physik und Astrophysik, directed at that time by Werner Heisenberg. In 1979, when the headquarters of the EUROPEAN SOUTHERN OBSERVATORY (ESO) came to Garching, the Institute also moved to its present location. It is now led by a board of three directors.

Research at the Institute is devoted to a broad range of topics in theoretical astrophysics. Major concentrations of interest lie in the areas of stellar evolution, stellar atmospheres, supernova physics, astrophysical fluid dynamics, high-energy astrophysics, galaxy structure and evolution, the large-scale structure of the universe and cosmology. While most of the Institute's research addresses theoretical issues, the neighboring institutes on the campus of Garching (ESO and the MAX-PLANCK-INSTITUT FÜR EXTRATERRESTRISCHE PHYSIK) provide complementary expertise on observationally oriented astrophysics, and there are many collaborative projects with them.

At any given time the Institute has about 30 scientists working on long-term positions, up to 10 foreign visitors brought in by various programs, and about 20 graduate students, mostly enrolled for degrees in one of the two large universities in Munich. Several of the senior staff members have affiliations with these universities.

Max-Planck-Institut für Extraterrestrische Physik

The Max-Planck-Institut für Extraterrestrische Physik (MPE) is one of the world's leading institutes dealing with space physics and astrophysics. The main activities are in infrared, x-ray and γ-ray astronomy and space-plasma physics, and extend to colloidal plasma physics. The institute is primarily involved in developing novel instruments and using them for performing observations and measurements. This is supplemented by theoretical activities. Major projects are Helios, AMPTE, Cluster, ISO, Sofia, First, Rosat, Chandra, XMM, COS-B, CGRO and Integral.

The institute, which is located in Garching near Munich in Germany, was founded in 1963. Today it comprises about 150 scientists and about 250 other staff members. Apart from physical laboratories, the institute has its own workshop, an integration and test facility for space experiments, a test facility (Panter) for calibration of x-ray telescopes and it runs a semiconductor laboratory as a collaborative enterprise with the Max-Planck-Institut für Physik in Munich. The MPE receives institutional support from the Max-Planck Society and project funds from government institutions (BMBF, DLR and DFG). The research activities are often carried out as cooperative projects together with research institutes and universities within and outside Germany, in particular with ESA and NASA, but also with national agencies.

Max-Planck-Institut für Radioastronomie

Founded in 1966, the Max-Planck-Institut für Radioastronomie in Bonn is one of the centers for radio astronomical research in Germany. Main fields of research include the interstellar medium of our own and external galaxies, cosmic magnetic fields, pulsars, star formation, late stages of stellar evolution, active galactic nuclei, theoretical high-energy astrophysics, and observational cosmology. Instrumentation for centimeter and (sub)millimeter wavelength observations and for optical and infrared interferometry is developed in-house. The institute operates the EFFELSBERG 100 m RADIO TELESCOPE, which frequently takes part in Very Long Baseline Interferometry (VLBI) observations. The 10 m Heinrich-Hertz Telescope on Mount Graham, Arizona, a facility for work at submillimeter wavelengths, is operated jointly with the University of Arizona's STEWARD OBSERVATORY.

Maxwell Montes

The highest mountain range on Venus, situated in the upland region Ishtar Terra, and centered at 65.2 °N, 3.3 °E. It extends for 797 km, and contains the highest point on the planet, nearly 12 km above Venus's average surface level (comparable in this respect to Earth's Mount Everest). It is the only Venusian feature to bear a male name, honoring James Clerk Maxwell. The range showed up prominently in early radar surveys as a 'radar-bright' region. It was given its name in 1970, before the convention of assigning female names was adopted; because the name had become well established it was allowed to survive.

The western slopes are very steep (35°), while to the east the descent is more gentle, toward the region known as Fortuna Tessera; the range itself is a complex of compressive faulting and folding. The steepness and height could point to a relatively recent formation, or it could mean that the underlying crust is thicker or stronger, or even that the rocks in this region are of lower than average density. The radar brightness of Maxwell Montes is thought to indicate that its peaks are covered with a thin deposit of a radar-reflective material similar to the mineral pyrite, which on Venus can exist in solid form only at high altitudes, where the pressure and temperature are low enough. To the east of the range is the 105 km diameter double-ringed impact crater Cleopatra.

Maxwell, James Clerk (1831–79)

Born in Edinburgh, Scotland, worked at Cambridge on electric and magnetic fields and their interrelation. Entered a prize-winning essay for a competition on the subject 'The Motion of Saturn's Rings' and showed that the rings could be stable only if they consisted of numerous small solid particles in Keplerian motion with the inner edge moving faster than the outer edge. GEORGE AIRY, a competition judge, wrote that it was one of the most remarkable applications of mathematics to physics that he had ever seen. Maxwell worked on the perception of color, inventing the three-color process used, for example by DAVID MALIN in astrophotography. At King's College, London, Maxwell proposed that light is an electromagnetic phenomenon and worked on the kinetic theory of gases, showing that temperatures and heat involved the motion of molecules and that the velocity distribution of molecules was '*Maxwellian*'. In 1871 he became the first Cavendish Professor of Physics, and wrote a *Treatise on Electricity and Magnetism* which unified what appeared to be two separate forces into one set of four partial differential equations, now known as *Maxwell's equations*. The *James Clerk Maxwell Telescope* in Hawaii is named for him.

Mayan Astronomy

The Mayas of Mexico, Belize, Guatemala and Honduras developed an urban civilization in the tropical rain forests. In their cities are many monuments, mainly stone, which contain accounts of their rulers' families, conquests, sacrifices, rituals and building programs. These are integrated into an elaborate calendrical system, which gives dates to the day. We also have pottery, painted with elaborate scenes, often with dates and depictions of the cosmic interaction of deities, and four books have survived. It was thought that each day was ruled by many separate deities, gods of numbers, gods of day names, gods of months and years, and others. The fate of each day was determined by the interaction of these gods in numerological and astronomically determined patterns.

The Mayas' knowledge of astronomy allowed them to calculate eclipses and planetary movements over thousands of years. Some inscriptions include calculations over many millions of years. These seem to be combinations of numerology and astronomy. Whereas we would say that the tropical year during the time that the Mayas flourished was 365.242 58 days, the Mayas gave dates indicating that 29 periods of 18 980 days equaled 1508 Maya years of 365 days and that this corresponded to 1507 tropical years. This calculation would require about 70 000 yr to accumulate a full day of error. Much longer calculations imply much greater precision although not necessarily greater accuracy. The greater the length of time specified, the higher the precision which is being claimed. Some such calculations involved periods substantially greater than the present geologically estimated age of the Earth.

The Maya calender

There were three major components of the CALENDAR: a tzolkin (a period of 260 days—20 repetitions of the numbers from 1 to 13 and 13 repetitions of a series of 20 named days); a 'year' of 18 named months of 20 days each plus a set of 5 days referred to by various euphemisms; an account of the number of days from a specified date in the past which served as an era base. The combination of the 365 day year with the 260 day sequence resulted in a repetition of the same combination after 18 980 days ($73 \times 260 = 52 \times 365$). This combination is called a Calendar Round and was found throughout Mesoamerica (the cultural area which shows a large grouping of similar traits—most of the non-Mayan peoples of Mesoamerica were in modern Mexico).

Astronomical observations

We have almost no direct evidence of observational techniques. There are indications that observers posted at fixed points at fixed times of the year, such as EQUINOXES or SOLSTICES, checked solar and planetary observations, often using a fixed alignment defined by two buildings or a building and a mountain peak or low point on a distant horizon. The Mayas had concave mirrors of obsidian (a naturally occurring volcanic glass, often black or green). Such a mirror could have been used directly as a reflecting telescope. This not only would have made fainter objects visible but would have permitted observations substantially closer to the Sun at sunrise and sunset. At Teotihuacan in highland Mexico, light from the Pleiades was projected onto a floor, apparently through a long tubular opening, causing a substantial enlargement (this technique is incorporated into any camera obscura in our own culture). Each dot of light from the 11 brightest stars of the Pleiades was marked on the floor by identical images of a jaguar, drawn by connecting 11 dots forming tiny maps of the Pleiades. These 'maps' or star diagrams are essentially elaborations of the so-called 'ball and link' designs (attested later among the Aztecs) in which solid line 'links' connect circular star markers ('balls'). Although no similar observational technique is attested for the Mayas, the amount of shared astronomy, calendrics and cosmology is such that it seems very probable that they shared the technique, particularly since there is a 'Maya quarter' at Teotihuacan.

The Mayas deliberately built some structures in such a way that the interaction of light and shadow created striking visual effects at specified times of the tropical year (i.e. the year measured from the spring equinox in 0° of the sign of Aries). At Chichen Itza, in Yucatan, there is a four-sided 'pyramid', with 91 steps on each side, which is associated with Kukulcan, the Feathered Snake. The balustrades are carved as gigantic feathered rattle-snakes, head down. At the equinoxes, shadows cast on the balustrades by different levels or stages of the pyramid create the illusion that the giant snakes are descending the stairs. Feathered snakes were primarily identified with Venus at the time when this monument was erected, although I have argued for an earlier identification with Mercury. This may suggest a particular Venus phenomenon which occurred at a particular spring equinox. Despite this equinoctial connnection, the building itself is aligned to the rising point of the Sun at the summer solstice and to its setting point at the winter solstice.

At Palenque, in Chiapas, an image of an old black god with an owl in his headdress is the last monument to be lit by the descending Sun at the winter solstice. I have suggested that he is a personification of Saturn, and that he rules the night, so that we may suppose that this was intended to mark a particular date when Saturn was visible in the east at sunset on a winter solstice. I have postulated that the calendar names of Mesoamerican deities, like those of human beings, were marked from the day of their 'birth', apparently usually identified as conjunction with the Sun for planets and as equinoxes or solstices for the Sun. In the case of the Moon, identification with particular eclipse intervals and series seems to have been usual. I have further argued that all calendar names were calculated from a single calendar round date, the date 12 Lanat on new year's day, the first of Pop. This date was about 3500 yr in the past

when the Maya first began erecting monuments, as will be explained. My interpretation of the calendar names of the gods has not been widely accepted, but neither has it been formally criticized and rejected, nor has anyone proposed a coherent alternative. To the extent that it is accepted, the Maya seem to have been interested in all the visible planets both in their movements relative to the sun and relative to the asterisms, or star groups which the Maya recognized. They were deeply interested in ECLIPSES of the Sun and of the Moon, and particularly interested in associating planetary movements with eclipses.

Deities might appear in human form or as animals, from the lowly centipede representing the high god Itzamna, to the deer representing the Sun and the rabbit representing the Moon. An example which clearly integrates these varied concepts is a representation of a heron with the head of a black god incorporated into the body and the glyph for 'star' attached. I think that it may be a representation of Jupiter.

Dates on inscriptions

Returning to the inscriptions, dates are normally given by five numbers counted from 4 Ahao 8 Cumku, previously mentioned, and followed by the resultant calendar round date. Thus the date 9.16.4.10.8 12 Lamat 1 Muan means that 9 baktuns (9×400 tuns of 365 days each, that is, $9 \times 144\,000 = 129\,6000$ days), 16 katuns (16×20 tuns; $16 \times 7200 = 115\,200$), 4 tuns ($4 \times 360 = 1440$), 10 uinals of 20 days each—$10 \times 20 = 200$ and 8 days passed (from the era base 4 Ahau 8 Cumku to 12 Lamat 1 Muan).

In an inscription of Palenque, a god is said to have been born on the date 1.18.5.4.0 1 Ahau 13 Mac. This is probably an implicit reference to a date 9.11.3.2.0 1 Ahau 13 Mac which fell during the lifetime of those who put up the inscription. The interval between 1.18.5.4.0 and 9.11.3.2.0 is 58 calendar rounds. The period of 29 calendar rounds and its multiples ($2 \times 29 = 58$) appears in a number of inscriptions. The astronomical characteristics of this period are very interesting. It consists of 1508 years of 365 days which is equivalent to 1507 tropical years with a minimal error which would amount to a day in about 70 000 yr. The double interval used here is 3016 Maya years, equivalent to 3014 tropical years or 1 100 840 days. We do not know the precise parameters used by the Mayas in any of their calculations except as these may be derived from the calculations themselves. The Maya used a minimal period of 2920 days to relate Venus and the year since $8 \times 365 = 2920$ and 5 approximate Venus periods of 584 days each also equal 2920 days. The Maya day name of Saturn is 13 Cimi which implies 378 days for the synodic period of Saturn. These factors suggest connections between Venus, Saturn and the tropical year, since 2920×377 is 1 100 840 days, and that the day 1.18.5.3.6 13 Cimi 19 Keh, 14 days earlier than 1.18.5.4.0 1 Ahau 13 Mac, is also given here as the birth of a god, the so-called 'Jaguar-Baby', one of twin heroes. Comparative mythology suggests that 'Jaguar-Baby' was the half- brother of a deity with water associations and that he ultimately replaced his Jaguar father as the opponent of youthful heroes. I assume that 'Jaguar-Baby' is Saturn.

One of the most apparent relationships between history and astronomy in the Mayan inscriptions is the not uncommon use of a star glyph with a place-name glyph to indicate that the place has been conquered. It has been suggested that these conquests occurred when Venus was at greatest elongation, but the statistical evidence for the view that Venus was at any specified or specifiable position at all the dates concerned is not strong and other planets may also be involved.

Astronomy in the codices

This brings us to the astronomical evidence found in the Maya books. These are called the *Dresden*, *Madrid*, *Paris* and *Grolier* codices. It has recently been determined that the *Madrid* codex was written after the Spaniards had arrived in the New World, but there is no trace of Spanish culture in the manuscript. The city names of the first three codices have to do with their present locations and nothing to do with their content. Many books were destroyed when the Spaniards conquered the Maya area, but most scholars at the present time recognize four surviving Maya documents which are pre-Spanish in content. The pre-Columbian books and maps of Mesoamerica are usually called codices, although Latin codices were bound books and these are not. The most information comes from the astronomical tables of the *Dresden* codex. The Venus table and the table of lunations and their relationships to eclipses are accepted by virtually all Mayanists. There is also a table of Mars accepted by a substantial minority of scholars and structurally similar tables which I think refer to Mercury, Jupiter and Saturn. In all cases, there is a date in the distant past (somewhat before the Maya era base), then an interval and a date during the Maya Classical Period or somewhat later. This is followed by a multiplication table of factors relevant to astronomy and divination for the particular planet, including apparent correction factors. We have a table of mean motion for the particular planet, sometimes divided in ways which seem unusual to modern Western scholars. Before discussing individual tables, it should be pointed out that the Maya era base is occasionally referred to as 13.0.0.0.0 4 Ahau 8 Cumku counting 13 baktuns or 5200 tuns from a previous era base. This is comparable with our saying that the Christian era base of AD 1 is equivalent to the year 754 of the era base counted from the foundation of Rome. Many early scholars thought that this meant that a new era base would begin every time the count reached 13 baktuns. We know that the Maya used 20 baktuns to make one of the next higher unit (called by Mayanists a pictun) and we know that they also used completely different era bases such as 9 Kan 12 Kayab, which was about 30 000 yr before 13.0.0.0.0 4 Ahau 8 Cumku according to the most likely interpretation of the data. There is, therefore, no reason to think that the end of 13 baktuns from a previous era base would necessarily begin a new world age or era.

In the case of the Venus table, the beginning date was a day 1 Ahau 18 Kayab falling 2200 days before the usual Maya era base, at a date which might be written 12.19.13.16.0 (counted from the previous implicit era base). From this there was a count forward of 9.9.16.0.0 to a date 9.9.9.16.0 1 Ahau 18 Kayab. The interval can be analyzed as 3744 years of 365 days, 2340 conventional Venus rounds of 584 days and 72 calendar rounds. This is 3741 tropical years and 189 days. It is also 2340 true Venus rounds and 189 days. Hence the true relationship of the Sun and Venus would have been the same at both ends of the table but shifted about half a year in the seasons. It is usually supposed that the ending date was approximately in step with reality and the beginning was badly off but it seems strange that they would back-calculate to a base which they knew was grossly in error. The multiplication table starts with 2920 days ($5 \times 584 = 8 \times 365$) going from an implicit 1 Ahau to a specified Ahau. It continues with multiples of 584 by 10, 15, 20, 25, 30, 35, 40, 45, 50, 55 and 60, the last reaching 6 Ahau. It is just possible that the initial 5 Venus cycles are counted from, rather than to, the recorded 9 Ahau, in which case 5 Venus cycles after 6 Ahau would reach 1 Ahau after 2 calendar rounds. We then have a reference to 9100 days reaching 1 Ahau. Read as it stands, this would be 35×260 days, which is not a Venus interval and has usually been regarded as an error. Lounsbury (1990) regarded it as a correction mechanism over 80 calendar rounds. This is certainly more likely than any alternative yet proposed but the specific mechanism suggested involves corrections which seem to me unlikely to have been applied as Lounsbury thought. The table then gives 57×118 and 317 multiples of 584, all of which reach 1 Ahau, before reverting to the 65×584 which restores 1 Ahau, then giving 130×195 and 260×584.

This is followed by a mean (synodic) motion of Venus in 5 sections each totalling 584 days and subdivided into 236, 90, 250 and 8 days. There are three sets of Venus intervals given, creating essentially three tables in one. The base of the top set is 1 Ahau 13 Mac, the base of the second set is 1 Ahau 18 Kayab (the CR date reached by the introduction) and the base of the third set is 1 Ahau 3 Xul. The relationship between these tables is much disputed. Lounsbury's analysis of the relationship between the multiplication table (interpreted as giving various calculations for corrections) and the three-in-one table led him to suggest a date of 11.0.3.1.0 1 Ahau 13 Mac for the top set and a still later date of 11.5.2.0.0 1 Ahau 3 Xul for the bottom set. However, the verbal affix -ah is found in all entries in the 18 Kayab and 3 Xul tables and all but one page (46) of the 13 Mac table. This should mean that the tables are referring to past events, except for part of the 13 Mac table. It seems to be much more likely that the implicit date 9.11.3.2.0 1 Ahau 13 Mac at Palenque in association with apparent Venus calculations is the intended date here as well. That date is 11 960 days after 9.9.9.16.0 1 Ahau 18 Kayab (generally accepted as the intended base for the middle set) which is, in turn, 9360 days later than 9.8.3.16.0 1 Ahau 3 Xul. Lounsbury rejects these dates because of *a priori* assumptions as to how corrections should be applied and the value of common factors. He also assumes all relevant factors of the Venus table are directly related to Venus. I assume, on the other hand, that an important factor of the tables was to relate Venus to other planetary phenomenon, to the tropical year and to eclipses. In this case, an interest in eclipses may be involved, since 11 960 days is the length of the Maya eclipse table ($32 \times \frac{3}{4}$ years) and 9360 seems to be the second most important eclipse interval. This need not imply that any of the Venus table dates were actually eclipse dates, but rather that certain Venus phenomena might serve as markers for eclipses.

This naturally leads to a discussion of the *Dresden* eclipse table. The introductory date falls 8 days after the Maya era base. The usual calculations appear, only partly understood, and then the table. This consists of 69 eclipse syzygies, each with an accompanying text, and with 10 pictures—in all cases except the table end, these pictures follow an interval of 148 days, rather than the normal interval of 177 days (6 lunations) (or occasionally 178 days). The base of the table is the date 9.16.4.10.8 12 Lamat 1 Muan. I have suggested that the calendar names of Mesoamerican deities are the dates reached by a count forward of a relevant astronomical interval from the base 12.8.19.0.8 12 Lamat 1 Pop (of the previous era). In this case, a count forward of 11 960 days reaches 12.10.12.4.8 12 Lamat 1 Muan, which I identify as the calendar name of the eclipse table god. The day 12 Lamat is associated with eclipses in the *Paris* and *Madrid* codices and the highland Mexican *Borgia* codex names an old Moon god as 12 Rabbit, the equivalent of 12 Lamat. If a standardized table of 11 960 days was used as I think, then the *Dresden* table base should be a multiple of 11 960 days from 12.8.19.0.8 12 Lamat 1 Pop and a multiple of calendar rounds from 12.10.12.4.8 12 Lamat 1 Muan. The least common denominator of the two intervals is 48 calendar rounds, which is the equivalent of 73 eclipse table lengths (6.1.5.4.0 or 873 080 days). It turned out that the first common occurrence was at 5.11.17.8.8 12 Lamat 1 Muan and the second at 11.13.2.12.8. 12 Lamat 1 Muan, thus passing over the entire period of the Classic Maya. However, an alternative occurred to me. If one counted 9360 days of the proto-table, one would reach 12.11.18.4.8 12 Lamat 11 Mol. If one then counted forward by multiples of 11 960 days one would reach 12 Lamat 1 Muan after 50 repetitions of the table at 3.14.19.6.8 12 Lamat 1 Muan (32 calendar rounds from 12.10.12.4.8 12 Lamat 1 Muan). If one then counts forward 48 calendar rounds, one reaches 9.16.4.10.8 12 Lamat 1 Muan; the total interval would be 80 calendar rounds plus 11 960 days or 124 eclipse table lengths plus 9360 days (10.12.11.0.0 or 1 530 360 days). The efficacy of that base would then depend in part on the accuracy of the original back calculation and the table itself would serve as a measuring stick against actually observed eclipses (which could theoretically be off by many days or even months). Using modern parameters they would be 41 days off on node passage and 45 days off on lunations, but we do not know what parameters they were using.

It may be noted that the interval from 9.11.3.2.0 1 Ahau 13 Mac to 9.16.4.10.8 12 Lamat 1 Muan is 5.1.8.8 or 36 528 days. This is about 40 days short of an eclipse interval and might suggest that 9.11.3.2.0 was actually an eclipse if the eclipse table base was removed from reality by an equivalent amount.

The first eclipse of the table after 12 Lamat fell on a day 7 Snake, which is the name of a well-known Aztec goddess, Chicomecoatl (Seven Snake). The day 7 Snake is also associated with eclipse syzygy imagery in the *Madrid* codex. The day associated with the first picture in the table is 7 Oc and the associated picture shows a death god on a throne of bones. Again, the *Madrid* codex shows a similar throne of bones with a column of dates including 7 Oc. The so-called 'SAROS' interval of 6585 days from 12 Lamat reaches 7 Ix or 7 Jaguar, said in highland Mexico to be a name for the gourd. The decapitated head of the Sun God was hung in a gourd tree and changed into a gourd. Pottery scenes and sculptures frequently depict the decapitation of the Sun God or Moon Goddess and associated dates suggest eclipses. Perhaps all the gourds in the tree represent previous eclipses. Only a constant back and forth between iconography and calendrical arithmetic will ultimately allow us to understand Mayan astronomy and the role it played in the culture. In the *Madrid* codex there are two cases in which there is a reference to two solar eclipses relative to a single date. In one case, this seems to be 13 tuns after 12 Lamat ($13 \times 360 = 4680$ days). This interval is the ideal short interval to go from a solar eclipse at the node to a lunar eclipse at the node. The latter would be midway between two solar eclipses, one in the far north and one in the far south, neither visible to the Mayas. This suggests at least a minimal concept of the geometry involved and a clear concept that eclipses were occurring even when they were not locally visible.

The table of Mars was satisfactorily identified by Willson in 1924 but was long doubted. More recently, work of the Bricher has again made it acceptable to many scholars, although there are still doubters. I have argued for tables of Mercury, Jupiter and Saturn, still not widely accepted, despite their similarity to the other tables. The stone coffin of Pacal at Palenque has a series of sequential designs which Thomas Barthel identified as symbols of the planets in their Eurasian and African week-day order. This seems to me correct.

Maya constellations

Our knowledge of Mayan CONSTELLATIONS is still very minimal but increasing. The tail of the Rattlesnake is identified with the Pleiades, their Scorpion constellation with ours and Orion's Belt with a turtle. The hearth stones ruled by the Fire God are nearby. I have suggested that the sequence of Mesoamerican day names represents ASTERISMS recognized by the Mayas, but this does not give us very clear definitions. There are problems with other suggested sequences. Some asterisms are still identified by modern Mayan groups.

The correlation problem

Finally, mention should be made of the problem of correlating the Maya chronology with our own. This is usually defined by a correlation constant which matches the era base with a particular Julian Day number. Thus the widely accepted Thompson correlation matches the era base with JD 584 285. I think that this correlation is certainly wrong, disagreeing with colonial and historical evidence, with the archaeology and with the astronomy. Recently, Bryan Wells has proposed alternate correlations at 660 205 or 660 208, the latter being independently suggested by Andreas Fuls. I have found strong historical evidence supporting Wells against my own proposal of 663 310. No yet-proposed correlation agrees well with my interpretation of the *Dresden* eclipse table. The chronological control of a correct correlation is necessary in order to understand Mayan astronomy with any clarity. In my view, we still do not have reasonable certainty about any of the more than 100 proposed correlations, but the Wells correlation is far superior to that proposed by Thompson. Mayan astronomy was complex and sophisticated but it used principles which often differ strikingly from ours, and we still have much work to do.

Mayer, Tobias (1723–62)

Mathematician, born in Marbach, Württemberg, Germany, who, self-taught, discovered the libration (back and forth oscillation on its axis) of the Moon, which won him the chair of mathematics at Göttingen. Made the first accurately measured map of the Moon. Attempted to formulate predictions of the motion of the Sun and Moon as a means to determine longitude at sea, sent them to the British government, which posthumously awarded his widow the sum of £3000. MASKELYNE described the work in the first issue of the *Nautical Almanac*, complimenting their accuracy (they could be used to determine longitude to within a degree, or 60 nautical miles error). Maskelyne noted that 'The Difficulty and Length of the necessary Calculations seem the only Obstacles to hinder them from becoming of general Use'.

McDonald Observatory

McDonald Observatory, located in West Texas near Fort Davis, is the astronomical observatory of the University of Texas at Austin. Discoveries at McDonald Observatory include water vapor on Mars, the abundance of rare-earth chemical elements in stars, the discovery of planets circling around nearby stars and the use of the measurements of rapid oscillations in the brightness of white dwarf stars to deduce their ages.

Telescopes at McDonald Observatory include the 9.2 m (diameter) Hobby–Eberly Telescope (HET) whose partners include (with Texas), Pennsylvania State University, Stanford University, the Ludwig Maximilians University in Munich and the Georg-August University in Göttingen, Germany. The HET came into operation in 1999 and specializes in astronomical spectroscopy. The other telescopes are owned exclusively by Texas and include the 2.7 m Harlan Smith Telescope, the 2.1 m Otto Struve Telescope and the 0.7 m, wide-field survey telescope. In addition, McDonald operates a 0.7 m laser-ranging telescope which measures the distance to reflectors on the Moon.

McDonald Observatory has a staff of 100 people located in Austin and at the Observatory. The operating funds for the Observatory come from the State of Texas, the University of Texas at Austin and from private and corporate benefactors. McDonald Observatory has an extensive set of public information programs including StarDate (English), Universo (Spanish) and Sternzeit (German) radio programs, *StarDate* magazine and a visitor center at the observatory. A new visitor center with extensive exhibits and displays in Spanish and English will be open in late 2001. The new visitor center, at the observatory, is open every day except Christmas Day, Thanksgiving Day, and New Year's Day.

MDM Observatory

MDM Observatory was founded by the University of Michigan, Dartmouth College and the Massachusetts Institute of Technology. Current operating partners include Michigan, Dartmouth, MIT, Ohio State University and Columbia University. The observatory is located on the southwest ridge of the KITT PEAK NATIONAL OBSERVATORY near Tucson, Arizona. It operates the 2.4 m Hiltner Telescope and the 1.3 m McGraw-Hill Telescope.

For further information see http://www.astro.lsa.umich.edu/obs/mdm/.

Mean Solar Time

The time system in use for most civil and many astronomical purposes and based on the motion of a hypothetical object called the mean Sun, the right ascension of which increases from day to day at a uniform rate. The local mean time is defined to be the local hour angle of the mean Sun plus 12 h. Greenwich mean time is taken as the standard for reference; the term Universal Time (UT) is synonymous with Greenwich mean time (GMT).

See also: apparent solar time, equation of time, Universal Time.

Measuring Machines

Astronomy is basically an observational science, rather than an experimental one, and the development and advancement of the subject has relied heavily on surveys of the sky at optical wavelengths to expand our knowledge of the observable universe. To date all of the major all-sky optical surveys have been carried out using photographic plates taken on wide-angle SCHMIDT TELESCOPES. Of particular note are the northern hemisphere surveys undertaken by the Palomar Schmidt telescope, and the southern hemisphere surveys using the ESO Schmidt telescope in Chile and the UK Schmidt telescope (UKST) in Australia. These surveys form a basic foundation of observational astronomy playing a similar role to cartographic maps of the Earth's surface.

Formerly, this photographic survey material could only be studied visually with the aid of low-power binocular microscopes. Even with large teams of dedicated observers only a minute fraction of the available wealth of information present on the survey plates could be mined. Objective, quantitative studies were difficult in many cases and impossible in most. However, in the late 1970s and early 1980s the advent of fast optical micro densitometers, or measuring machines, capable of automatically digitizing and routinely analyzing the enormous information content of these survey plates, revolutionized optical astronomy, placing it firmly at the forefront of the computer age. By routinely processing the 4 Gbytes of information on a Schmidt plate in a matter of a few hours, these machines opened up new areas of quantitative survey astronomy. Around 2000 such plates are needed to cover the whole sky in one passband. Add another passband, or two, to provide colour information and possibly different epoch observations to open up proper motion and variability studies, not to mention special plates for specific studies, and the total data volume becomes well over a staggering 50 Tbytes.

This ability to digest huge volumes of information (see also SOFTWARE: DIGITAL SKY SURVEYS) and produce the sort of numbers astronomers are really interested in, such as position, magnitude, colour, star or galaxy and so on, is the key to the success of the measuring machine era. Most of the area on a survey plate belongs to the smoothly varying sky background and hence can be accurately represented using much lower-resolution sampling. Faint images and all stellar images are reducible to simple descriptors such as those above. It is only the handful of bright galaxies where more detailed mapping is required. These straightforward concepts have been exploited by the measuring machine community to significantly compress the original data volume by factors of typically $\times 100$ with little or no loss of pertinent information. Nowadays, it is common practice among astronomers to use the world wide web (WWW) to dial up arbitrary parts of the sky and be presented with catalogs of objects and two-dimensional pictures.

The initial breakthrough came in the 1950s, when Peter Fellgett proposed a machine that could look for and measure images automatically. It was called GALAXY and used a 'flying spot' produced by a cathode ray tube (CRT). When the image of a star on the plate blocked off the light from the CRT the machine registered an object and measured its position using an analogue implementation of a maximum likelihood (i.e. optimal) centering algorithm. GALAXY, completed in 1968 at the Royal Observatory Edinburgh (ROE) by Vincent Reddish, represented a significant advance over previous efforts, but it was still very slow. It could process 1000 stars per hour but, as each survey-grade Schmidt plate contains well over 250 000 stars, measuring a complete plate still took an impracticably long time. Furthermore, as GALAXY was designed to do stellar astrometry only, much of the information content of the plates was still untapped.

GALAXY's successor, COSMOS, also based on a CRT-illuminated flying spot, was commissioned at the ROE in the late 1970s. Unlike GALAXY, COSMOS was designed to digitize first, prior to performing image detection and analysis, and took about a day to process each plate completely. In this way, both stellar and galaxy images could be detected and parameters describing their position, intensity and morphology readily derived. COSMOS has been used to construct digital maps and catalogs of many UKST plates including the complete Southern BJ sky survey and these are available on the WWW. COSMOS was retired in 1993 and has recently been superseded by Super COSMOS, a multichannel system based on a linear CCD and xenon arc lamp source. Telecentric optics helps to control the scattered light. The X–Y table is a modification of a commercial off-the-shelf system and represents the current state-of-the-art in accurate (few tenths of a micron) positional measurement. At the same time, the sampling interval, in this case 10 μm, and the processing speed have been enhanced such that a complete Schmidt plate has a turnround time of some 3 h. Programs for SuperCOMOS include rescanning the UKST BJ survey plates, incorporating the UKST OR and I survey plates and measuring the second epoch Palomar sky survey plates (POSSII) of the northern hemisphere. Both digital maps and image catalogs will be made available over the WWW.

Meanwhile back in Cambridge, also in the 1970s, Ed Kibblewhite, an electronics graduate, started work on a different system, the APM machine. Kibblewhite's breakthrough was to use a laser beam to scan the plate and a series of high-speed special-purpose computers to analyze the data in real time. An acousto-optic deflector generates the 'flying spot', or multichannel parallelism, necessary for fast scanning, by using a sound wave of varying frequency to diffract parts of the incident laser beam. The plate is held on a massive X–Y table which moves under the laser beam and the scanner samples the plate 250 000 times per second with a positional accuracy of a few tenths of a micron. The APM has been used to scan the first epoch Palomar sky survey plates (POSSI) of the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

northern hemisphere and the UKST BJ, OR and I survey plates. Catalogs for these plates are available on-line for fields at GALACTIC LATITUDES further than 20° from the plane.

In the US, Willem Luyten had pioneered the use of a manual BLINK COMPARATOR for locating stars of high proper motion. This early work culminated in the publication of measured proper motions of 94 263 stars that form the Bruce Proper Motion Survey, which he finished in 1937. This work continued and Luyten went on using the blink comparator to measure the proper motions of about 100 000 other stars. However, as this work extended to ever fainter stars, measurement by hand became too difficult. As a result, he and the Control Data Corporation designed a new fully automated computer-controlled blink machine based on laser optics, which was constructed in the late 1960s. This machine was specifically designed to do accurate astrometry and played a major role in the production of Luyten's Palomar proper motion catalogs.

After a major electronic upgrade in the 1980s under the direction of Roberta Humphries, this rather specialized machine was renamed the APS and was used on a wide-ranging program to digitize the POSSI red and blue sky survey plates. The APS is based on a laser spot deflected with a rotating prism and is capable of scanning two plates simultaneously in a few hours. Current projects include remeasuring the Luyten proper motion red survey plates and incorporation of catalogs based on POSSII. All the catalogs are available on the WWW.

Similar astrometric measurements using manually operated machines had also been undertaken at Lick Observatory as part of the Lick Proper Motion program. These culminated in the development of the Lick Automatic Measuring Engine (LAME) by Vasilevskis and Popov in 1966. Approximate positions of targets were read from punched cards, and used to drive the plate carriage to within 50–100 μm of the target. Photometric and astrometric measurements were made and recorded on a new card, with an iris being used for photometry and a spinning-sector scanner for centering. Initially LAME required frequent operator intervention, but later modifications to the electronics and computer system in the early 1970s greatly enhanced the efficiency and degree of automation, enabling the goals of the Lick Proper Motion program to be achieved.

Throughout all this, the main difference in focus between UK and US effort in measuring machine development was that GALAXY was the forerunner for a series of general-purpose machines in Britain, while in the US measuring machines were used solely for astrometry until the latter half of the 1980s (see also ASTROMETRY: HISTORY).

One of the main drivers for the latter-day expansion of measuring machine effort in the US was the mission requirement for the Hubble Space Telescope (HST), for a catalog of acquisition and guidance stars covering the whole sky down to roughly 15th magnitude in the visual (see also ASTROMETRY WITH HUBBLE SPACE TELESCOPE). In order to guarantee this objective Barry Lasker at the Space Telescope Science Institute (STSci), in Baltimore, initiated a program using two PDS micro densitometers to scan the Palomar Quick V survey and the UKST BJ survey. This catalog was made widely available to the astronomical community and has become the mainstay for ground-based telescope acquisition and guidance systems too. PDS machines are classical single-channel two-microscope instruments and, although slow compared with the other measuring machines previously mentioned, have the advantage of superior dynamic range. However, by digitizing the survey plates at a more modest resolution, and by being operated around the clock, they were able to digitize the whole sky prior to the launch of HST. In addition to the Guide star catalog, digitized maps of the whole sky were also made available for the first time. The STSci PDS systems were recently upgraded to include laser illumination and an acousto-optic deflector to provide a small number of channels, a compromise hedging between control of scattered light (a problem in all flying spot scanners) and increase of scanning speed. The upgraded system is being used to measure the UKST OR and POSSII survey plates. All the data, including digitized maps and object catalogs, are being made available on the WWW for public access.

The only other major system that is scanning large amounts of sky survey plates is Monet's PMM machine at the US Naval Observatory, Flagstaff. This machine is based on two-dimensional CCD cameras and features extensive software to correct for astrometric field effects in the individual footprint scans from each CCD camera. The PMM is capable of scanning four plates simultaneously in a few hours and has been used to measure all of the POSSI, UKST and POSSII blue and red survey plates, as well as a special set of short exposure plates in the north made on the same grid to improve the astrometric reference frame. Although the main goal of the project was a new ASTROMETRIC SURVEY, an all-sky object catalog with magnitude and color information for over 500 million objects to the limiting depths of the plates, is available on request.

The future of photographic sky survey material is guaranteed by the past. Although the current generation of all-sky survey material is based on photographic plates, the new large-format mosaic CCD cameras are performing the next generation of optical sky surveys to much deeper limits. However, the historic record provided by a century of photographic plates is invaluable and ensures that both archival plates in addition to sky survey plates will have a strong role to play in the foreseeable future.

Media

Astronomy is one of the sciences that can be experienced by everyone. The skies can be seen directly by all, and it is possible through disciplined observation for everyone to make contributions to current science, e.g. through observations of variable stars, comets, etc. An enhanced view of the sky is available through incredibly beautiful images from the Hubble Space Telescope (see http://oposite.stsci.edu/pubinfo/subject.html) and large ground-based instruments, such as the Anglo-Australian Telescope (see http://www.aao.gov.au/images.html).

Astronomy is mind expanding. The large distances, the effects of the connection between distance and time past ('look-back'), contemplation of the origin of the planets, the Sun, the stars and the Universe, the possibility that there are planets similar to the Earth elsewhere in space: amazing thoughts like these provoke wonder and excitement (see ART AND LITERATURE).

Thus astronomy is one of the most popular sciences, and is represented strongly in the information media, such as newspapers and broadcasting.

Astronomy is also connected with the adventure of space travel. It was possible to follow on TV the landings on the Moon made by the Apollo astronauts, and the later flights of the Space Shuttle. NEIL ARMSTRONG's 'one small step' onto the bleak rocks of the lunar Sea of Tranquillity was watched by many millions of viewers, world wide. Through the internet, very large numbers of people indeed followed the landing of Mars Pathfinder and the explorations by its rover Sojourner. Under its Administrator Dan Goldin, NASA has put an emphasis on a scientific return to the tax-payers of the USA who finance the NASA program, and there has thus been a rise in the opportunities for public participation in NASA space missions. The European Space Agency is increasing its emphasis on the public understanding of science.

Sound broadcasting does not have the immediacy of appeal of television, but is better suited to convey the ideas of astronomy. The superlatives of distance, time, size and energy appeal directly to the imagination but can best be conveyed through words.

A pioneer 'broadcast astronomer' in the UK was Sir JAMES JEANS (1877–1946). Midway in his academic career he was invited to write a popular book and produced *The Universe Around Us* (1929), which was an immediate success. He was soon invited to make a series of radio broadcasts, and these too were so well received that the rest of his career was concerned largely with the popularization of astronomy. Other early broadcasters included Sir ARTHUR EDDINGTON (1882–1944) and Guy Porter, of the Royal Observatory, Greenwich. FRED HOYLE's *The Nature of the Universe* (c 1955) was an influential BBC radio series that developed a reputation for the steady-state theory of the origin of the universe that still survives, although the theory itself is moribund.

The BBC's *The Sky at Night* television series began in 1957, presented by PATRICK MOORE; the programs have been broadcast late at night every four weeks since that time, and are said to be the longest-running TV series in Britain apart from the news. The series has given a large number of astronomers access to an audience of 2 or 3 million in the UK to whom they can directly communicate their work, as well as developing a large number of astronomical media 'experts'. There have also been various other shorter-lived series, on all networks, particularly the BBC channels and Channel 4.

In the United States, CARL SAGAN's *Cosmos* television program attracted a vast following. The Discovery channel in the USA broadcasts many astronomy programs. In France, the annual *Nuit des Etoiles* devotes a whole evening to astronomy and space, with segments of the program originating from across the country. Curiously, no country other than Britain has produced a regular television series like *The Sky at Night*, certainly not one of comparable length.

In presenting a scientific program, there has to be a compromise between the overtechnical and the oversimple approach. Therefore, the facts have to be given clearly without any impression of 'talking down' and to go into more detail means that the script writer and the presenter have to be highly skilled. Confusing programs tend to turn viewers away from science.

Ideas and images combine in the printed media, both in book form and in journals, magazines and newspapers. Newspapers carry predictions of astronomical phenomena, lunar phases, star charts, etc, as well as news reports on astronomical advances. In France, NICOLAS CAMILLE FLAMMARION (1842–1925) was especially noteworthy as a pioneer popularizer of astronomy through these forms, including many lavishly illustrated books (for example *L'Astronomie Populaire*) and a journal *L'Astronomie*, which he founded with the Société Astronomique de France in 1897 and which is still published. In the United States, the magazine *Sky and Telescope*, the largest-circulation astronomical magazine (circulation 125 000) traces its history to a four-page bulletin called the *Amateur Astronomer*, begun in 1929 and absorbed by a monthly magazine called *The Sky* started 1935 by the Hayden Planetarium. *The Sky* went independent in 1941 and merged with *The Telescope*, which had first appeared as a quarterly magazine in March 1931. In Britain, *Astronomy Now* has a circulation between 25 000 and 30 000.

Astronomical and space stories in the press are second only to stories about human biology in attracting public interest. In Britain, the decade of the 1990s has seen in magazines and newspapers an increase in the proportion of articles about astronomy. The rate of increase relative to the volume of published material is some 10% per year. This rise has been associated with a rise in enrolment in university courses in astronomy, doubling over a decade, and an increasing number of universities offering such courses (about half of British universities do so). There is evidence from surveys in Britain that an interest by young people in astronomy and space plays a key role

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

in attracting undergraduates into university studies of science and technology in general.

The world geographic distribution of institutes for astronomy, observatories, planetaria, astronomical societies and astronomical publishers is given by André Heck (http://vizier.u-strasbg.fr/~heck/aamaps.htm; see also A Heck *Astronomy Now* August 1998). The Eastern and the Western United States and Japan, the Netherlands, central European countries and the rest of Europe have a strong density of astronomical interest. France has a strong centralization of research in the Paris area (which has the highest concentration in the world of astronomy organizations). By contrast, the distribution of interest in astronomy in the USA and the UK is broadly based and follows the population distribution, particularly the astronomical societies. The London area is a world centre for global astronomical publishing.

The Royal Astronomical Society (http://www.ras.org.uk/ras/press/press.htm) and the American Astronomical Society maintain press offices that regularly issue press releases on scientific stories of astronomical interest. The take-up is by editors who are keen to balance the diet of serious political news, disturbing crimes and tragic accidents, which they feel obliged to cover, with more optimistic stories.

The key to the continued production of successful press releases includes above all the maintenance of scientific integrity, but there are additional factors which help the press take up a science story. There should be some national or local interest in it; it is helpful if one of the scientists is someone with whom the reader can identify. The international nature of science is helpful in getting an astronomical story published in many countries. In general, press interest increases with size of expenditure—the more money, the more important. Journalists are also influenced by the availability of scientists for follow-up interviews—each journalist looks for his/her unique 'angle' to the story via direct contact.

Pictures, especially color pictures, help produce a favorable editorial decision to publish. Such a decision is made by the scientifically uninformed, and an editor can be swayed by a picture (or an animation, in the case of TV). If the story contains a superlative (biggest, furthest, most massive, . . .) or a fancy name or picturesque metaphor, it is also more likely to be published. A widely reported astronomical press release in 1998 in the UK was about a rather technical study of peanut-shaped bipolar instabilities in star distributions within rotating barred spiral galaxies. This is not promising material for a popular scientific press release. Its take-up was due to the inspired label on the press release, using the name of a chocolate-nut confection, and referring to the 'Snickers hypothesis', that there is a peanut in every bar. It was possible to combine the scientific integrity of the work with enjoyment, and this is the essence of the presentation of astronomy in the information media.

Medieval Cosmology

During the early Middle Ages (ca 500 to ca 1130) scholars with an interest in cosmology had little useful and dependable literature. They relied heavily on a partial Latin translation of PLATO's *Timaeus* by Chalcidius (4th century AD), and on a series of encyclopedic treatises associated with the names of Pliny the Elder (ca AD 23–79), Seneca (4 BC–AD 65), Macrobius (fl 5th century AD), Martianus Capella (ca 365–440), Cassiodorus (ca 480–ca 575), Isidore of Seville (ca 560–636) and Venerable Bede (672–735). Even if we add certain works of the church fathers, especially St Basil (ca 330–379) and St Augustine (354–430), the cosmology embedded in all of these treatises was meager and insubstantial. Beginning in the 12th century, this changed dramatically when a large number of Greek and Arabic scientific treatises were translated into Latin, thus laying the foundation for the development of early modern science in the 17th century.

During the late Middle Ages, cosmology was not an independent discipline, but a branch of natural philosophy, a subject taught at the medieval universities, which had come into existence by 1200. Medieval cosmology was derived primarily from the natural philosophy of ARISTOTLE (ca 384–322 BC), the great Greek philosopher and scientist. Cosmology was also dependent on mathematical astronomy, which was associated with the name of Claudius PTOLEMY (ca 100–ca 170). The works of Aristotle relevant to cosmology, and the works of Ptolemy relevant to astronomy, were unknown in Western Europe until the second half of 12th century, following their translations into Latin from Greek and Arabic.

The large body of cosmological literature produced in the Middle Ages derives largely from questions that medieval natural philosophers drew from Aristotle's books on natural philosophy, especially his treatise *On the Heavens*. Nicole ORESME (ca 1320–1382), a famous natural philosopher and theologian, discussed the following questions in his treatise on Aristotle's *On the Heavens*:

> Whether it is possible that several worlds exist.
>
> Whether the heaven is of another nature than inferior things.
>
> Whether all the stars receive their light from the Sun or [whether] some [stars produce light] in themselves.
>
> Whether the entire Earth always rests.

Responses to these, and hundreds of similar, questions, posed over the centuries, formed the basis of medieval cosmology. There were also straightforward commentaries on Aristotle's works, together with questions and commentaries on a widely used 13th century work by JOHN OF HOLYWOOD, titled *Treatise on the Sphere*.

Aristotle and Christianity

The introduction of Aristotle's works posed a dilemma for medieval natural philosophers. From the Bible, they learned that the world was created by a divine power, who would eventually destroy it. From Aristotle's *On the Heavens* came a powerful contrary message: the world could not have had a beginning and could never come to an end. Aristotle's conviction that the world was without beginning or end conflicted with the basic Christian belief that our unique world was divinely created and of temporal duration. Indeed, by the early 13th century, it was accepted dogma in Latin Christendom that the world was created out of nothing (*ex nihilo*). Reactions to Aristotle's claims for eternity varied. Some, like St Bonaventure (1221–1274), were convinced that the temporal creation of the world was demonstrable. By contrast, Thomas Aquinas (ca 1225–1274) held that logical argument and evidence favored neither judgment. In his view, there was no contradiction in the possibility that God could have willed the existence of the world without a temporal beginning, making it both created and eternal.

The creation account in Genesis compelled Christian cosmologists to explain biblical claims. How, for example, does the heaven (*caelum*), or firmament, created on the first day, differ from the heaven (*caelum*) created on the second day? How does the light created on the first day compare with the light created on the fourth day? How could plants come forth on the third day when the Sun, whose warmth and light are required, was not created until the fourth day? What are the waters above and below the firmament? The various solutions to these questions were proposed in terms of contemporary Aristotelian physics and cosmology.

Can anything exist beyond our finite cosmos?

Most natural philosophers believed the world was a finite sphere. Did anything lie beyond it? Aristotle had argued that it was impossible for bodies, motions, places, time and vacuum to exist outside of our finite cosmos. To Christians, Aristotle's argument implied that not even God could create these things, and therefore He could not create other worlds beyond ours. Aristotle's arguments were viewed as placing constraints on God's absolute power to do as He pleased. In 1277, the Bishop of Paris condemned 219 articles that were deemed theologically offensive and unacceptable. Many of them were directed against Aristotle and his followers. One of the condemned articles claimed that God could not make other worlds. To repudiate Aristotle's claim, scholastic authors showed, by a variety of arguments, that identical and distinct worlds—and this type was most frequently discussed—could exist simultaneously. Many insisted that each of these identical worlds could exist as a self-contained, independent, closed system with its own center and circumference, thus rejecting Aristotle's argument for the existence of a unique center and circumference from which he had inferred a unique spherical world. The possibility of other worlds led to further challenges to Aristotle's authority. What Aristotle had deemed impossible was shown to be possible and intelligible.

Not all extracosmic entities were merely possible. One was real. On theological grounds, Thomas Bradwardine (ca 1290–1349), and a few other theologians,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

assumed the existence of a real, infinite space beyond our world, a space Bradwardine identified with God's infinite, omnipresent immensity. Because God was a being devoid of dimensions, the theologians who identified infinite void space with God's omnipresent immensity followed Bradwardine and also characterized that space as without extension. Bradwardine's ideas about space and God form an integral part of the history of spatial conceptions between the late 16th and 18th centuries, the period of the scientific revolution.

The celestial region of the cosmos

Aristotle divided the world into two radically different parts: (1) a celestial region of stars, planets and orbs that ranged from the Moon to the sphere of the fixed stars, and beyond, and was composed of a special ether, or fifth element; (2) a sublunar realm immediately below, ranging from the concave surface of the lunar orb to the center of the Earth and encompassing four elements—fire, air, water and earth—and the bodies compounded of them.

The celestial region, which is the part that will be described here, consisted of stars, planets and the orbs that carried them around the heavens. They were all made of the same transparent ether, which was assumed indivisible and incorruptible. Although the transparent orbs were invisible, the stars and planets were visible, because they were highly concentrated regions of ether that reflected light to Earthly observers. Most scholars assumed that the stars and planets received their light from the Sun and then transmitted that light to the Earth. Some further suggested that the planets were also weakly self-luminous. Both planets and stars were regarded as spherically shaped.

In what was a virtually self-evident truth, derived ultimately from Aristotle, the celestial bodies were believed to govern the behavior of material things in the terrestrial region below the lunar orb. Not only was this the basis of astrology, but it played an important role in natural philosophy. The influence of the celestial bodies was accomplished by their motions, by light transmitted from their bodies and by general influences that were invoked to explain many otherwise inexplicable phenomena (for example, the formation of metals within the depths of the Earth, magnetism and the tides caused by the Moon).

Natural philosophers were agreed on the existence of seven planets and the fixed stars. Without the detection of parallax, the order of celestial bodies was made on non-astronomical grounds. Since the planets moved against the background of the stars, the latter were assumed farthest from the Earth and equidistant from it. The superior planets—Saturn, Jupiter, and Mars—were ranked by their sidereal periods in that order. Because Venus and Mercury always remained in the vicinity of the Sun, the order of these three planets was not determinable except by non-astronomical arguments. Most followed Ptolemy's arrangement and located the Sun, Venus and Mercury in descending order, followed by the Moon. Because of its life-giving properties, the Sun was regarded as the largest, noblest and most important planet. Counting upward from the Moon or downward from Saturn, the Sun occupied the fourth, or middle, position and was perceived as a 'wise king in the middle of his kingdom' or as the 'heart in the middle of the body'.

The celestial spheres

Although to the naked eye it appeared that planets were self-moved, like fish in water or birds in air, natural philosophers denied appearances and assumed, with Aristotle and Ptolemy, that each planet was embedded in a single transparent, invisible, ethereal sphere, which carried it around. Similarly the stars, which always remained at fixed intervals from each other, were located on a single sphere, which carried them around. Not only was each planet assigned a single sphere, but each motion of each planet—daily motion, sidereal motion, motion in latitude, etc—was also assigned its own orb. Although Ptolemy and Aristotle assumed that each planet was attached to a single sphere, both employed a plurality of spheres to account for the resultant motion of each planet. By assigning one orb to each motion of a planet, both Aristotle and Ptolemy were compelled to assign multiple orbs to each planet. Aristotle assigned as many as 55 for all the planets, while Ptolemy assigned as many as 41.

Aristotle's spheres, however, differed from Ptolemy's. Aristotle's orbs were concentric with respect to the Earth, which lay at the center of the world, whereas Ptolemy's were basically eccentric. This meant that the centers of the planetary orbits were geometric points that did not coincide with the Earth's center, which was assumed identical with the geometric center of the world. It followed that the planets orbited around centers other than the Earth's center, a clear violation of Aristotle's dictum that all planetary orbs move around the Earth's center. It became apparent that Aristotle's concentric orbs could not account for observed variations in the distances of the planets and that Ptolemy's eccentrics and epicycles, which had been devised to cope with that problem, could. Natural philosophers confronted a dilemma: either adopt Aristotle's concentric system with the Earth serving as the center of all planetary orbits, but abandon any attempt to account for variation in planetary distances, or adopt Ptolemy's system of eccentrics and account for the variation of planetary distances, but yield up the central tenet of Aristotle's natural philosophy, namely that the Earth is the sole center of planetary orbits.

Medieval natural philosophers adopted a compromise that retained both concentricity and eccentricity. It was a compromise that had already been made by Ptolemy (in his *Hypotheses of the Planets*) and hinged on a distinction between the concept of a 'total orb' (*orbis totalis*) and a 'partial orb' (*orbis partialis*), to use medieval terminology. The 'total orb' is a concentric orb whose center is the center of the Earth, whereas a 'partial orb' is an eccentric orb whose center is a geometric point lying outside the center of the world. The concentric total orb contains within

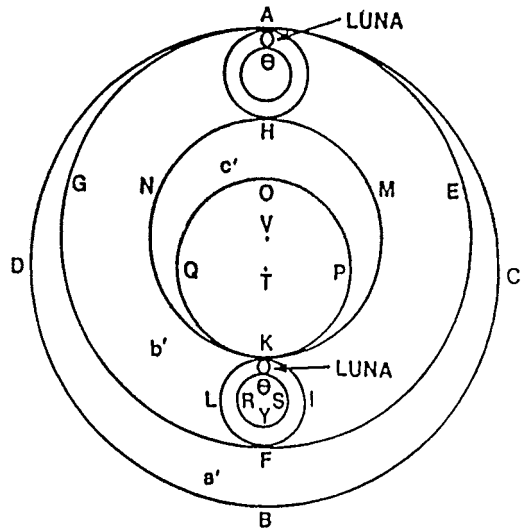

Figure 1. Representation of the Moon's concentric, eccentric and epicyclic orbs as described in Roger Bacon's *Opus tertium* in Duhem P (ed) 1909 *Un fragment inédit de l'Opus Tertium de Roger Bacon précedé d'une étude sur ce fragment* (Florence: Collegium S. Bonaventurae) p 129.

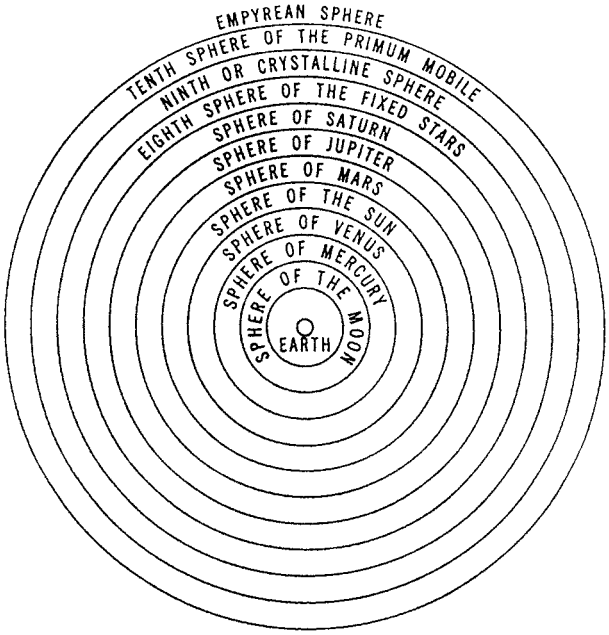

Figure 2. The order of the celestial orbs in the medieval cosmos. Reprinted from Grant E 1977 *Physical Science in the Middle Ages* (Cambridge: Cambridge University Press) p 72.

its concave and convex surfaces at least three partial orbs, one of which, the eccentric deferent, carries an epicycle in which a planet is embedded. (In figure 1, which represents the Moon, the three partial orbs lie in the spaces between ADBC and AGFE, AGFE and HNKM, and HNKM and OQKP.) In this way, Ptolemy's eccentric orbs were encompassed and encircled by the surfaces of Aristotle's concentric orbs.

The number of celestial orbs could thus be determined in two different ways: either as the totality of concentric, or 'total', orbs or as the totality of eccentric, or 'partial', orbs. Aristotelian natural philosophers were interested in the former and rarely in the latter. In fact, the most popular question in medieval cosmology was about the number of spheres. The response required a count of total, or concentric, orbs. The answers to this question varied anywhere from 8 to 11 (see figure 2). Eight concentric orbs represented the seven planets and the sphere of the fixed stars. However, as many as three different motions were assigned to the sphere of the fixed stars (the daily motion, precession and a motion called trepidation that turned out to be non-existent). Applying the principle that a single sphere must be assigned to each distinct celestial motion, two additional spheres, plus an immobile empyrean sphere, were usually added for a total of 11. No celestial bodies were embedded in these three invisible orbs.

The eighth to eleventh orbs had important scriptural associations. The biblical firmament was most frequently identified with the eighth sphere of the fixed stars. Early in the history of Christianity, the waters above the firmament were conceived as crystalline, a term that was sometimes thought of as applying to fluid waters, and sometimes to waters that were congealed and hard, like a crystal. The crystalline orb was usually located above the firmament and was identified with a starless ninth sphere and occasionally with both the ninth and tenth spheres. The outermost orb of the universe was the empyrean sphere, which, in contrast to the perpetually moving orbs it enclosed, was immobile. It was conceived as 'the dwelling place of God and the elect', a place filled with the purest light. If the number of mobile orbs was n, the empyrean orb was always numbered $n + 1$.

Medieval natural philosophers frequently asked: what caused the orbs to move? Most believed that each orb was assigned an immaterial, spiritual intelligence distinct and separate from the orb it moved. Intelligences, often identified with angels, were conceived as voluntary agents divinely endowed with inexhaustible powers to move their respective orbs with uniform circular motion. Not all scholastics invoked intelligences. A small minority held that God created the orbs with an intrinsic power for self-motion. John BURIDAN (ca 1295–ca 1358) even invoked a divinely impressed force, or impetus, that enabled the orbs to move forever through a celestial ether that was assumed to offer no resistance to their motion.

The status of the Earth at the center of the world was much debated. John Buridan held that the Earth's center of gravity was always changing as a consequence of geological alterations of the Earth's surface. These alterations caused the Earth to move continually with small movements as it sought to bring its center of gravity into coincidence with the geometric center of the universe. Buridan and Nicole Oresme contemplated

a more radical motion of the Earth when they asked whether the daily rotation of the heavens might not actually derive from a daily axial rotation of the Earth. For different reasons, they both eventually rejected this alternative, but were agreed that, on the assumption of the immobility of the heavens, the Earth's daily rotation saved the astronomical phenomena just as well as the traditional opinion. NICOLAUS COPERNICUS (1473–1543) found their arguments in favor of an axially rotating Earth worthy of inclusion in defense of his heliocentric system, in which the Earth is assigned both a daily rotation and an annual motion around the Sun.

By modern standards, the medieval cosmos was miniscule. In a popular 13th century astronomical treatise by Campanus of Novara, the distance from the center of the Earth to the concave surface of the fixed stars, which was the outermost orb that contained celestial bodies, was given as approximately 73 million miles. The lunar orb was only 108 000 miles from the Earth, while the Sun was approximately 4 million miles away.

Medieval, Aristotelian cosmology remained functional until the end of the 17th century, by which time the efforts of Copernicus, TYCHO BRAHE, GALILEO GALILEI, KEPLER and NEWTON had produced a new cosmology, which rendered the old obsolete and irrelevant.

Menelaus of Alexandria (*c*. 70–*c*. 130)

Greek mathematician, born in Alexandria, Egypt (possibly), wrote many books, of which only one, *Sphaerica*, on spherical astronomy, has survived, and including *Menelaus Theorem*, on a property of spherical triangles. PTOLEMY mentions astronomical observations made by Menelaus in Rome in the year 98.

Mensa

(the Table; abbrev. Men, gen. Mensae; area 153 sq. deg.) A southern constellation which lies between Hydrus and Volans, and culminates at midnight in mid-December. It was named Mons Mensae (Table Mountain) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky from the Cape of Good Hope, South Africa, in 1751–2, as the presence of the southern portion of the Large Magellanic Cloud in the northern part of the constellation reminded him of cloud enveloping the summit of Table Mountain.

A small, inconspicuous constellation, the brightest star in Mensa is of magnitude 5.1. Interesting objects include NGC 1841, an eleventh-magnitude globular cluster, and IC 2051, an eleventh-magnitude spiral galaxy.

See also: Large Magellanic Cloud.

Mercator, Gerardus [Gerhard Kremer] (1512–94)

Cartographer ('cosmographer'), born in Rupelmonde, Flanders (now Belgium), studied mathematics, its applications to geography and astronomy, and how to make scientific instruments. Constructed terrestrial and celestial globes. Was charged with heresy, a result of suspicion aroused by his travel to collect data for maps, and was imprisoned for several months, after which charges were dropped. Invented the *Mercator map projection* (1569) which has perpendicular longitudes and latitudes, and an expansion towards the poles, such that the bearing from one place to another can be found by a protractor, without the use of spherical trigonometry (a development of an earlier Chinese discovery). He published a comprehensive geographical 'atlas' (he was the first to use the word in this way). His break with PTOLEMY was as important for geography as was Copernicus's for astronomy.

Mercury

Mercury is the innermost and second smallest planet in the solar system (Pluto is smaller). It has no known satellites. To date, MARINER 10 is the only spacecraft that has explored the planet. It flew past Mercury on 29 March and 21 September 1974, and on 16 March 1975. Mariner 10 imaged only about 45% of the surface at an average resolution of about 1 km, and less than 1% at resolutions between about 100 to 500 meters. This coverage and resolution is comparable to telescopic Earth-based coverage and resolution of the MOON before the advent of space flight. The Mariner 10 data, however, are still our best source of detailed information on the planet. As a consequence, there are still many uncertainties and questions concerning the history and evolution of Mercury. However, recent ground-based observations have provided information on the radar and microwave characteristics of its surface, discovered new constituents in its exosphere, and helped constrain its surface composition. Because of its close proximity to the Sun, missions to Mercury are extremely difficult; more so than to the outer solar system. However, a new mission to Mercury called MESSENGER is scheduled for launch in 2004. It will make one flyby of Earth, two of Venus and two of Mercury before going into Mercury orbit in 2009. This mission will provide vital new information on this poorly known planet. Mercury missions are also being considered by the European and Japanese space agencies.

General characteristics

Mercury's diameter is only 4878 km, but it has a relatively large mass of 3.301×10^{23} kg. Because of its large mass in relation to its volume, Mercury has an exceptionally high mean density of 5.44 g cm^{-3}. The manner in which it reflects light is very similar to the way light is reflected by the Moon. Mercury is covered with a REGOLITH consisting of fragmental material derived from the impact of meteoroids over billions of years. Mercury's surface is heavily cratered with smooth planes filling and surrounding large impact basins. Long lobate scarps traverse the surface for hundreds of kilometres, and large expanses of intercrater plains (the most extensive terrain type) fill regions between clusters of craters in the highlands. A terrain consisting of large blocks and linear troughs occurs antipodal to the CALORIS BASIN. Although Mercury superficially resembles the Moon, there are major differences which set it apart from the Moon, and all other planets and satellites in the solar system.

Motion and temperature

Mercury has the most eccentric (0.205) and inclined (7 degrees) orbit of any planet except Pluto. Although its average distance from the Sun is 0.3871 AU (5.79×10^7 km), its large eccentricity results in a distance varying from 0.3075 AU (4.6×10^7 km) at perihelion to 0.4667 AU (6.98×10^7 km) at aphelion. Consequently, Mercury's orbital velocity averages 47.6 km s^{-1}, but varies from 56.6 km s^{-1} at perihelion to 38.7 km s^{-1} at aphelion.

Mercury's rotation period is 58.646 Earth days and its orbital period is 87.969 Earth days. Therefore, it has a unique 3:2 resonant relationship between its rotational and orbital periods. It turns exactly three times on its axis for every two orbits around the Sun. This resonance was apparently acquired over time as the natural consequence of the dissipative processes of tidal friction and the relative motion between a solid mantle and a liquid core. Because of this resonance, a solar day (sunrise to sunrise) lasts two Mercurian years or 176 Earth days. The obliquity of Mercury is close to 0 $^\circ$ and, therefore, it does not experience seasons. Consequently, the polar regions never receive the direct rays of sunlight and are always frigid compared to very hot sunlit equatorial regions.

Another effect of the 3:2 resonance between the rotational and orbital periods is that the same hemisphere always faces the Sun at alternate perihelion passages. The hemisphere facing the Sun at one perihelion will rotate one and a half times by the next perihelion, placing it directly facing the Sun again. Another consequence of the 3:2 resonance is that an observer on Mercury (depending on location) would witness either a double sunrise, a double sunset, or the Sun would backtrack in the sky at noon during perihelion passage. Near perihelion Mercury's orbital velocity is so great compared to its rotation rate that it controls the Sun's apparent motion in the sky as viewed from Mercury.

Because Mercury is so close to the Sun, has no insulating atmosphere, and has such a long solar day, it experiences the greatest range (day to night) in surface temperatures (635 K) of any planet or satellite in the solar system. Its maximum surface temperature is about 725 K at perihelion on the equator, but drops to about 90 K at night.

Exosphere

Mercury has an extremely tenuous atmosphere with a surface pressure a trillion times less than Earth's. The number density of atoms at the surface is only 10^5 atoms cm^{-3} for the known constituents. It is, therefore, an exosphere where atoms rarely collide; their interaction is primarily with the surface. Mariner 10's ultraviolet spectrometer identified hydrogen, helium and oxygen, and set upper limits on the abundance of argon. The hydrogen and helium are probably derived largely from the solar wind, although a portion of the helium may be of radiogenic origin and some hydrogen could result from the photodissociation of H_2O. The interaction of high-energy particles with surface materials may liberate enough oxygen to be its principal source, but breakdown of water vapor molecules by sunlight could also be a possible source.

In 1985–86, Earth-based telescopic observations detected sodium and potassium in the exosphere. Both sodium and potassium have highly variable abundances (10^4–10^5 Na atoms cm^{-3} and 100–10^4 K atoms cm^{-3})

Dirac House, Temple Back, Bristol, BS1 6BE, UK

near the surface on time scales of hours to years. Their abundances also vary between day and night by a factor of about 5, the day side being greater. The temperature of the gas is about 500 K, but a hotter more extended Na coma sometimes exists.

Although both sodium and potassium are probably derived from the surface of Mercury, the mechanism by which they are supplied is not well understood. They could be released from sodium- and potassium-bearing minerals by their interaction with solar radiation, or by impact vaporization of micrometeoroid material. Both sodium and potassium show day-to-day changes in their global distribution.

Polar deposits

In 1991, high resolution, full disk radar images of Mercury were obtained from both the Arecibo and the linked Goldstone–Very Large Array radar facilities. The radar signals show very high reflectivities and polarization ratios centered on the poles of Mercury. Mariner 10 images of Mercury's polar regions show cratered surfaces where ice could be concentrated in permanently shadowed portions of the craters, and the radar studies show that the anomalies are indeed concentrated in the permanently shadowed portions of these polar craters. Because the obliquity of Mercury is near 0 degrees, it does not experience seasons, and therefore, temperatures in the polar regions should be <135 K. In permanently shaded polar areas the temperatures should be less than 112 K, and water ice should be stable to evaporation on time scales of billions of years. If the deposits are water ice, then they could originate from comet or water-rich asteroid impacts that released the water to be cold-trapped in the permanently shadowed craters. Because comets and asteroids also impact the Moon, similar deposits would be expected to occur in the permanently shadowed regions of lunar craters. Indeed, the Lunar Prospector mission did detect water ice in these regions of the Moon.

Interior and magnetic field

Mercury's internal structure is unique in the solar system. It also imposes severe constraints on any proposed origin of the planet. Mercury's mean density of 5.44 g cm^{-3} is only slightly less than Earth's (5.52 g cm^{-3}), and larger than Venus' (5.25 g cm^{-3}). Because of Earth's large internal pressures, however, its uncompressed density is only 4.4 g cm^{-3} compared to Mercury's uncompressed density of 5.3 g cm^{-3}. This means that Mercury contains a much larger fraction of iron than any other planet or satellite in the solar system. If this iron is concentrated in a core, then the core must be about 75% of the planet diameter, or some 42% of its volume. Thus, its silicate mantle and crust is only about 600 km thick. For comparison, Earth's iron core is only 54% of its diameter, or just 16% of its volume.

Mercury is the only other terrestrial planet, aside from Earth, with a significant magnetic field. Mariner 10 discovered that Mercury has a global intrinsic dipole magnetic field, but it is not well characterized because the spacecraft only made two passes through the field. The magnitude of the dipole moment is about 330 nT, or over 1000 times smaller than Earth's. Although relatively weak, the field has sufficient strength to hold off the solar wind, creating a bow shock, a magnetosheath, and a magnetosphere (see MERCURY: MAGNETOSPHERE). Because of the weaker field, Mercury occupies a much larger fraction of the volume of its magnetosphere than do other planets, and the solar wind actually reaches the surface at times of highest solar activity. The size of the magnetosphere is about 7.5 times smaller than Earth's. Also, because of the small size of Mercury's magnetosphere, magnetic events happen more rapidly and repeat more often than in Earth's magnetosphere.

Although other models may be possible, the maintenance of terrestrial planet magnetic fields is thought to require an electrically conducting fluid outer core surrounding a solid inner core. Therefore, Mercury's dipole magnetic field suggests that Mercury currently has a fluid outer core of unknown thickness. Thermal history models indicate that Mercury's core should have solidified long ago unless there was some way of maintaining high core temperatures throughout geological history. The preferred way is to lower the melting point of the core material by adding a light alloying element. Sulfur is considered to be the most likely candidate. If sulfur is the alloying element, then Mercury probably contains between 0.2 and 7% sulfur in its core in order to have an outer fluid portion at the present time.

Geology and composition

In general, the surface of Mercury can be divided into four major terrains: (1) heavily cratered regions, (2) intercrater plains, (3) smooth plains, and (4) hilly and lineated terrain. Other relatively minor units have been identified, such as ejecta deposits exterior to the Caloris basin and other large impact CRATERS. The heavily cratered uplands record the period of late heavy meteoroid bombardment that ended about 3.8 billion years ago. In the heavily cratered terrain on Mercury there is an increasing paucity of craters with decreasing crater diameter relative to heavily cratered terrain on the Moon. This paucity of craters is probably due to obliteration of the smaller craters by emplacement of intercrater plains during this period of late heavy bombardment. The crater population superimposed on the smooth plains within and surrounding the Caloris basin shows a same size distribution but at a much lower crater density. This suggests that unlike the lunar maria the Caloris smooth plains formed near the end of late heavy bombardment.

Fresh impact craters on Mercury exhibit similar morphologies as those on the other terrestrial planets. Small craters are bowl-shaped, but with increasing size they develop central peaks, flat floors, and terraces on their inner walls. The transition from simple (bowl-shaped) to complex (central peak and terraces) craters is about 10 km. At diameters between about 130 to 310 km mercurian craters have an interior concentric ring, and

Dirac House, Temple Back, Bristol, BS1 6BE, UK

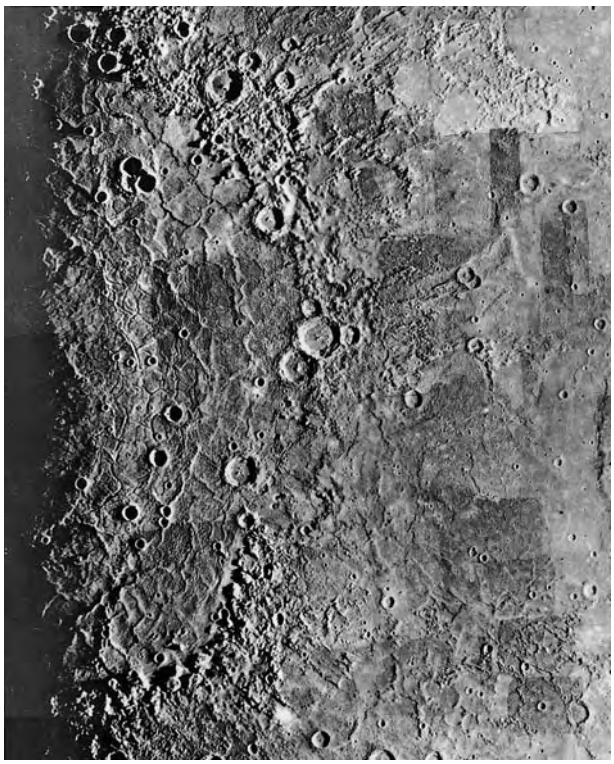

Figure 1. Photomosaic of the 1300 km diameter Caloris impact basin showing the highly ridged and fractured nature of its floor.

at diameters larger than about 300 km they may have multiple inner rings. The freshest craters have extensive ray systems, some of which extend for distances over 1000 km. For a given rim diameter the radial extent of mercurian continuous ejecta is uniformly smaller by a factor of about 0.65 than that for the Moon. Furthermore, the maximum density of secondary impact craters occurs closer to the crater rim than for similar-sized lunar craters. All of these differences are probably due to the larger surface gravity of Mercury (3.70 m s^{-2}) compared to the Moon (1.62 m s^{-2}).

The largest relatively fresh impact feature seen by Mariner 10 is the 1300 km diameter Caloris basin. The floor structure consists of closely spaced ridges and troughs arranged in both a concentric and radial pattern (figure 1). The ridges are probably due to compression, while the troughs are probably tensional graben that post-date the ridges. This pattern may have been caused by subsidence and subsequent uplift of the basin floor.

Directly opposite the Caloris basin (the antipodal point) is the unusual hilly and lineated terrain that disrupts pre-existing landforms, particularly crater rims (figure 2). Stratigraphic relationships suggest that the age of this terrain is the same as the Caloris basin. The hilly and lineated terrain is thought to be the result of seismic waves generated by the Caloris impact and focused at the antipodal region.

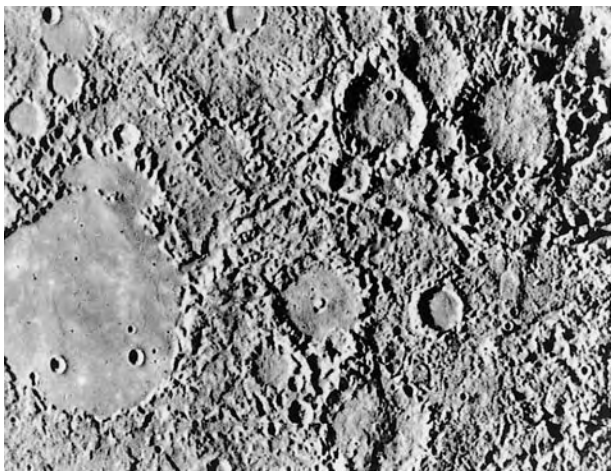

Figure 2. A portion of the hilly and lineated terrain antipodal to the Caloris impact basin. The image is 543 km across.

Mercury's two plains units have been interpreted as lava plains. The older intercrater plains are the most extensive terrain on Mercury (figures 3(a) and 3(b)). They have probably been responsible for obliterating a significant number of craters as evidenced by the paucity of craters less than about 40 km diameter compared to the highlands of the Moon. Intercrater plains were emplaced over a range of ages contemporaneous with the period of late heavy bombardment. They are thought to be volcanic plains erupted through a fractured crust. They are probably about 4.0 to 4.2 billion years old.

The younger smooth plains are primarily associated with large impact basins. They also fill smaller basins and large craters. The largest occurrence of smooth plains fill and surround the Caloris basin, and occupy a large circular area in the north polar region that is probably an old impact basin about 1500 km in diameter. They are similar in morphology and mode of occurrence to the lunar maria, and, therefore, they are interpreted to be lava flows erupted relatively late in mercurian history. They may have an average age of about 3.8 billion years as indicated by crater densities. If so, they are, in general, older than the lunar maria.

Three large radar-bright anomalies have been identified on the unimaged side of Mercury. One of these is similar to the radar signature of a fresh impact crater, and another has a radar signature unlike any other in the solar system. However, the third radar anomaly has a more or less structureless radar-bright halo (500 km diameter) and a radar-dark center (70 km diameter). This is similar to the radar signatures of large shield volcanoes on Venus and Mars. If this radar feature is indeed a shield volcano, then it is as large as Mons Olympus on Mars. Furthermore, the fact that it is bright means it is relatively fresh, otherwise it would not give a radar signature. If this feature is, indeed, a relatively fresh shield volcano, then the history of Mercury is probably radically different than previously believed.

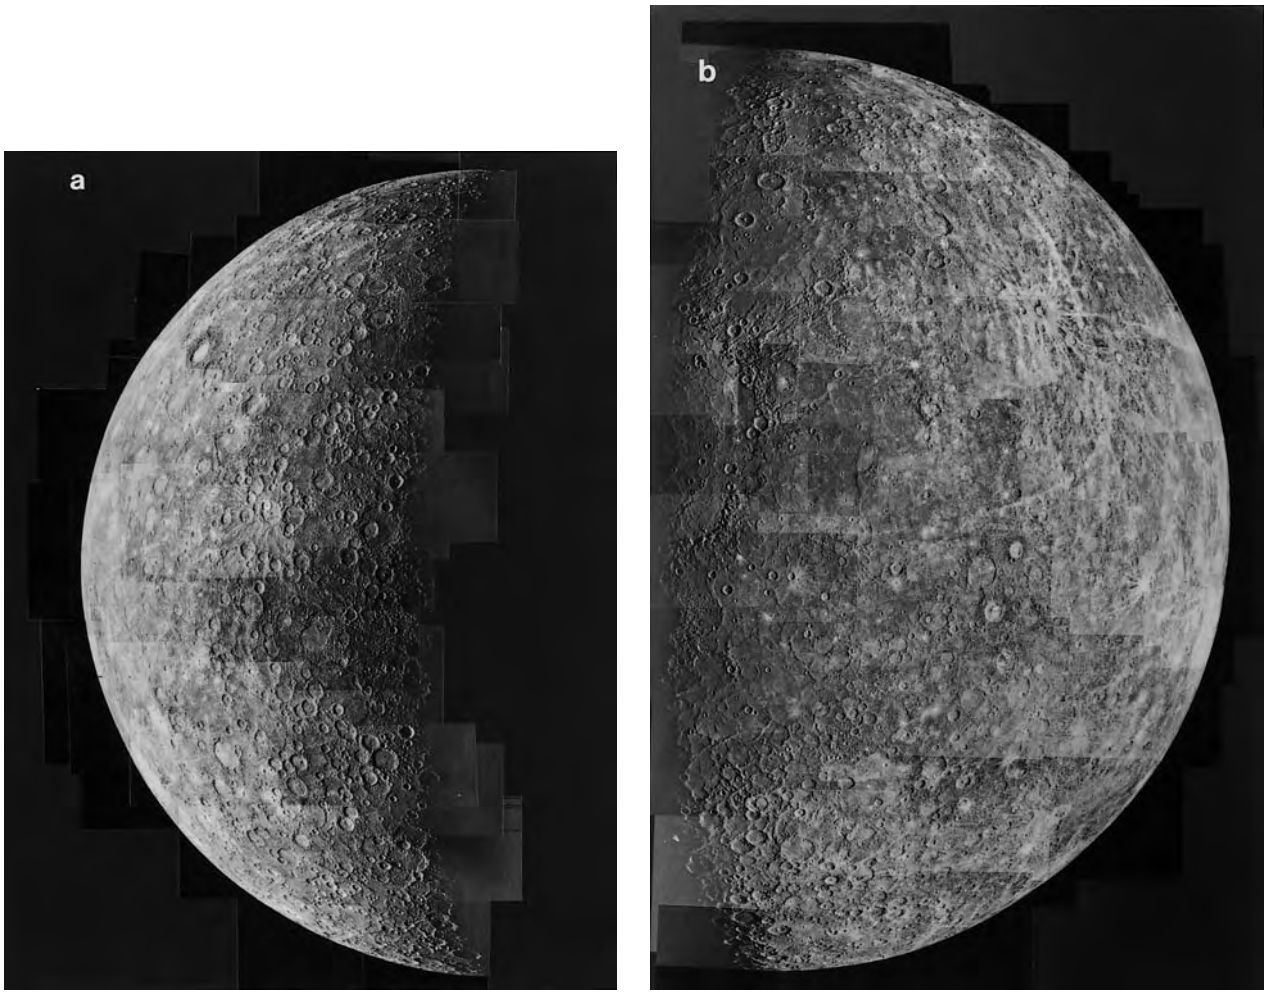

Figure 3. (a) Mercury as viewed by Mariner 10 on its first approach in March, 1974. (b) Mercury's opposite hemisphere viewed by Mariner 10 as it left the planet on the first encounter.

Mercury's tectonic framework consists of a system of compressive thrust faults called lobate scarps. Individual scarps vary in length from about 20 km to over 500 km, and have heights from a few 100 m to about 3 km. They have a random spatial and azimuthal distribution over the imaged half of the planet and presumably occur on a global scale. This suggests that Mercury was subjected to global compressive stresses. The only occurrences of features indicative of tensile stresses are localized fractures associated with the floor of the Caloris basin and at its antipode, both of which are the direct or indirect result of the Caloris impact. Stratigraphic evidence indicates that the system of thrust faults post-dates the formation of intercrater plains and formed relatively late in mercurian history. This tectonic framework was probably caused by crustal shortening resulting from a decrease in the planet radius due to cooling of the planet. The amount of radius decrease is estimated to have been about 2 km.

Very little is known about the surface composition of Mercury. Recalibration and color ratioing of Mariner 10 images have been used to derive the FeO abundance, the opaque mineral content, and the soil maturity over the region viewed by Mariner 10. The probably volcanic smooth plains have a FeO content of <6% by weight, which is similar to the rest of the planet imaged by Mariner 10. The surface of Mercury, therefore, may have a more homogeneous distribution of elements affecting color (e.g. more alkali plagioclase) than does the Moon. At least the smooth plains may be low iron or alkali basalts. There are some dark blue, low albedo, and high opaque mineral regions with diffuse boundaries that may be associated with fractures. These areas could be more mafic volcanic pyroclastic deposits. The bright rayed craters on Mercury have a very low opaque mineral index that may indicate the craters have excavated into an anothositic crust similar to that on the Moon. Earth-based spectroscopic measurements suggest that Mercury's surface is low in titanium and iron compared to the surface of the Moon. This is consistent with Mercury's lower ultraviolet reflectivity and smaller albedo contrast.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

This has been interpreted to mean that Mercury's surface is largely devoid of basalt, but it could also mean that the basalts only have a low iron content or are fluid alkali basalts.

Geological history

Mercury's earliest history is very uncertain. The earliest events are the formation of intercrater plains ($\geq$4 billion years ago) during the period of late heavy bombardment. These plains may have been erupted through fractures caused by large impacts in a thin lithosphere. Near the end of late heavy bombardment the Caloris basin was formed by a large impact that caused the hilly and lineated terrain from seismic waves focused at the antipodal region. Further eruption of lava within and surrounding the Caloris and other large basins formed the smooth plains about 3.8 billion years ago. The system of thrust faults formed after the intercrater plains, and resulted in a radius decrease of about 2 km. The volcanic history is very uncertain. If the radar anomaly on the unseen side is truly a relatively fresh shield volcano then the unimaged portion of Mercury may have a totally different volcanic history from the imaged side. We will have to await the results of the MESSENGER mission to fully evaluate the history of Mercury.

Origin

The origin of Mercury and how it acquired such a large fraction of iron compared to the other terrestrial planets is not well determined. Three hypotheses have been put forward to explain the enormous iron core. One involves an enrichment of iron due to mechanical and dynamical accretion processes in the inner-most part of the solar system. Another proposes that intense bombardment by solar electromagnetic and corpuscular radiation in the earliest phases of the Sun's evolution vaporized and drove off much of the silicate fraction of Mercury leaving the core intact. A third proposes a planet-sized object impacted Mercury and essentially blasted away much of the planet's silicate mantle leaving the core largely intact. Discriminating between these hypotheses may be possible from the chemical make-up of the surface because each one predicts a different composition. MESSENGER is designed to measure the composition of Mercury's surface so it may be possible to answer this vital question in the near future.

Mercury: Magnetosphere

Among the major discoveries made by the MARINER 10 mission to the inner planets was the existence of an intrinsic magnetic field at Mercury with a dipole moment of $\sim$ 300 nT R_M^3. This magnetic field is sufficient to stand off the solar wind at an altitude of about 1 R_M (i.e. $\sim$2439 km). Hence, Mercury possesses a 'magnetosphere' from which the solar wind plasma is largely excluded and within which the motion of charged particles is controlled by the planetary magnetic field. Despite its small size relative to the magnetospheres of the other planets (see PLANETARY MAGNETOSPHERES), a Mercury orbiter mission is a high priority for the space physics community. The primary reason for this great interest is that Mercury, unlike all the other planets visited thus far, lacks a significant atmosphere; only a vestigial exosphere is present (MERCURY). This results in a unique situation where the magnetosphere interacts directly with the outer layer of the planetary crust (i.e. the regolith). At all of the other planets the topmost regions of their atmospheres become ionized by solar radiation to form ionospheres. These planetary ionospheres then couple to electrodynamically to their magnetospheres or, in the case of the weakly magnetized Venus and Mars, directly to the solar wind. This magnetosphere–ionosphere coupling is mediated largely through field-aligned currents (FACs) flowing along the magnetic field lines linking the magnetosphere and the high-latitude ionosphere. Mercury is unique in that it is expected that FACs will be very short lived due to the low electrical conductivity of the regolith.

Furthermore, at the Earth it has been shown that the outflow of neutral atmospheric species to great altitudes is an important source of magnetospheric plasma (following ionization) whose composition may influence subsequent magnetotail dynamics. However, the dominant source of plasma for most of the terrestrial magnetosphere is the 'leakage' of solar wind across the magnetopause and more direct entry through the northern and southern cusps. Although Mariner 10 did not return plasma composition measurements, the Hermean magnetosphere should be ideal for measuring the manner and rate of solar wind plasma entry due to the lack of strong internal atmospheric sources. Finally, the solar wind conditions experienced by Mercury as it orbits the Sun at 0.31 to 0.47 AU are quite different from those typically encountered by the Earth. This may allow for new understanding of the external factors affecting the transfer of mass, momentum and energy from the solar wind to planetary magnetospheres. This article provides a brief overview of what is now known about Mercury's magnetosphere and why it is a priority target for future planetary missions.

Mariner 10 encounters

Following its launch on 2 November 1973, the Mariner 10 spacecraft executed three close encounters with the planet Mercury on 29 March 1974, 21 September 1974, and 16 March 1975. The first encounter was targeted to pass through the wake of the planet in order to determine its interaction with the solar wind. The closest approach to the surface of the planet occurred over the post-midnight equatorial region at an altitude of about 700 km. Figure 1 displays 1.2 s averages of the magnetic fields observed during the first Mariner 10 encounter in Mercury-centered solar ecliptic coordinates. The intensity of the magnetic field observed by Mariner 10 peaked near closest approach at just under 100 nT. This maximum is due to the increased contribution from the planetary magnetic field which varies as the inverse third power of the distance from the planet. The second encounter passed well upstream of the planet to return dayside images and did not allow observations of the magnetosphere. The third encounter was intended to achieve higher latitudes and lower altitudes in order to confirm the intrinsic nature of the magnetic field. This effort was successful with a closest approach altitude of only 327 km near local midnight at $\sim$68° N latitude and a peak measured magnetic field intensity of $\sim$400 nT.

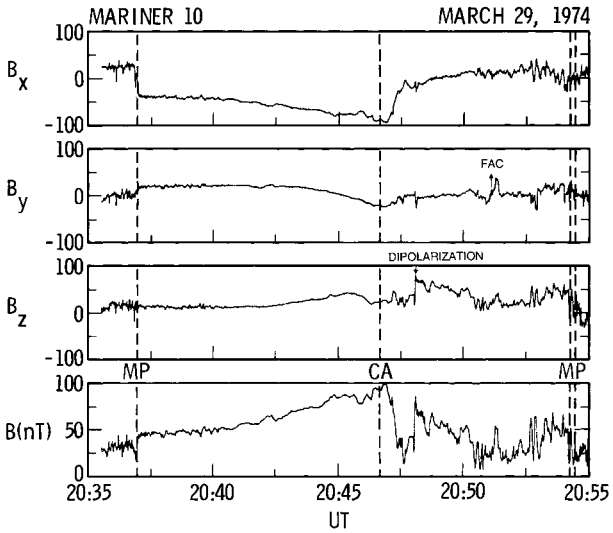

Figure 1. The Mariner 10 magnetic field observations (1.2 s averages) taken during the first encounter are displayed in Mercury centered solar ecliptic coordinates. In this system the X_{ME} axis is directed toward the Sun and the Y_{ME} axis is in the plane of the ecliptic, perpendicular to X_{ME} and directed oppositely from the direction of planetary orbital motion. The Z_{ME} axis completes the right-handed orthogonal system and is positive toward the north. Magnetopause, dipolarization and field-aligned current signatures in the observations are labeled. (From Slavin *et al* (1997).)

Magnetospheric structure

Both of Mariner 10's magnetospheric traversals began and ended with the magnetic field and plasma investigations observing clear magnetopause boundaries (see MAGNETOSPHERE OF EARTH: MAGNETOPAUSE). The magnetopause is the current layer formed by the interaction between the solar wind plasma and a planetary magnetic field. The magnetopause current layer confines most of the magnetic flux

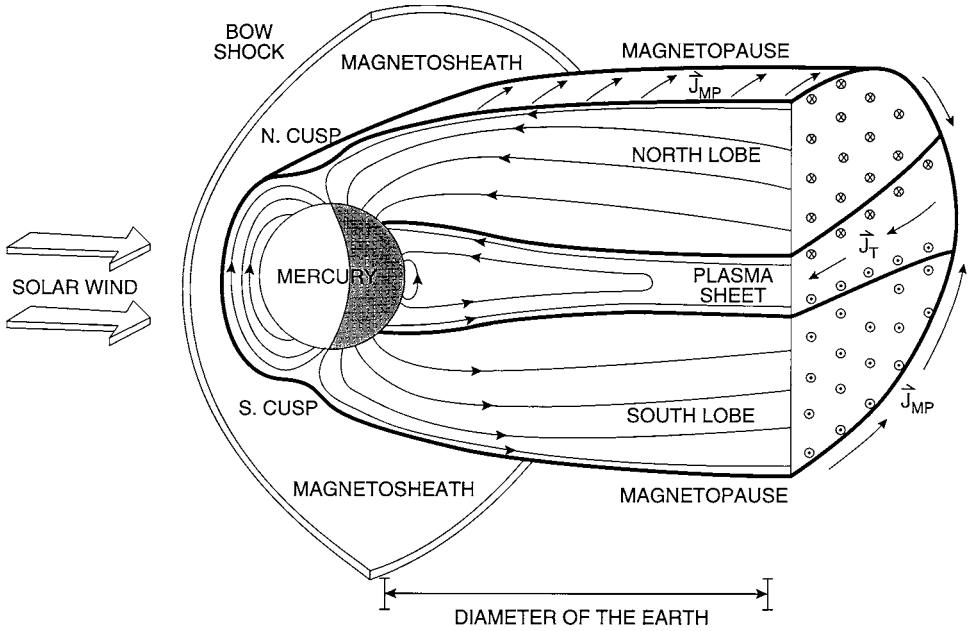

Figure 2. A schematic view of Mercury's magnetosphere as glimpsed by Mariner 10 with its primary regions, some representative magnetic field lines, and the tail current system labelled. Note that the regions typically occupied by radiation belts and the plasmasphere at the Earth are taken up by the planet in this miniature magnetosphere.

tubes rooted in the planet to the magnetospheric cavity. Vertical broken lines in figure 1 mark the inbound and outbound magnetopause crossings as well as the point of closest approach (CA) to the planet. Across the magnetopause current layer the magnetic field rotates in direction to its magnetospheric orientation and increases in magnitude until it is in equilibrium with the external solar wind pressure. The entry of Mariner 10 into the near-tail (see MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL) of this magnetosphere is apparent in the tail-like nature of the magnetic field with $B_x \gg B_y$, B_z just inside the magnetopause during the first inbound passage.

Analysis of the Hermean magnetopause using the data sets collected by Mariner 10 has revealed some differences from what is usually observed at Earth. For example, the higher solar wind plasma density at 0.3–0.5 AU produces solar wind ram pressure that are about four to ten times greater than at the Earth. This results in higher magnetopause current densities and stronger magnetic fields inside the magnetopause at Mercury than are observed elsewhere in the solar system. The low altitude of the dayside magnetopause at Mercury has provoked much interest as to whether this boundary ever intersects the planetary surface and exposes it to direct impingement by the solar wind. Simple compression of the magnetopause by solar pressure enhancements would probably cause this to happen if it were not for the induction currents which are expected to be driven deep within the planet to oppose such changes in the magnetic field. However, this induction effect will, at times, be countered by the 'erosion' of magnetic flux tubes by reconnection (see MAGNETIC RECONNECTION) at the dayside magnetopause. The net result of dayside reconnection is to remove flux tubes from the dayside magnetosphere, where they participate in standing-off the solar wind, and transport them into the magnetotail. In addition, it has been suggested that the reconnection rate at Mercury may be enhanced by the low Alfvén Mach numbers in the solar wind at 0.3 to 0.5 AU. Ultimately, the balance between these competing effects, induction and erosion, will rest in the actual nature of the electrical conductivity profiles in the planetary interior and the efficiency of the magnetic reconnection at the magnetopause.

During the outbound portion of the first Mariner 10 encounter the magnetic field variations were extremely dynamic. These large-amplitude variations in the field intensity and direction have a number of sources. The large dip in magnetic field strength just after closest approach coincided with the spacecraft becoming immersed in a hot plasma sheet (see MAGNETOSPHERE OF EARTH: PLASMA SHEET). These observations are consistent with the spacecraft abruptly transitioning from the magnetic field pressure-dominated lobes to the plasma pressure-dominated plasma sheet. In addition, there are large-amplitude variations in the B_y field component in figure 1 around 20:51 UT. This magnetic field signature is well known to magnetospheric scientists and can be readily interpreted as being due to the spacecraft traversing several quasi-planar field-aligned current sheets. Given the Mariner 10 trajectory, the main gradient in B_y from negative to positive is indicative of an upward FAC being traversed by the spacecraft. This

upward current sheet is largely balanced by two less intense downward current sheets seen just before and after the central upward current sheet. At Earth the occurrence of such multiple current sheets is particularly common over the nightside auroral oval during geomagnetically disturbed intervals. These currents are the primary means by which the magnetosphere transmits energy and momentum to the ionosphere, or in the case of Mercury, the regolith. Given the expectation of a highly electrically resistive regolith at Mercury, field-aligned currents will probably be very short lived and hence, only transient features of the Hermean magnetosphere.

Based on the Mariner 10 measurements, and terrestrial-style extrapolation, figure 2 depicts our present image of Mercury's magnetosphere; included are the primary regions, sample magnetic field lines, and the tail current system. Concerning the physical dimensions of this small magnetosphere, it was noted by the original flight investigators that a scaling in which $1R_M$ at Mercury corresponds to $\sim 6R_E$ at Earth produces good correspondence between the boundaries and regions at these two planets. Hence, the $\sim 2R_M$ distance from the center of Mercury to the subsolar magnetopause maps to about $12R_E$ at the Earth which is, indeed, similar to the average terrestrial magnetopause nose distance of $10–11R_E$. More importantly, the surface of Mercury would correspond roughly to geosynchronous distance within Earth's magnetosphere. This scaling rules out the possibility of a plasmasphere even if the planet possessed the atmospheric plasma source and the rotation rate to create such a region. (Mercury's rotational and orbital periods are 59 and 88 days, respectively.) Trapped radiation belts such as are found in the terrestrial magnetosphere at distances of $2–4R_E$, are also impossible. Finally, the observed near-tail diameter of $4–5R_M$ scales to about $24–30R_E$ which is somewhat less than the typical near-tail diameter at Earth of $30–40R_E$. The reason for this discrepancy in this Earth-based scaling is the higher ratio of static to dynamic pressure in the solar wind at Mercury's orbit. The higher static solar wind pressures reduce the diameter of the tail relative to the subsolar magnetopause radius which is determined largely by the dynamic or 'ram' pressure.

Magnetospheric substorms

A *substorm* is a magnetosphere-wide disturbance which involves the conversion of large amounts of electromagnetic energy, either drawn directly from the solar wind or first stored in magnetic fields of the tail lobes, into plasma sheet heating, high-speed bulk plasma flows, energetic particle acceleration, and field-aligned currents which transfer energy to the planetary ionosphere, or at Mercury, to the regolith (see MAGNETOSPHERE OF EARTH: SUBSTORMS). The energy conversion mechanism is magnetic reconnection between the oppositely directed magnetic fields of the tail lobes in much the same manner as is thought to occur in solar flares. The understanding of the reconnection process and how it is influenced by both local plasma conditions in the tail and electrodynamic coupling to the rest of the magnetosphere and the ionosphere, or regolith at Mercury, is one of the overarching objectives of magnetospheric physics research.

Less than 1 min after Mariner 10 entered the plasma sheet during the first encounter, i.e. beginning around 20:48 UT, it detected a sharp increase in the B_z field component. As displayed in figure 3, the initial sudden B_z increase and subsequent quasi-periodic increases are all coincident with strong enhancements in the flux of >35 keV electrons observed by the Mariner 10 cosmic ray telescopes. This energetic particle signature, and several weaker events observed later in the same pass, have been widely interpreted as evidence for substorm activity. Analyses of the energetic particle and magnetic field signatures for this interval have led to the conclusion that this Mariner 10 event is qualitatively identical to the substorm energetic particle injections and magnetic field dipolarizations observed at altitudes between geosynchronous orbit and the inner edge of the plasma sheet at the Earth. However, there are issues surrounding how a magnetosphere with such small dimensions compared with the relevant charged particle Larmor radii can be such a copious source of energetic particles. More complete energetic particle measurements to be returned by future missions to this planet may yield important clues to how the most energetic charged particles are accelerated in the tails of planetary magnetospheres.

The very short duration of the substorm signatures at Mercury, about 1 min as compared with 1–2 h at the Earth, is also of fundamental interest. Although much remains to be understood concerning substorm processes, it is clear that they correspond to intervals of greatly enhanced magnetospheric convection which leads to the dissipation of large amounts of magnetic energy drawn from the tail lobes. It has been argued that the temporal scale of isolated substorms at the Earth is determined by the time necessary for plasma to convect across the polar cap or, equivalently, from the magnetopause down to the plasma sheet where reconnection can take place. It has been estimated, using typical solar wind and magnetotail parameters, that the time necessary to 'cycle' all of the flux in the tail lobes at the Earth is, indeed, close to the typical duration of a substorm, i.e. ~1–2 h.

For Mercury, corresponding convection time constants of a few minutes have been calculated in agreement with the Mariner 10 measurements. The brevity of the convection time constant at Mercury is due largely to the small tail radius and relatively intense $-\boldsymbol{V} \times \boldsymbol{B}$ electric fields present in the solar wind at 0.3 to 0.5 AU. Furthermore, it must be noted that at Earth the dawn-to-dusk magnetospheric electric field is typically only 10–20 per cent of the total electric potential drop available from the solar wind. However, for Mercury it has been argued that the electric potential drop across the magnetosphere should more closely approach the maximum available potential drop

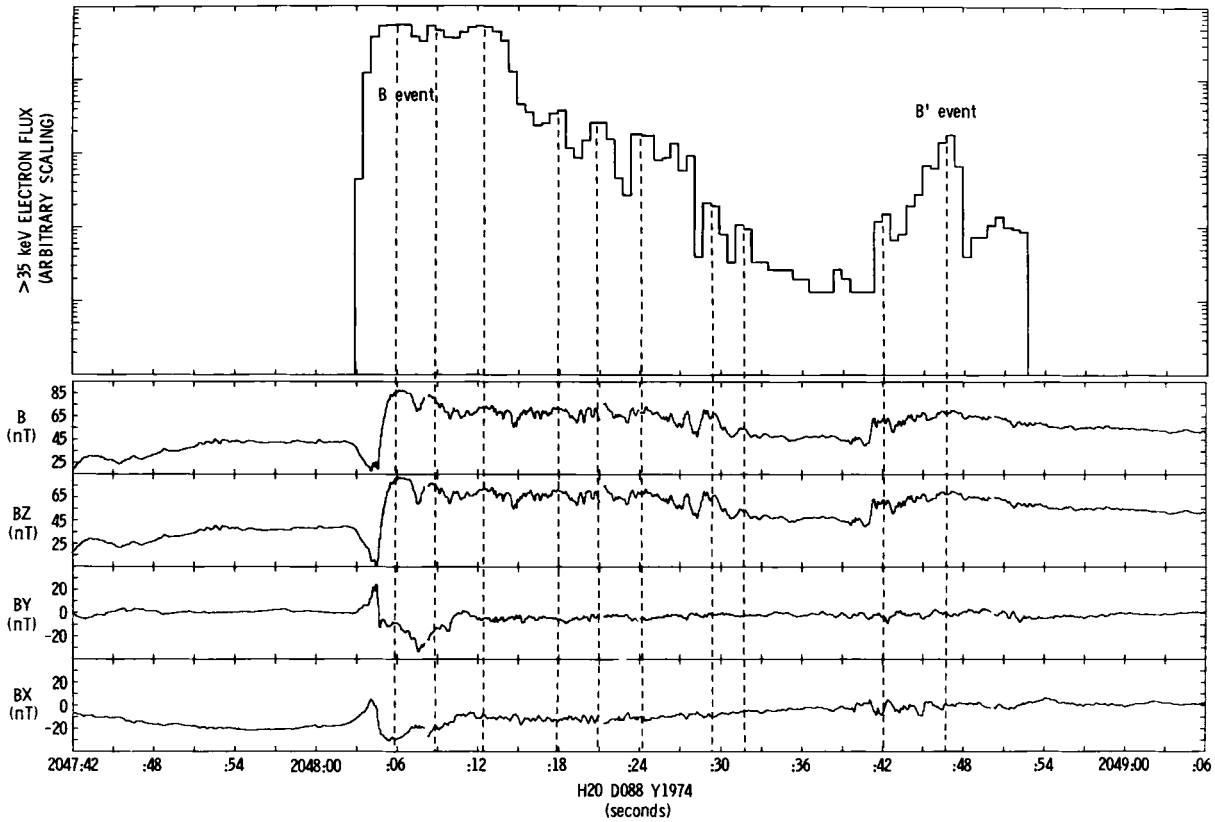

Figure 3. Highest sample rate measurements of the Mariner 10 energetic electron (>35 keV) flux (0.6 s resolution) and magnetic field (0.04 s resolution) are displayed for the substorm dipolarization event observed during the first encounter. (From Christon *et al* (1987).)

than is possible at other planets. The reason is that conducting ionospheres at the other planets act to 'short-out' a portion of this electric field that the solar wind is attempting to impose across the magnetosphere and, therefore, limit the intensity of the internal magnetospheric electric field. Hence, a determination of the factors responsible for the short substorm time scale at Mercury may be very important for our general understanding of electric fields and convection in all planetary magnetospheres.

Summary

From the preceding discussion, it can be seen that Mercury's miniature magnetosphere offers a unique testing ground for theories regarding many important processes. In particular, the very tenuous nature of its atmosphere implies that internal plasma sources are far less significant than at Earth or any of the other known magnetospheres. This fact should make Mercury ideal for quantitative modeling of how and to what degree solar wind plasma enters terrestrial-type magnetospheres. Mercury's relative proximity to the Sun also exposes this magnetosphere to solar wind conditions which are relatively rare at 1 AU. In particular, it has been suggested that the lower Alfvénic Mach numbers and stronger interplanetary magnetic fields at 0.3 to 0.5 AU will result in higher dayside reconnection rates and more intense large-scale magnetospheric electric fields than at the Earth. Hence, measurements at Mercury could also be pivotal to the testing of existing models of reconnection and electrodynamic coupling between the various regions of the magnetosphere. Observations from a future Mercury orbiter mission should also lead to great improvement in our understanding and modeling capability with respect to magnetospheric substorms. With durations at Mercury of only about 1 min, it should be possible to observe huge numbers of complete substorms at a variety of different locations throughout the magnetosphere in a relatively short time. Such a data set would be especially beneficial in the testing of substorm theories with respect to the role of electrodynamic 'feed-back' between the region at the foot of the magnetospheric flux tubes and convection in the magnetotail. Indeed, this small magnetosphere may offer our only opportunity to observe electrodynamic coupling in the asymptotic limit of a magnetosphere rooted in a relatively non-conducting planetary regolith.

Meridian

A great circle on the Earth's surface, running perpendicular to the equator and passing through the north and south poles. To an observer located at a particular position on the Earth, the meridian represents his north–south line. The Greenwich meridian (i.e. the meridian passing through the Old Greenwich Observatory) is taken as the zero of longitude measurement; thus the longitude of a point on the Earth's surface is the angle (measured parallel to the equator) between the Greenwich meridian and the meridian passing through that point.

For purposes of astronomical position and time measurement, the meridian is taken to be a circle on the celestial sphere passing through the north and south celestial poles and the observer's zenith; i.e. for an observer on the Earth's surface, the celestial meridian is the projection of his terrestrial meridian onto the celestial sphere.

The term 'central meridian' refers to the line joining the north and south poles of a planet that crosses the center of the visible disk of that planet. (The Greenwich meridian is also known as the 'prime meridian'.)

MERLIN/VLBI National Facility

The Multi-Element Radio Linked Interferometer Network (MERLIN) is a unique synthesis radio telescope which was originally developed by the University of Manchester in the late 1970s and came into operation in 1980. After further development, in 1993 it formally became a National Facility operated by the University of Manchester on behalf of the UK PARTICLE PHYSICS AND ASTRONOMY RESEARCH COUNCIL. MERLIN operates in discrete wavelength bands within the range 2 m to 1 cm and has corresponding angular resolutions ranging from 1.4 arcsec to 8 milliarcsec. At its prime operating wavelength of 6 cm, it has a resolution which matches that of the Hubble Space Telescope. In addition to its normal self-contained operations, it is regularly used in conjunction with the European Very Long Baseline Interferometry Network (EVN) to provide angular resolution up to a few hundred microarcsec. MERLIN is used for the study of a wide range of astronomical subjects, including stellar formation, interstellar material, nebulae, active stars, supernovae, external galaxies, and quasars and active galaxies at the extremities of the known universe. It was the first instrument to resolve the outflow of material from novae within the Galaxy and to resolve the shells of supernovae in external galaxies. It has played a key role in the discovery of approximately twenty gravitational lenses and in the establishment of the coordinate frame of the Hubble Deep Field.

Merrill, Paul Willard (1887–1961)

Astronomer, staff-member of the Mount Wilson Observatory, spectroscopist who studied variable stars. He identified the element technetium in an S-type star R Andromedae. The atoms of this element have no stable nuclear isotopes, so the element must have been made within the last million years, although the star was much older. The discovery proved that the element must have been made recently in the star. The process by which it was made was identified by B2FH (see W FOWLER) as the 's-process' of nucleosynthesis.

Mersenne, Marin (1588–1648)

Born in Oize in Maine, France, joined the order of the Minims. The name signifies that the Minims regard themselves as the least (*minimi*) of all the religious orders, and this encapsulates Mersenne's self-effacing status in science. His own scientific work was modest, but he corresponded with numerous other eminent scientists and acted as a bulletin board among scientists and a scientific commentator at a time when there were no scientific journals. He defended DESCARTES and GALILEO against criticism. He proposed the use of the pendulum as a timing device to HUYGENS, inspiring him to invent the pendulum clock. He published *Les Méchanique de Galilée*, to promulgate Galileo's lectures on mechanics. He translated parts of Galileo's *Dialogo* and his *Discorsi* into French disseminating Galileo's work in Europe outside Italy. After his death letters in his cell were found from nearly a hundred correspondents including Fermat, Huygens, Pell, Galileo and Torricelli.

Meshchersky, Ivan Vsevolodovich (1859–1935)

Born in Arkhangelsk, Russia, studied mechanics, in particular the motion of bodies of variable mass, applying this to the doubtful case of comets. But his work formed the basis to calculate the case of rocket flight, developed after 1945. He was the first to study the inverse problem of determining the loss of mass from knowledge of the orbit and the forces.

Mesons

Particles that are composed of a quark and an antiquark. Mesons are short-lived particles that decay rapidly into leptons or photons either directly, or by first decaying into other types of meson. Their masses range from about 15% of the mass of a proton, in the case of the pion (pi-meson), to more than ten times the mass of a proton. Their mean lifetimes range from 2.6×10^{-8} s, in the case of the positively charged and negatively charged pions (neutral pions have lifetimes of about 10^{-16} s) to less than 10^{-20} s, in the case of the heaviest mesons.

Although the first meson (the pion) was not discovered experimentally until 1947, the existence of a particle of this kind had been proposed in 1935 by the Japanese physicist, Hideki Yukawa (1907–81), in order to explain how the strong nuclear force could be conveyed between protons and neutrons in an atomic nucleus. At the scale of an atomic nucleus, the pion may be regarded as the 'force-carrying' particle of the strong nuclear force. However, because the pion is composed of quarks, it is not a genuinely elementary (or 'fundamental') particle. At the fundamental level, the strong force is conveyed between quarks by particles called gluons.

Messier Catalog

In the eighteenth century the French astronomer, Charles Messier (1730–1817), drew up a catalog of 109 of the brighter nebulae, clusters and galaxies. Objects in this catalog are denoted by the letter M followed by a number, for example, M31 is the Andromeda Galaxy. Messier's prime interest was comets. His purpose was to make comet hunting easier by tabulating permanent deep-sky objects that could be mistaken for comets. He published a preliminary list of 45 such objects in 1771 and compiled the bulk of his catalog 10 years later. The catalog is still a valuable guide to amateur astronomers, although it has been superseded by the New General Catalog (NGC) and modern astro-physically based catalogs.

See also: Fundamental catalogs, Index Catalog, M1 to M110, New General Catalog.

Messier, Charles (1730–1817)

Comet seeker, nebula avoider, born in Badonvillier, Lorraine, France, became interested in astronomy as a child. Went to Paris, employed by JOSEPH-NICOLAS DELISLE to search for Comet Halley on the 1757 return. While doing so, he discovered a comet-like patch in Taurus on the comet's expected path. The patch did not move, and he later identified it as a nebula (now known as the Crab Nebula), earlier found by JOHN BEVIS. Messier decided to make a list of nebulous objects that simulate comets, with Bevis's nebula the first entry, M1. While discovering two comets in 1763–4, he recorded two more nebulae, M2 (previously discovered by Maraldi) and M3 (the unresolved globular cluster, his first original nebular discovery). He undertook systematic searches for comets and nebulae, and searched the literature. This eventually brought his catalog to 110 (some entries are spurious), of which 42 objects were discovered by himself. After 1781, the year of Herschel's discovery of a new planet (which Messier himself observed), his strategy seems to have changed, adding few entries to his catalog although maintaining his comet search. Perhaps he knew of Herschel's survey (see HERSCHEL FAMILY), with superior instrumentation. Messier lost his position in the 'Year of Terror' in 1793–4, but resumed observing afterwards, bringing his total score of comets to 19, 13 being original and 6 being independent co-discoveries. In his old age, Messier accepted the Legion of Honor from Napoleon, but disgraced himself in front of his colleagues by publishing an astrological memoir identifying the great comet of 1769 with Napoleon, born that year. This was, as Admiral Smyth put it, 'The last comet put astrologically before the public by an orthodox astronomer'. The *Messier Catalog* (with the letter 'M' identifying entries in the list) stands as the fitting memorial to a lifetime's astronomical work, its nomenclature used daily by astronomers throughout the world.

Meteor Crater

A terrestrial impact crater 55 km east of Flagstaff, in the Arizona desert, discovered in 1891. Its several alternative names include Barringer Crater, after Daniel M Barringer, who in the 1930s was the first to investigate it and the first to suggest its extraterrestrial origin. Meteor Crater has an average diameter of 1.2 km, the floor is 180 m below ground level and the rim is 30–45 m high. It is estimated to have been produced 50 000 years ago by the impact of an iron meteorite about 40 m across with a mass in the region of 250 000 tonnes. The energy of the blast produced by the impact, which excavated 175 000 tonnes of limestone, would have been 20 megatonnes or more. Thousands of meteoritic nickel–iron fragments have been found at distances up to 7 km from the crater, suggesting that the incoming body fragmented shortly before impact. Excavations have revealed no masses of nickel–iron below the crater floor, and the main crater-forming mass of the asteroid is assumed to have vaporized.

Meteor Shower

The appearance in the sky, at a particular time of the year, of higher-than-average numbers of meteors, all appearing to emanate from a specific point on the celestial sphere known as the *radiant*. Most showers are named after the constellation in which the radiant lies, by adding the suffix '-id': the Lyrid shower, or Lyrids, for example, have their radiant in the constellation Lyra. The Quandrantid shower is named after the obsolete constellation Quadrans Muralis, now part of Boötes. Where there is more than one radiant in a constellation the showers are distinguished by adding the Bayer letter of a bright star near the radiant, as for example with the Delta Aquarids and Eta Aquarids. A few showers are named after their *parent comets*—the comets that produced the meteor streams—for example the Giacobinids, after Comet 21P/Giacobini–Zinner.

A shower occurs when the Earth intersects a meteor stream. The activity of a shower, which is calculated as a quantity called the *zenithal hourly rate* (ZHR), lasts for as long as the Earth is passing through the stream, and peaks where the stream is at its most concentrated. Young, tight meteor streams tend to produce showers of short duration which build quickly to a high peak ZHR and then tail off sharply. Older, more evolved streams which have spread either side of the primary orbit are of longer overall duration, building slowly to a more modest ZHR and fading slowly thereafter.

The 10 or so most active showers, with a ZHR of about 10 or more, are known as *major showers*. There are dozens of less active, *minor showers*. table 1 gives details for the most active major showers (where there is more than one radiant, the position given is that of the main one). In the great majority of cases the parent body of a meteor shower is a comet. A rare exception is the Geminid shower, which is associated with the asteroid (3200) Phaethon. The connection between a meteor stream and its parent body is established by correspondences between the orbital elements of each.

Meteors that belong to showers are called *shower meteors*, as distinct from *sporadic meteors*, which are produced by meteoroids that do not come from identifiable meteor streams. *Annual showers* are those whose ZHRs normally vary little from one year to the next, being produced by meteor streams in which the meteoroids are evenly spread around the orbit. Meteor streams in which the meteoroids are concentrated in a swarm in one part of the orbit give rise to *periodic showers*, which are highly active only in years when the Earth intersects the swarm, and show little or no activity in other years. Details of two periodic showers, the Leonids and the Giacobinids, are given in table 1.

Meteor Storm

An intense burst of meteor activity of short duration (typically about an hour) associated with a periodic meteor shower. A meteor storm occurs when the Earth passes through a meteor swarm or a concentrated ribbon of debris recently shed by a comet. There is no generally agreed quantitative definition of what constitutes storm-level activity, but an hourly rate of 1000 is a reasonable lower limit. Meteor storms are rare events, those produced by the Leonid shower being the best known. The Leonid maximum of 16/17 November 1966 produced the highest documented storm levels of modern times, with an estimated hourly rate of 200 000 over a 40 min period. Some annual meteor showers occasionally show sharp rises above their normal hourly rates; such outbursts are sometimes called *substorms*.

Meteor Stream

A continuous ribbon of meteoroids in a closed orbit around the Sun. (The more correct term *meteoroid stream* is seldom used.) A meteor stream consists of dust particles shed by a comet on its perihelion passages which have gradually spread around the comet's orbit. When the Earth passes through a meteor stream, there is a meteor shower when up to about 100 meteors per hour may be seen. Most of the debris from young comets remains bunched together over a small arc of the orbit in what is known as a *meteor swarm*. When the Earth passes through a swarm the result is a meteor storm, with many thousands of meteors per hour. As a meteor stream ages, and the meteoroids spread round the orbit, the stream assumes the shape of an elliptical toroid. Within the stream there may be filaments containing a greater concentration of meteoroids shed by the parent comet on its most recent circuits of the Sun. The evolution of individual filaments and the stream as a whole may be affected by planetary perturbations, of both the meteoroids and the parent comet, and the structure of a meteor stream can grow increasingly complex. Eventually, under repeated perturbations, a meteor stream will disperse to the point where the concentration of meteoroids is reduced to that of the interplanetary dust.

Meteorites

A meteorite is a natural solid object of extraterrestrial origin, fallen onto the surface of the Earth. Whatever its provenance, it has to traverse the atmosphere of our planet at high speed, which gives rise to a brief luminous phenomenon, called a METEOR. This modifies its shape, size and external aspect, but leaves the interior part intact. Hence the scientific interest of meteorites: they give us the opportunity to study worlds that we have not reached yet. Twenty-six meteorites are widely believed to be samples of the planet MARS. Around twenty-one others come from the MOON, from regions that have not been sampled by the Apollo nor the Luna missions, including probably the far side. The overwhelming majority of the meteorites are fragments of ASTEROIDS, the tiny planets that orbit the Sun between Mars and Jupiter. This has allowed us to study the geology and past evolution of these very diverse small bodies for many decades, while their exploration by space probes is only at its very beginning, and no sample from any of them will be brought back before 2007. But the interest in meteorites is more general: because of their small sizes, many of their parent asteroids did not experience the geological processes which have reprocessed all the materials of the large planets like Earth, Mars, or even the Moon. Although some of them have also gone through significant geological reprocessing, most meteorites are thus samples of 'primitive matter' (the only ones we have at our disposal up to now, if we include the smallest ones, micrometeorites or INTERPLANETARY DUST particles) which keep memories of the sequence of physico-chemical processes which gave birth to the SOLAR SYSTEM, 4.5 billion years ago. Meteorites have allowed us to study the composition and structure of the materials from which the planets were made, and to establish the age of the solar system. In 1987, rare and tiny crystals were isolated from meteorites, which were made in the environment of other stars, before the birth of the Sun, giving us direct access to the nuclear processes which take place in stars and lead to the synthesis of the chemical elements.

Although rare phenomena, meteorite falls have been known since antiquity. Various explanations were advanced, including ejection from volcanoes or transport by violent winds, but by the end of the 17th century, the most widely accepted one was that meteorites were formed in the atmosphere, by the action of lightning on mysterious exhalations from the Earth's interior. Hence the name 'meteoric stones' (stones from the atmosphere) which later gave 'meteorites'. At the beginning of the 18th century, scientists realized that this was unreasonable but, because of the view they had of the universe, they could not imagine that stones could come from beyond the atmosphere. Unable to find a sound explanation of the phenomenon, they simply ignored it. For the whole of the 18th century, the official scientific opinion was that stones which were said to have fallen from the sky were in fact ordinary stones, which had been hit by lightning on the ground. Only at the end of the 18th century, after several widely witnessed falls in various countries, analyses of meteoric stones by the English chemist Howard, and the publication of a visionary book by the German physicist Chladni, did meteorite falls start to gain official recognition again. In 1803, after the historic fall of some 2000 stones near the city of L'Aigle, in northwestern France, and the report on it made by the physicist Biot, no doubt remained. Meteoritics, the science of meteorites, was launched. However, the idea that prevailed then was that meteorites were ejected from lunar volcanoes, and it was not for several decades that the ideas of Chladni, close to the modern ideas on the origin of meteorites, were generally accepted.

Meteorite falls

The fall of a meteorite is a rare but impressive show. As the meteoroid (the initial arriving cosmic body) reaches the top of the atmosphere, friction against the air decelerates it and the conversion of kinetic energy to heat can raise the temperature of the bolide surface and of the surrounding air to several thousand Kelvin. The characteristics of a fall depend on the velocity and mass of the meteoroid, the orientation of its trajectory, and the density and strength of its material. The lower the mass, the more efficient the air drag. Small particles, in the millimeter size range, are stopped in the upper atmosphere and the corresponding meteors do not last more than a fraction of a second: these are the familiar 'shooting stars'. Larger masses penetrate deeper into the atmosphere and make a longer and more spectacular show, in particular in the case of meteorite-producing events. The initial velocity in this case is generally about 15-20 km s^{-1}. A fireball appears at a height of about 100 km. The outermost part of the bolide matter is melted, vaporized and ejected, leaving a trail of vapor, dust and ionized atoms. The mass of the meteoroid thus decreases continuously, a process known as ablation. In addition, because of the very strong tensions to which it is submitted the bolide very often breaks into several, or sometimes thousands of fragments. At a height of about 20 km, the velocity has been so much reduced—it is now about 3 km s^{-1}—that incandescence can no longer be maintained, ablation ceases and the fireball switches off. In general, no more than 10 s have elapsed since it appeared, but in exceptional cases (nearly horizontal trajectories) it can be seen for up to about 40 s. The trajectory now bends over to nearly vertical, and the meteorite finally reaches the ground with its velocity of free fall (one or a few hundred m s^{-1}). If fragmentation occurred in flight, the larger fragments, being less efficiently braked, travel farther, so that the fragments are found distributed on an elliptical

Figure 1. A few fragments of the L'Aigle meteorite, which fell in 1803. It can be seen on the broken fragment at the bottom left that the heat-affected zone, the black fusion crust, is extremely thin. The largest fragment is approximately 10 cm long. (Photo courtesy of G Segerer, MNHN.)

strewnfield, with the largest fragments at one end and the smallest ones at the other. Meteorite falls are accompanied by sound phenomena. Sonic booms are heard after the disappearance of the fireball, but generally before the landing of the meteorite. Rumbles follow, with those produced in the lowest part of the trajectory arriving first.

Because of this fiery arrival, meteorites have a typical aspect: their surface is black, smooth, with rounded angles (figure 1). However, as the fall is so short, and the heat generated is in large part carried away by the vaporized material and the surrounding air, the interior of the meteorite suffers fortunately very little: the black vitrified pellicle that surrounds it, called the fusion crust, is not usually thicker than a fraction of a mm. A few mm away from the fusion crust, the meteoritic materials are essentially unaffected by the fall.

The largest known meteorite, the Hoba meteorite, found in Namibia, has a mass of about 60 tons. Much bigger meteorites are little decelerated in the atmosphere, which leads to catastrophic issues. Stony meteorites in the size range 10–100 m explode in the atmosphere; the higher the mass and the mechanical strength, the lower the height of the explosion. Such events occur about 8 times per year, without being noticed from the ground. This is probably what happened on 30 June 1908 above the region of the river Tunguska, in Siberia, but in this case, the explosion took place low enough to destroy approximately 2000 km^2 of forest. Still larger stony meteorites, and iron meteorites over ~10 m, reach the ground with almost their original velocity. Most of their enormous kinetic energy transforms into heat and they are entirely vaporized upon impact, together with a much larger quantity of target rock, leading to the formation of an impact CRATER. Some 150 of these craters are known on Earth, and many more on all solid bodies, from Mercury to the satellites of Uranus, making impact cratering a major geological process in the solar system. The largest known crater on Earth, the Chicxulub crater in Mexico with a diameter of ~200 km, resulted from the impact of a meteorite about 10 km in size, 65 Myr ago. There is no doubt that such large impacts cause ecological catastrophes on the scale of the whole planet. 65 Myr ago is the time of the Cretaceous–Tertiary boundary crisis, when a large fraction of the then-living species, including the dinosaurs, disappeared.

Composition and classification

Depending on their structure and composition, meteorites are classified into different classes and groups. This is not just of academic interest, but is aimed at deciphering their various origins. The traditional classification sorted meteorites into stony, iron and stony-iron meteorites. Although this purely descriptive classification can still be convenient, it is now preferred to make the major separation between differentiated and non-differentiated meteorites. Differentiation is the process by which melted rocks separate into different phases having different compositions. The Earth is a differentiated planet: it is composed of a metallic iron core, surrounded by a rocky mantle and a rocky crust. Thus, no single sample is representative of the global composition of the Earth. Moreover, melting not only induced modifications of the chemical composition of the original materials from which the Earth was built, it also erased their structures. This is true for all large planets, including the Moon. Non-differentiated meteorites—also called CHONDRITES—have not been melted in the tiny planets they come from, so that they keep memories of the materials of the solar nebula, the gas and dust cloud from which the solar system was born. They can thus be considered as witnesses of the birth of the solar system. Differentiated meteorites are very diverse, but they have all experienced extensive melting on their parent planets. They have lost to a large extent memories of nebular processes, but are useful to study planetary processes, in particular those which took place on small planets in the early solar system. The various meteorite classes and groups, which are designated by names or symbols, are summarized in table 1. Some groups (CK, CR, CH, R chondrites, Acapulcoites-Lodranites, Brachinites) have been introduced fairly recently, and a few peculiar meteorites which do not fit into existing groups have been omitted.

Non-differentiated meteorites

Chondrites are remarkable in that their chemical composition is very similar to that of the Sun, except for the most volatile elements. Subtle differences have led us to sort them into various groups, as shown in table 1, each of them probably corresponding to at least one parent asteroid. The CI carbonaceous chondrites are believed to

be the most primitive of all chondrites, those whose composition most closely reflects that of the solar nebula. Figure 2 shows a comparison between the chemical abundances measured in CI chondrites and in the solar photosphere. Each point corresponds to an element; a few points have been labeled with the element symbol. The line corresponds to equality between solar and chondritic abundances. The agreement is excellent over 9 orders of magnitude, except for H, He and other rare gases (not plotted), C, N, and O, all volatile elements which have been only partly incorporated into solid bodies, and for Li, which is destroyed by nuclear reactions in the sun. As CI chondrite abundances are measured with a greater precision than those of the solar photosphere and for a larger number of elements, they form the basis for the standard solar system abundances.

Most chondrites are made of silicates, iron-nickel alloys (Fe–Ni) and iron sulfide (troilite, FeS). The most common silicates are olivine ($[Fe,Mg]_2SiO_4$), pyroxene ($[Fe,Mg]SiO_3$), and feldspar (solid solution of $[Na, K]AlSi_3O_8$ and $CaAl_2Si_2O_8$). Many other minerals have been identified in chondrites, but usually only in minor amounts. In the most primitive chondrites, minerals occur as small crystals, arranged in more or less spherical structures, with diameters in the range 50 μm to several mm, called chondrules (see figure 3). The space between chondrules is filled by a matrix made of very fine grains (<1 μm) of similar minerals.

Chemical groups of chondrites differ, in particular, by their oxidation state, which is most conveniently revealed by the chemical form of iron. In table 1, chondrite groups are arranged in roughly decreasing order of degree of oxidation from top to bottom. Carbonaceous chondrites are the most oxidized: many do not contain any Fe–Ni metal, all Fe is in oxidized form, in silicates or other minerals. Enstatite chondrites are the most reduced: they contain large amounts of Fe–Ni metal, but almost no Fe in their silicate which is nearly exclusively enstatite, a purely magnesian pyroxene ($MgSiO_3$). Ordinary chondrites are intermediate, with Fe–Ni alloy content increasing from LL to L to H. These differences probably reflect different local conditions in the solar nebula at formation time.

Although chondrites have a primitive chemical composition, they have nevertheless experienced various amounts of planetary processing. To account for this, they have been sorted into 6 petrologic types. Types 3–6 correspond to increasing effects of thermal metamorphism, i.e. moderate transformations due to temperature increases soon after accretion of their parent asteroids. Type 3s are the least affected: their minerals have variable compositions, in particular the Fe/(Fe+Mg) ratio

varies among silicates, they are said to be unequilibrated chondrites; chondrules are abundant and sharply defined (figure 3). Type 6s are the most metamorphosed: their minerals have uniform compositions, they are equilibrated chondrites; the chondrule texture has been almost entirely erased by recrystallization, chondrules can hardly be recognized in these chondrites. Types 1 and 2 correspond to negligible planetary thermal processing, but considerable effects of alteration by water on the parent asteroids. Type 1 chondrites, the most primitive from a chemical point of view, are almost entirely composed of very fine-grained hydrous minerals, in particular phyllosilicates analogous to clay minerals found on Earth, which are the products of aqueous alteration of anhydrous silicates. Chondrules are totally absent from these chondrites, but it is not known whether they never existed there, or were destroyed by the action of water. Not all petrologic types are represented in the various chemical groups. For instance, there are no types 1 and 2 among the ordinary and enstatite chondrites, CIs are mostly type 1, CMs are mostly type 2, CVs and COs are type 3.

Chondrule textures imply that they formed as small, independent melted droplets (figure 4). Simulation experiments closely reproduce these textures and suggest formation temperatures in the range 1550–1900°C, and heating times of seconds to hours. However, the physical phenomenon responsible for the (transient) energy inputs necessary to make chondrules is still unknown, although many have been suggested. Most of the hypotheses refer to processes taking place in the solar

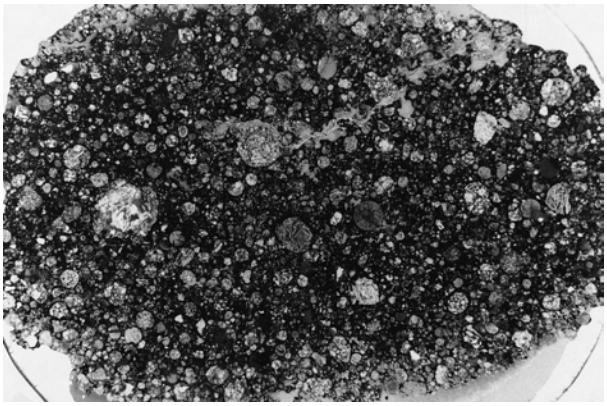

Figure 3. The H3 chondrite Sainte Rose is almost entirely made of chondrules of various textures and sizes. Sample is 2.8 cm long. (Photo courtesy of C Caillet, MNHN.)

nebula, but planetary processes, *a priori* less probable, are periodically revived. This ignorance is all the more irritating in that the high abundance of chondrites (85% of all meteorite falls) and the high proportion of chondrules in chondritic matter (up to 80% in ordinary chondrites) strongly suggest—but do not prove—that chondrule formation was a common process and one of those which most affected the solid matter of the early solar system. Let us mention two of the most recently developed models of chondrule formation: the shock model and the x-wind model. In the former, solid chondrule precursors are melted by friction with the gas accelerated to supersonic speeds by shock waves propagating within the solar nebula. The model accounts for the thermal history of chondrules as inferred from observations and experiments as well as for some other properties of chondrules. The origin of the shocks remains an open question, although the proponents of the model suggest gravitational instabilities in the disk. In the x-wind model,

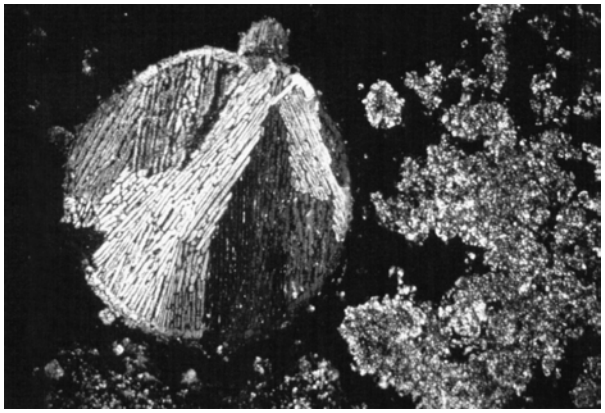

Figure 4. A chondrule (circular, left) and a Ca-Al-rich inclusion (CAI, right) in the Allende CV3 chondrite. These structures once formed independently in the solar nebula. The black background is the fine grained matrix. Width of photo 1 mm. (Photo courtesy of M Bourot-Denise, MNHN.)

chondrules are melted by impulsive protosolar flares at the inner edge of the accretion disk, close to the protosun, and launched to planetary distances by an x-wind outflow. This model is in a large part based on observations of young stellar objects. It offers explanations not only for a number of properties of the chondrules themselves but for more general characteristics of the chondrites (see below). It has not been shown, however, that it can match the chondrule thermal history in detail.

Refractory inclusions are another important type of structure formed at high temperatures (figure 4). They are found in most carbonaceous chondrites, especially in CV3s where they are the largest (few mm to cm), and, rarely, in ordinary and enstatite chondrites. They are assemblages of refractory, Ca- and Al-bearing minerals and are designated for that reason calcium-aluminum-rich inclusions (CAIs). CAIs appear to be the first solids to have formed in the solar system, and they keep memories of events which took place before the birth of the Sun, in the form of ISOTOPIC ANOMALIES for many elements, as will be discussed below. They were made by condensation and/or evaporation in the very first instants of the solar system. In the x-wind model, CAIs are formed by a mechanism similar to chondrules, but closer to the Sun, and they are heated for longer times, including during transport in the x-wind. As a consequence, many elements evaporate, leaving a refractory residue rich in calcium and aluminum oxides and silicates.

Carbon is present in small amounts in all chondrites, and represents up to about 4.5% by mass of the CI and CM chondrites, the most carbon-rich of all. In these chondrites C is mainly in organic matter, the most abundant form of which is a poorly characterized macromolecular component, but many molecules are also present, such as aliphatic and aromatic hydrocarbons, carboxylic and amino acids, etc. Isotopic analyses of hydrogen in this organic matter show that it is strongly enriched in its heavy isotope, deuterium (^{2}H or D), which is difficult to explain by processes that have taken place in the solar system. This suggests that at least part of this organic matter is of interstellar origin, i.e. was synthesized in the interstellar medium before the birth of the Sun, and was thereafter incorporated into the materials of the solar nebula, and survived up to now in some meteorites. It is well known that ion-molecule reactions that occur at low temperatures in interstellar molecular clouds can yield considerable hydrogen isotope fractionation, and indeed D-rich molecules have been detected in the interstellar medium.

The presence in meteorites of complex organic molecules, in particular amino acids that serve to build proteins, have led to some speculation about their possible role in the emergence of life on Earth. It would have been simpler to start making the complex molecules necessary for life from already existing complex molecules coming from space than from the carbon dioxide and nitrogen of the primitive Earth atmosphere. Asymmetric molecules like amino acids possess two forms (two enantiomers), right-handed (R) and left-handed (L), which are mirror images of one another. Biological synthesis only produces the L molecules, while non-biological syntheses lead to a mixture of the two in equal quantities. This latter case applies to most meteoritic organic matter. However, evidences have been found of excesses of the L enantiomer in several meteoric amino acids. These findings need to be scrutinized as terrestrial contamination is an enormous problem for these analyses. Excesses of 34% for L-alanine and 54% for L-glutamic acid in the Murchison (CM2) chondrite, associated with non-terrestrial isotopic ratios of carbon and nitrogen, have been reported by one group, but have not been confirmed by others. Small (1–9.2%) L-enantiomer excesses were found recently in six amino-acids in the Murchison and Murray (CM2) chondrites. These amino-acids are absent or rare in the terrestrial biosphere, thus virtually eliminating the possibility of terrestrial contamination. If confirmed, this could be considered as supporting the hypothesis of extraterrestrial organic matter being at the origin of life.

The discovery, in 2001, of sugar and several related organic compounds in the same two carbonaceous chondrites suggests another fundamental building block of life on Earth may have come from outer space. Sugars and the closely related compounds collectively called polyols, are critical to all known life forms. They act as components of the nucleic acids RNA and DNA, constituents of cell membranes and cellular energy sources. A small sugar called dihydroxyacetone and several sugar acids and sugar alcohols, have been identified in Murchison and Murray. All these are important for life today. One sugar alcohol, glycerol, that is used by all contemporary cells to build cell walls has also been found. In addition, preliminary evidence of other compounds that may contain larger sugars critical in cellular metabolism, such as glucose has been discovered.

Differentiated meteorites

Unlike chondrites, differentiated meteorites have compositions widely different from that of the Sun. They result from total or partial melting of their parent asteroids, followed by a sequence of fractional crystallization. The extreme case is iron meteorites, which are made of only two major elements: iron and nickel. They consist of Fe–Ni alloys, with variable amounts of inclusions of iron sulfide, graphite, silicates and other minerals. On the basis of the concentrations of Ni and minor elements (especially Ga, Ge and Ir), they are sorted into 13 groups (table 1) corresponding to different parent asteroids, but many (~13%) do not fit into any of these groups. Most iron meteorites are believed to be

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

fragments of metallic cores resulting from extensive early melting of asteroids.

Pallasites are made of Fe–Ni and centimeter-sized crystals of olivine in about equal proportions. They probably originate from the interface between the metallic core and the rocky mantle of differentiated asteroids. Eucrites, diogenites and howardites are collectively known as basaltic achondrites, because they resemble a basalt (lava) crystallization sequence. Eucrites are made of pyroxene and feldspar, diogenites of pyroxene, and howardites of agglomerated fragments of eucrites and diogenites. They are magmatic rocks ejected from the crust of a differentiated asteroid. As discussed below, there is evidence that this asteroid is 4 Vesta. Mesosiderites are irregular mixtures of Fe–Ni metal and of silicates similar to those found in eucrites and diogenites. They are thought to result from a collision involving a metallic and a silicate asteroid. Angrites are a very small group of magmatic meteorites which crystallized very early in the solar system history and are most probably from a parent body different from that of the eucrites. Ureilites are distinguished from all other achondrites by their high carbon content (1.5–3%). Their origin is far from clear; various hypotheses include differentiation of a carbonaceous asteroid and/or an asteroid collision. Aubrites consist almost entirely of enstatite. They have a magmatic texture, but are almost surely related to the enstatite chondrites. The rare Acapulcoites–Lodranites and Brachinites are often referred to as primitive achondrites, although they are quite different from each other (the former are Fe–Ni metal-rich, the latter almost entirely made of olivine). In spite of a magmatic texture, they have a nearly chondritic composition. The lunar origin of some 21 achondrites has been established beyond any doubt by comparison with the lunar samples returned by the Apollo and Luna missions. These meteorites comprise both anorthosites from the lunar highlands and basalts from the lunar maria.

Meteorites from Mars

As no sample taken from Mars has yet been brought to Earth, the origin of the Martian meteorites (also called SNCs) cannot be considered as definitely established, but little doubt remains. These meteorites first attracted attention by their very young age (which does not apply to a more recent find) that pointed to an origin from a large planet, as will be discussed in the next section. Gases trapped in vitreous inclusions in two of them exactly match the composition of the Martian atmosphere, as measured by the Viking probes that landed on Mars in 1976. More isotopic and chemical data also support a Martian origin. In 1996, it was claimed that evidence for past life activity on Mars had been discovered in the Martian meteorite ALH84001. The claim was based on several findings including organic matter (polycyclic aromatic hydrocarbons, PAHs), associations of very small grains of iron sulfides and iron oxide, as are produced by bacteria on Earth, and tiny 'worms' about 0.1 μm long, resembling nanobacteria. None of these observations was really compelling by itself, but altogether they could be taken as evidence for primitive life on early Mars. Since then, a number of studies have suggested other interpretations of the observations, including contamination from the Antarctic ice where the meteorite has been collected, and artifacts due to sample preparation. The question is not settled, but it is clear that it has not been proven yet that life was ever present on Mars, and that it will be extremely difficult to do so.

Relation with asteroid classes

Reflectance spectroscopy not only provides information on the mineralogical composition of asteroid surfaces, it also allows a direct comparison between meteorites and asteroids. On the basis of their spectral characteristics in the visible and infrared wavelengths, asteroids have been sorted into some 16 classes. Similarities have been noted for a long time between the spectra of some asteroid classes and laboratory spectra obtained on various powdered meteorites, establishing possible genetic links between asteroid and meteorite classes. For instance M asteroids have been linked either to iron meteorites or enstatite chondrites, and C asteroids to CI and CM chondrites.

A longstanding issue has been that the ordinary chondrites, which make up 80% of all meteorite falls on Earth, have no spectral equivalent in the asteroid belt. Data acquired during the fly-by of S asteroids Gaspra and Ida by the Galileo spacecraft suggest a solution: local spectral variations tend to demonstrate that an ill-defined space weathering process is operating that modifies the spectral properties of asteroid surfaces. Younger terrains have spectra closer to those of ordinary chondrites than older ones. More can be learned on this subject from the data acquired by the NEAR-Shoemaker spacecraft during its orbital rendezvous with the S asteroid Eros from February 2000 to February 2001. Gamma-ray, x-ray, visible and mid infrared spectra recorded by diverse instruments on-board NEAR yield information on the chemistry and mineralogy of Eros surface. The data are far from being as precise and complete as laboratory data, and there are some inconsistencies, which can be due to a number of causes, for instance the fact that, depending on the instrument, the detected photons came from Eros surface layers of different thickness (100 μm for the x-ray spectrometer, several tens of cm for the gamma-ray spectrometer). There is no unambiguous match with any known group of meteorites. Nevertheless, considering the inferred chemistry (relative abundances of O, Mg, Al, Si, K, Ca, Fe) and mineralogy (presence of olivine and pyroxene, the former being more abundant), and taking into account other factors

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

such as the high spectral homogeneity of Eros, the measured values of its density (2.67 g cm^{-3}) and albedo (0.27), the data are overall most consistent with Eros being analogous to ordinary chondrites. A more precise correspondence is not possible, as the x-ray composition favors a link with the H chondrites while the infrared data are more in favor of LL chondrites. Some of the observations (apparently variable Fe/Si abundance ratio, depletion of sulfur with respect to ordinary chondrites) imply that the surface composition of the asteroid has been altered by a range of processes, e.g. impact-related partial melting and migration of metal and sulfide. In any case, it now appears probable that at least part of the S asteroids, the most numerous in the inner asteroid belt, are related to ordinary chondrites.

Most striking is the resemblance between spectra of basaltic achondrites and that of Vesta. The hypothesis that Vesta is the parent body of these meteorites has received strong support from two recent discoveries. Firstly, some 20 small asteroids (<10 km in diameter) with spectra similar to that of Vesta have been found in the main belt. Their orbits are distributed between that of Vesta and the 3:1 RESONANCE, a region where asteroid orbits are unstable and which is believed to be a source of meteorites. Secondly, Hubble Space Telescope images have revealed a huge impact crater (460 km in diameter) on Vesta. This crater may well be the site of origin of both the small Vesta-like asteroids and the basaltic achondrites.

Meteorite ages

Different ages can be defined for meteorites, depending on the method used for the determination.

Crystallization age—age of the solar system

The clock used to determine the age of a rock is generally a couple of isotopes present in the rock, one of which is produced by the radioactive decay of the other, for instance ^{87}Rb–^{87}Sr, ^{40}K–^{40}Ar,^{238}U–^{206}Pb, etc. The transformation of the parent isotope (P) into the daughter isotope (D) follows a law whose time dependence is well established:

$$N_D(t) = N_P(t)(e^{\lambda t} - 1)$$

where $N_D(t)$ is the number of atoms of D produced at time t, $N_P(t)$ is the number of remaining atoms of P, and λ is the decay constant of P. By measuring N_D and N_P, one can thus determine the time t, called the age of the rock. This is just complicated by the fact that one has to take into account the quantity of D initially present at t=0, but there are technical solutions to this problem. Now what does t=0 mean, in other words, when did the clock start? The clock started at the closure of the system, i.e. at the time when no more addition or removal of either P or D occurred in the sample studied, except for what is due to radioactive decay. This happened when the temperature of the sample became low enough to prevent atomic diffusion. The (crystallization) age of a rock is thus the time elapsed since its temperature passed below the closure temperature of the system.

The CAIs mentioned above are present in primitive meteorites, whose temperature always remained low. Their age is thus the time elapsed since the end of the high-temperature event in which they formed. Using the U-Pb clock, an age of 4.566 Gyr has been determined, with an uncertainty of only 2 Myr. No older material has been found, and this age of 4.566 Gyr is taken as the age of the solar system. As all terrestrial rocks have been heated after the formation of the Earth, they are all younger than their planet: the oldest ones have an age of only 3.8 Gyr. Chondrites have ages between 4.56 and 4.50 Gyr, which reflects moderate variations of their thermal histories in their parent asteroids. The ages of the differentiated meteorites vary between 4.56 and 4.45 Gyr, which shows that the thermal activity of their parent bodies, although more intense than that of the chondritic asteroids, occurred at about the same time, very early in the solar system history. The first Martian meteorites studied had very young ages, around 1.3 Gyr. As no asteroid was still hot at such a recent time, the conclusion was inescapable: these meteorites had to come from a large planet that could still have magmatic activity as recently as 1.3 Gyr ago.

Exposure age

When a meteoroid is extracted from its parent body, it starts being exposed to irradiation by cosmic rays, from which it was protected before by overlying rocks. Energetic cosmic ray particles induce nuclear reactions in the meteoroid within the first few meters below the surface, breaking atomic nuclei and creating new ones, called cosmogenic nuclides. This irradiation stops when the meteorite reaches the surface of the Earth, whose atmosphere protects it against cosmic rays. A measurement of the amount of cosmogenic nuclides, for instance ^{21}Ne, yields the duration of the exposure, i.e. the time it took the meteorite to travel from its parent body to the Earth. Typical exposure ages of chondrites are 1–100 Myr, those of irons extend to more than 2 Gyr.

Terrestrial age

As cosmic ray irradiation stops upon arrival on Earth, radioactive cosmogenic nuclides decay within a meteorite without being produced any more. A comparison of their concentration in a collected meteorite with that normally found in a fresh fall gives the time elapsed since arrival on Earth, called the terrestrial age. ^{14}C and ^{36}Cl have convenient half-lives for this kind of measurement (5700 yr and 0.3 Myr, respectively). Terrestrial ages up to 1 Myr have been determined for meteorites collected in Antarctica.

Isotopic anomalies and presolar grains

CAIs not only are the oldest solar system solids, they extend their memory to before the birth of the Sun. In 1976, isotopically anomalous magnesium was found in Al-rich minerals from CAIs of the Allende carbonaceous chondrite: there was an excess of ^{26}Mg of up to a few per cent with respect to the normal composition of Mg. In addition, this excess was correlated with the Al/Mg ratio. The explanation is that, when these minerals formed, they incorporated, together with the stable isotope ^{27}Al, the radioactive isotope ^{26}Al. The decay of ^{26}Al to ^{26}Mg produced the observed excess. ^{26}Al is thought to be synthesized in supernova explosions. As its half-life is only 0.73 Myr, the inferred initial $^{26}Al/^{27}Al$ ratio in the CAIs has been interpreted as implying that a supernova exploded in the vicinity of the molecular cloud that was to become the solar system, no more than a few million years before formation of the CAIs. This interpretation was strengthened by later discoveries of evidence for in-situ decay of other short lived radioactivities (^{53}Mn, ^{41}Ca).

This was the generally accepted picture until very recently, when evidence was found for in-situ decay of ^{10}Be in a CAI from the Allende chondrite. ^{10}Be, as other isotopes of the light elements Li, Be and B, is not produced in stellar nucleosynthesis. It is made by high energy nuclear reactions (spallation reactions) between galactic cosmic ray particles and the interstellar medium. However, the quantity of ^{10}Be inferred to be so produced in an interstellar cloud falls short of explaining that found in the Allende CAI by two orders of magnitude, and ^{10}Be needs to be made in the solar nebula itself. The x-wind model provides a natural framework for that: the protosolar flares that melt the CAIs also irradiate their materials with energetic particles capable of inducing spallation reactions. ^{26}Al and other short lived nuclides can also be made by spallation. With specific, but not unreasonable assumptions, it seems possible to account for all short lived radioactivities at the levels detected in CAIs. In this model, of course, the need for a late supernova disappears. Moreover, the lower amount of ^{26}Al initially present in chondrules compared to CAIs, interpreted in the supernova model as due to a time difference of a few Myr between CAI and chondrule formation, results in the x-wind model from their different formation site: chondrules are made slightly farther away from the Sun than CAIs, at a place where the higher gas pressure partially shields them from the protosolar energetic particles. The question of supernova or not supernova needs further study, but it is clearly among one of the most fundamental questions to answer in meteoritics and related astrophysics at the present time.

Anomalous isotopic compositions had already been found for oxygen in CAIs in 1973. Here, the anomalies could not be explained by the decay of a radioactive isotope. Moreover, it turned out that it was not possible to define a normal solar system isotopic composition of O, because it was different in all analyzed bodies. Indeed, every meteorite group listed in table 1 (hence every parent body) has its own oxygen isotopic composition. Even though this is not well understood, it offers an additional powerful tool for meteorite classification. Oxygen isotope data support an origin from the same parent body for all Martian meteorites. The identical O isotopic composition in enstatite chondrites and enstatite achondrites confirms what their mineralogy suggests, that they are somehow related.

This isotopic variability is generally interpreted in terms of the existence, in the solar nebula, of two oxygen reservoirs, one ^{16}O-rich (probably dust), the other ^{16}O-poor (probably gas). Thus, contrary to what has long been believed, the solar nebula was not thoroughly homogenized. This was confirmed later by the discovery of isotopic anomalies for many other elements (Si, Ca, Ti, Cr, Sr, Ba, Nd, Sm), implying that various nucleosynthetic components issued from different stellar sources escaped homogenization and were preserved with their own isotopic characteristics until they were incorporated into forming CAIs.

However fascinating these isotopic anomalies may be, there is no doubt that CAIs were produced in the solar system, and that individual isotopic components were mixed and diluted in the process. Hence the rather low magnitude of these anomalies: a few per cent at most. In 1987, things changed with the discovery in carbonaceous chondrites of nanometer-sized presolar crystals of diamond, i.e. diamonds made in stellar environments prior to the formation of the solar system, which managed to find their way to the solar nebula and to survive up to now in primitive chondrites. Diamonds were soon followed by larger presolar silicon carbide (SiC, figure 5), graphite, titanium carbide, silicon nitride, and corundum (Al_2O_3). These grains are big enough (up to a few μm) to be analyzed individually with an ion microprobe. The isotopic compositions of their major elements, as well as those of all analyzed minor or trace elements, are very different from the solar system composition. For instance, the $^{12}C/^{13}C$ ratio, which is equal to 89 in the solar system, varies from 2 to 7000 in presolar graphite grains; the $^{16}O/^{18}O$ ratio, 500 in the solar system, varies from 200 to 40000 in presolar corundum grains. Comparison with stellar observation data and with models of stellar nucleosynthesis allows us to identify the stellar sources of the grains. Apparently, many stars provided dust grains to the solar system. Most SiC and corundum grains originate from red giant and asymptotic giant branch stars; diamond, some of the graphite and a small fraction of SiC probably come from supernova(e). The study of presolar grains has quickly expanded to become a field of its own, a new branch of

laboratory astrophysics, whose achievements were just unimaginable fifteen years ago. More discoveries are to come. In particular, for experimental reasons, attention has mainly focused up to now on carbonaceous grains. It is conceivable that many presolar oxide grains are still hiding within the oxygen-rich solar system matter, but could be soon unveiled. Not all observations are explained, in particular concerning graphite grains. In addition, large isotopic anomalies have been found in meteorites and interplanetary dust particles for some elements (H, N), suggesting an interstellar origin, but the carrier phases of these anomalies are not known yet. On the other hand, doubts have been raised recently about the presolar nature of the nanodiamonds, as these have been found to be absent in interplanetary dust particles believed to come from comets. Comets are expected to be at least as rich in presolar grains as asteroids. A lower abundance of diamonds in comet samples could mean that at least part of the diamonds formed in the solar system. These are just a few of the questions that remain to be solved.

Meteorites from Mars

The SNC METEORITES, named after the initials of the first discovered members (Shergotty, Nakhla and Chassigny), are a group of stony meteorites that are thought to come from Mars, rather than the asteroid belt. They are all igneous rocks (i.e. formed by crystallizing from molten material) and are distinguished from other meteorites by their ages, which are as low as 165 million years old. A young age implies formation on a body that was still active (that is, not totally cooled and solidified) well after the initial aggregation of the solar system about 4560 million years ago. In other words, the SNCs must originate from a planet-sized body, not an asteroid. There are several reasons why the planet from which they originated is almost certainly Mars.

How do we know that the meteorites come from Mars?

On the basis of their young crystallization ages, the SNC meteorites were recognized as different from asteroidal meteorites long before their Martian origin was accepted. It was suggested that the meteorites might actually be terrestrial, or from the Moon, but there are convincing counterarguments for both of these possibilities. Impactors frequently hit the Earth, so it could be argued that the SNC meteorites were broken from the Earth's surface with insufficient energy to escape totally. The counter-argument to this is that all oxygen-bearing rocks from the Earth show a characteristic variation in composition of the three stable oxygen isotopes (see figure 1). Data from the SNCs also fall on a single line indicating that they all come from the same planet, but, because this line is displaced from that for terrestrial samples, the SNCs cannot come from the Earth.

The Moon is heavily cratered and was also considered a possible source object for SNC meteorites. However, the Apollo and Luna samples returned directly from the Moon are so different in age and composition from the SNCs that the latter cannot be from the Moon.

The specific observations that linked SNC meteorites to Mars came with analysis of gases trapped within one of the samples, the Antarctic meteorite named Elephant Moraine (EET) A79001. This meteorite contains inclusions of black glass scattered throughout its mass. The glass was formed by shock melting of mineral grains, presumably during the impact event that lofted the meteorite from the surface of its parent body. Analysis of gas trapped within the glass during the impact shock shows that it is identical in composition to that of the atmosphere on Mars (as measured by the Viking landers in 1976; see figure 2). The only way that this could happen is if EET A79001 came from Mars. Since (on the basis of their oxygen isotopic composition) all the other SNC meteorites come from the same parent as EET A79001, then they too must come from Mars.

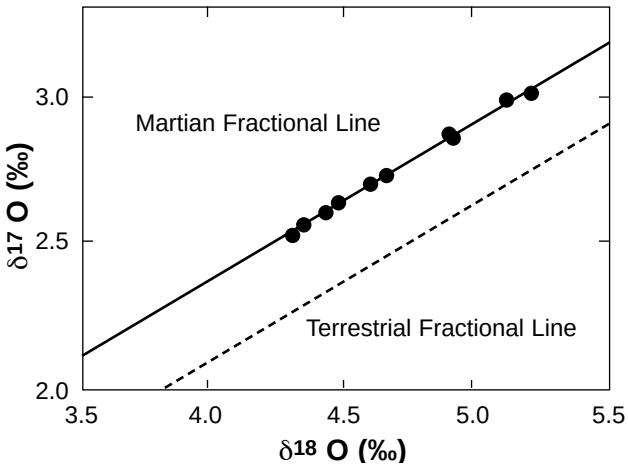

Figure 1. The oxygen isotopic composition of SNC meteorites (adapted from Franchi *et al*, 1999).

What are the SNC meteorites?

The SNCs are named after the type specimens of the three original subgroups. Collection of additional Martian meteorites from Antarctica and the Sahara Desert has extended the number of subgroups to five. The subgroups are rocks that formed in different locations at or below the Martian surface. The groups have different mineralogies and chemistries and cannot all have come from a single impact event. At least three

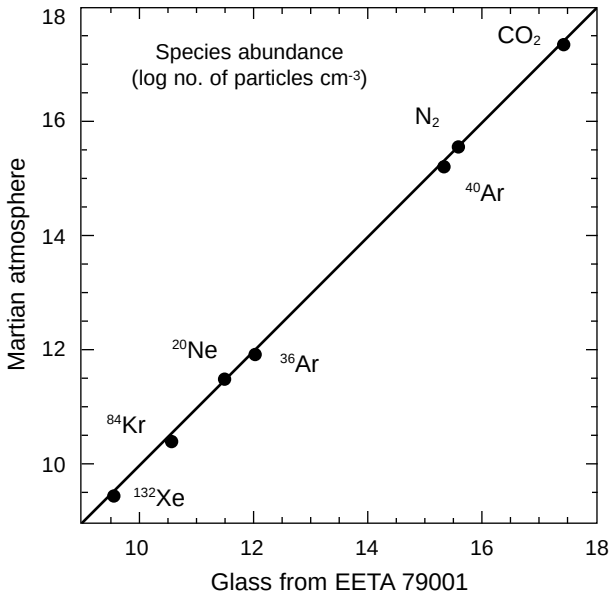

Figure 2. Comparison of the composition of Mars' atmosphere with gas trapped in the shergottite EETA 79001 (after Pepin, 1985).

craters, with minimum diameters of about 12 km, are required to produce the variety of Martian meteorite types.

The shergottites are silicate rocks that are now further divided into two subgroups, with different formation localities. One group is of fine-grained rocks that originated in a lava flow, while the other is of more coarse-grained rocks that cooled deeper below the Martian surface. The shergottites have crystallization ages of between 165 and 450 Myr. At least two cratering events ejected shergottites from Mars into space; these events happened in much more recent times, 0.5–3 million years ago.

The nakhlites are almost unshocked rocks that formed at or near the Martian surface in a thick flow. They solidified from melts about 1.3 billion years ago, and were ejected from the planet about 10–12 million years ago. The meteorites have been altered by weathering on Mars' surface, leading to the production of secondary minerals (clays, carbonates and sulfates) associated with which are low concentrations of Martian organic material. It has thus been suggested that nakhlites might contain evidence for a Martian biosphere.

Chassigny is the only member of its subgroup. It is almost completely composed of the iron and magnesium silicate mineral olivine, and it crystallized below the Martian surface about 1.3 billion years ago.

Like Chassigny, Allan Hills 84001 (ALH 84001) is the only member of its subgroup. It is the oldest of all the Martian meteorites, having crystallized about 4500 million years ago. It has had a long and complex history of shock and thermal metamorphism and also contains carbonate minerals, indicating that at some stage in its history it has been in contact with Martian water. Since few hydrated minerals (such as are found in clays on Earth) have been identified among the alteration products in ALH 84001, it has been proposed that the carbonates were produced at the surface of Mars in a region of restricted water flow, such as an evaporating pool of brine.

Are there microfossils in Allan Hills 84001?

Throughout ALH 84001 there are patches of bright orange carbonates, up to a few millimeters across. A team in the USA, led by Dr David McKay from NASA in Houston, Texas, studied ALH 84001. They found tiny structures in the carbonates that looked like fossilized bacteria. Associated with the carbonates were organic compounds. Although some of the organics are probably terrestrial contamination, a proportion is Martian. Also present in ALH 84001 are crystals of an iron-rich mineral called magnetite. Magnetite can be produced by bacteria. In 1996, McKay's team reported that the shapes, with their associated organic compounds and magnetite grains, were probably fossilized Martian bacteria. This conclusion has not been widely accepted; however, the report of possible fossils in a meteorite from Mars has inspired much research and re-ignited the debate about life on Mars.

Meteoroid

A piece of debris from a larger parent body, pursuing its own orbit around the Sun, which has the potential to strike the Earth and produce a meteor or meteorite. There is no agreed dividing line between a meteoroid and a small asteroid, but by 'meteoroid' is usually meant a sub-meter sized particle. A typical meteoroid is roughly 5 mm in size with a density of about 0.2 g cm^{-3}. Such low-density meteoroids are dust particles shed by comets, and are spread around cometary orbits in meteor streams. When these friable particles strike the Earth's atmosphere, they are rapidly ablated and burn up entirely, the friction of their passage producing a brief luminescent trail visible as a meteor. Higher-density meteoroids (about 2 g cm^{-3}) originate from collisions suffered by asteroids. Their higher structural integrity enables them, if of sufficient size, to survive their passage through the Earth's atmosphere and penetrate to the surface as a meteorite.

Meteors

Meteors are transient luminous phenomena visible in the night sky and popularly called shooting stars. They are caused by small solid cosmic bodies called meteoroids. Meteoroids enter the atmosphere of the Earth with cosmic velocities of several tens of kilometers per second, evaporate and radiate typically at about 90 km above the surface. Most meteoroids are products of disintegration of COMETS and ASTEROIDS but a small percentage may be of interstellar origin. Meteoroids producing typical meteors visible to the naked eye are only few millimeters across.

Meteors brighter than the planet Venus are called FIREBALLS or BOLIDES. Some fireballs may be brighter than the full Moon and in rare occasions a fireball may be visible also during the daytime. Such bright events are caused by meter-sized meteoroids. Fragments of sufficiently large and sufficiently strong meteoroids can survive the atmospheric passage and can reach the ground as METEORITES. However, it is not true that the brighter the fireball the larger is the meteorite that is produced.

Most meteors come from random directions. These are called sporadic meteors. In certain periods of year, however, meteors coming from the same direction on parallel trajectories and with almost identical velocities appear. This phenomenon is called a METEOR SHOWER and the meteors are called shower meteors. All meteors of a particular shower have a common origin in one parent body, in most cases a comet. The meteoroids released from a comet spread along the comet trajectory and form a meteoroid stream. The encounter of the Earth with a meteoroid stream produces the meteor shower. The direction the meteors come from is called the radiant. The apparent paths on the sky of all meteors of a shower intersect in the radiant.

Extremely rich meteor showers are called METEOR STORMS. Meteor storms are rare phenomena occurring a few times per century and lasting only a few hours. Bright fireballs and meteor storms belong to the most impressive astronomical phenomena observable by the naked eye.

Terminology

meteor: luminous phenomenon in the sky, shooting star

meteoroid: cosmic body 0.01 mm–10 m in size; meteoroids produce meteors as they enter the atmosphere

meteorite: any meteoroid remnant which survived the atmospheric flight and reached the ground

Meteor investigation

Meteor astronomy, as a science, started in 1833. On 13 November of that year, a meteor storm was widely observed in Northern America. Although meteor storms had been observed before—there are records in Chinese, Japanese and European chronicles—they were considered as solely atmospheric effects. During the 1833 storm, scientists noted that the apparent point of emergence of the meteors, i.e. the radiant, remained fixed relatively to the stars in the constellation of Leo during the storm. This pointed out the cosmic origin of meteors. The storm was named the Leonids (see figure 1). The radiant was then recognized also for less impressive annual meteor showers such as the PERSEIDS. The relation to comets was established in 1867 when Schiaparelli showed that the Perseid stream has a similar orbit to comet Swift–Tuttle. Subsequently, the parent comets of several other streams were also identified.

The connection of fireballs (see figure 2) and meteorites had also not been recognized for long time. In 1794 CHLADNI argued for a cosmic origin of stones falling from the heavens; nevertheless, his idea was accepted only at the beginning of the 19th century.

During most of the 19th century meteor observations were restricted to visual methods. The first meteor photograph was obtained by Weinek in Prague in 1885 during the Andromedid meteor storm. In 1897 PICKERING in Harvard captured by chance the first photographic meteor spectrum. The first successful program of meteor spectrophotography was started by Blajko in Moscow in 1904. Photography proved to be a very successful method of meteor investigation. Wide-field cameras can be open for hours and wait for a passage of a sufficiently bright meteor. The reduction of photographs from two stations provides the meteor's trajectory. The first meteorite fall was photographed by Ceplecha in 1959—the Příbram meteorite became the first meteorite with a reliably known orbit.

The advancement of electronics during World War II opened the way for radar observation of meteors. The abnormal radio echoes observed by military radars were proved to be due to meteors. Meteors form ionization trails in the atmosphere which reflect radio waves. Meteor radioastronomy was developed in JODRELL BANK OBSERVATORY by LOVELL and his colleagues. The radar technique enables meteors to be observed also during cloudy weather and during daytime.

In the 1970s a television technique started to be used for both direct and spectral meteor observations. The sensitivity of TV systems is higher than photographic sensitivity but the resolution is lower. More recently, atmospheric lidars have been used to detect distinct trails of heavy atoms deposited in the upper atmosphere by meteors.

The description of effects of meteoroids on the atmosphere of the Earth is one motive of meteor studies. Years ago, meteors even served as probes for determining the atmospheric density at large altitudes. This is now better done by rockets. The main goal of meteor astronomy, however, is gathering information on meteoroids themselves: their mechanical properties, chemical composition, abundance and distribution in the solar system, size distribution etc. Meteoroids represent samples of their parent bodies, asteroids and comets and testify to the history and evolution of the solar system.

Meteor atmospheric interaction

The process of meteoroid entry into the atmosphere has several phases. The first phase is preheating, which occurs at the heights about 300–100 km above the Earth's surface. The surface of the meteoroid is heated by the impacts of air molecules. The duration of this phase is from several seconds to tens of seconds. There is no time to heat the body through; the interior remains cool, except for meteoroids smaller than 1 mm which can be heated completely.

After the temperature of the surface reaches 2200–2600 K, ablation, i.e. mass loss, starts. This occurs at heights of 80–130 km, depending on meteoroid velocity, size and material. Ablation can take the form of melting, evaporation and fragmentation of the meteoroid, and all these processes can act simultaneously. A hot gaseous envelope from the ablated material and air is formed. The radiation of the gases produces the meteor phenomenon. The duration is typically 0.1–10 s. As well as losing mass the meteoroid is also decelerated. Deceleration is important for larger meteoroids deep in the atmosphere. Recently, meteor radiation up to heights of 200 km was discovered. The mechanism of this high altitude radiation is not known.

The ablation ceases at a velocity of $\sim$3 km s^{-1}—there is not enough energy to heat the body. If the body is decelerated to this velocity without being completely disintegrated, it continues its flight without ablation and radiation. This phase is called dark flight and takes several minutes. The meteorite is further decelerated and falls by free fall to the surface. The motion is, however, influenced by atmospheric winds. Dark flight starts usually somewhere below a height of 30 km.

Typical meteorites of mass 0.01–10 kg impact the surface with velocities of 10–100 m s^{-1}. The direction at the impact does not reflect the original direction of the meteor; this information is completely lost during the dark flight. Impact creates a pit comparable in size with the meteorite. An explosive impact occurs for very large meteoroids which have not succeeded in being decelerated

before reaching surface (no dark flight). An impact crater much larger than the body itself is then formed.

Bodies smaller than about 0.01 mm suffer no ablation and produce no meteors. Such small particles are called dust, not meteoroids. Dust particles are decelerated during the preheating phase and do not reach the temperature necessary for ablation. The heat is radiated out and the particles sediment gradually to the surface. They can be collected in the upper atmosphere as INTERPLANETARY DUST particles (IDPs).

In the upper size range, the terminological boundary between meteoroids and asteroids is rather arbitrary. A 10 m diameter can be used as the dividing value. This nearly corresponds to the largest bodies observed so far during their interaction with the Earth's atmosphere and at the same time to the smallest bodies observed in space in reflected sunlight.

Meteor brightness is usually given in magnitudes as determined by comparison with stars. The absolute magnitude is the magnitude as seen from a distance of 100 km. The meteor light curve is the meteor brightness displayed as a function of time or other quantity (e.g. height). A meteor flare is a sudden increase of brightness. The duration of flares is usually between 0.01 and 0.1 s. A meteor wake is a 'tail' of radiation behind the meteor 'head'. The wake is easily observed in bright fireballs which often have a 'comet-like' appearance in part of their trajectory. The length of the wake may reach a few km. A meteor train is the radiation left in the meteor path after the meteor's disappearance (an afterglow). The visibility of a train may reach 1 h in exceptional cases.

Meteor trajectories and orbits

Meteor trajectories can be considered as straight lines during the few seconds of the ablation phase. Only for long fireballs on nearly horizontal trajectories can the curvature due to gravity become significant. The orientation of the trajectory is described by the equatorial coordinates of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

apparent radiant α_R, δ_R. Another important parameter is the meteor velocity, which, however, changes owing to atmospheric drag. By an extrapolation, the pre-atmospheric velocity, v_∞, can be determined.

The heliocentric orbit of a meteoroid before it encountered the Earth can be computed from α_R, δ_R and v_∞. Since the meteor is observed from the surface of the rotating Earth, the observed velocity must be firstly corrected for this effect which is called diurnal aberration. The second effect is the zenith attraction which is due to the Earth's gravity. Gravity accelerates the meteoroid and bends its trajectory, attracting the radiant to the zenith. The corrected radiant and velocity are called geocentric radiant and velocity. They express the meteoroid velocity vector relative to the Earth's center as it would be without the Earth's gravity. Subtracting the Earth's orbital velocity, the meteoroid heliocentric velocity vector is obtained. From this vector and the position of the Earth at the time of collision, the meteoroid heliocentric orbit is computed.

The minimum meteor initial velocity is 11.2 km s^{-1} which is equal to the escape velocity from the Earth. The meteoroid would be accelerated to this velocity even if the geocentric velocity were zero. The maximum velocity for a meteoroid on a bound heliocentric orbit is 73.5 km s^{-1}. This is given by the maximum meteoroid heliocentric velocity (42.4 km s^{-1}), the maximum Earth orbital velocity (30.2 km s^{-1}) and the gravitational acceleration.

The absolute majority of the meteoroids encountering the Earth move in elliptical heliocentric orbits and are therefore members of our solar system. No interstellar meteoroid has been confirmed among bright photographic meteors. There are indications that about 1% of faint television meteors (produced by meteoroids of the mass of the order of 0.1 mg) are interstellar and that the proportion of interstellar meteoroids may be even higher among much fainter radar meteors.

The distribution of radiants of sporadic meteors on the sky is not isotropic. Five radiant concentrations were identified in radar and photographic surveys. They are called the Helion, Antihelion, Apex, Northern Toroidal and Southern Toroidal sources. The first three lie near the ecliptic, at about 20°, 160° and 90° west from the Sun, respectively. The toroidal sources lie at +60° and −60° from the ecliptic, above and below the apex. The existence of the sources reflects the distribution of meteoroid orbits. The Helion and Antihelion sources are produced by low-inclination prograde meteoroids with significant eccentricity, originating from asteroids and short-period comets. The Apex source is produced by retrograde orbits similar to those of long-period comets. The origin of the toroidal sources is less understood. The corresponding orbits are prograde with high inclination (60°).

Of particular interest are the precise trajectories and orbits of meteorite-dropping fireballs with recovered meteorites. There are only four such cases. The falls of meteorites Příbram, Lost City and Innisfree were photographed and Peekskill was recorded by video cameras. The data are given in table 1. All meteorites are ordinary CHONDRITES and the orbits suggest their origin in the asteroid belt.

Above the sporadic background, meteoroid streams can be recognized. There is no problem in recognizing compact major streams like the Perseids. The existence of low-activity streams with non-distinctive orbits is more difficult to establish. Various criteria which combine the orbital elements and provide a measure of orbital similarity have been proposed. The most widespread is the so-called D-criterion (see p 135 of Ceplecha *et al* 1998). The D-criterion is also used to relate the meteoroid orbits to the orbit of a suspected parent body.

Meteor counts

Meteor counts provide information on distribution of meteoroids in the solar system and on the structure of meteoroid streams.

Meteor showers

The traditional measure of meteor shower activity is the ZENITH HOURLY RATE (ZHR). It is defined as number of meteors observable by one visual observer with the radiant in the zenith under standard conditions. 'Standard conditions' means the limiting magnitude for stars is 6.5. If the radiant lies at an elevation h above the horizon, the ZHR can be computed from the observed hourly rate HR by the formula $\mathrm{ZHR} = \mathrm{HR}/\sin^{\gamma} h$, where the empirical value of the exponent γ is 1.4. If the limiting magnitude is different, the correction depends on the shower magnitude distribution index χ defined as $\chi = n(m+1)/n(m)$, where $n(m)$ is the number of meteors of magnitude m. The correction is $\mathrm{ZHR} = \mathrm{HR}\,\chi^{6.5-L}$, where L is the actual limiting magnitude.

A list of the most pronounced annual showers is given in table 2. The typical maximum ZHR and the duration of noticeable activity (ZHR > 3) are given. The Arietids are a daytime shower observable only by radar. The magnitude distribution index is lower in most showers than in sporadic meteors (where $\chi = 3.4$). The radiant coordinates are given for the time of maximum. The radiant positions drift owing to a systematic change of curvature of heliocentric orbits. Except for GEMINIDS, the known parent bodies of meteor showers are comets. It is not clear whether Phaeton, the parent body of Geminids, is a normal asteroid or an extinct comet.

In addition to the regular annual activity, meteor outbursts occur from time to time. They include exceptional activity of annual showers, observed in LYRIDS, Perseids and especially LEONIDS, as well as the notable appearance of showers which show only negligible or no activity in normal years. The outbursts are often related to the passage of the parent comet near the Earth's orbit. However, outbursts occurred also when the parent comet was far from the inner solar system. Extremely strong outbursts (ZHR > 1000) are called meteor storms. Meteor outbursts and storms are caused by compact filaments of meteoroids and their duration is typically only few hours. The showers which produced meteor storms in the

Table 1. The observed meteorite falls.

	Fireball characteristics						Heliocentric orbit					
Meteorite	v_∞ (km s^{-1})	m_∞ (kg)	z_R (deg)	M (mag)	h_E (km)	m_{Er} (kg)	a (AU)	e	i (deg)	ω (deg)	Ω (deg)	q (AU)
Příbram	20.9	3500	47	−19	(13)	5.8	2.40	0.671	10.5	241.7	17.1	0.789
Lost City	14.2	160	52	−12	20	17.3	1.66	0.417	12.0	161.0	283.0	0.967
Innisfree	14.5	30	22	−12	20	4.6	1.87	0.473	12.3	178.0	316.8	0.986
Peekskill	14.7	1300	86	(−15)	(30)	12.4	1.49	0.41	4.9	308.0	17.0	0.886

v_∞, initial velocity; m_∞, initial mass; z_R, angle to vertical; M, absolute magnitude; h_E, end height; m_{Er}, total mass of recovered meteorites; a, semimajor axis; e, eccentricity; i, inclination; ω, argument of perihelion; Ω, longitude of the ascending node; q, perihelion distance.

Table 2. The most active annual meteor showers.

Name	Maximum date	Duration (days)	ZHR maximum	χ	Parent body	Radiant α	Radiant δ	Velocity (km s^{-1})
Quadrantids	4 January	4	130	2.5	P/Machholz ?	232	+45	43
Lyrids	22 April	6	15	2.7	P/Thatcher	272	+33	49
η-Aquarids	6 May	25	40	2.7	P/Halley	338	−1	66
Arietids	8 June	20	50	2.7	P/Machholz ?	45	+23	38
δ-Aquarids S	29 July	15	10	3.3	P/Machholz ?	339	−17	43
Perseids	13 August	30	80	2.5	P/Swift–Tuttle	44	+58	61
Orionids	22 October	15	25	3.1	P/Halley	95	+16	67
Taurids	3 November	30	10	2.3	P/Encke	48	+18	30
Leonids	17 November	6	20	3.4	P/Tempel–Tuttle	153	+22	71
Geminids	14 December	10	90	2.6	(3200) Phaeton	112	+32	36

last 200 yr were Leonids (1799, 1833, 1866, 1966, 1999), Andromedids (1872, 1885) and Draconids (1933, 1946). The 1966 Leonids reached a ZHR of 144 000 according to some (uncertain) reports.

The year-to-year observation of the activity of meteor showers provides information on the distribution of meteoroids along the cometary orbits and, consequently, on the ejection processes from comets. The storms are probably related to the cometary dust trails observed in infrared light.

Influx of sporadic meteors

Typical hourly rates of sporadic meteors are 5–10. Because of the geometric conditions, more meteors can be seen in morning hours than in evening hours (a diurnal variation). About 700 000 zero magnitude meteors appear on the entire Earth every day.

Sporadic meteors are the major source of cosmic material on the Earth. After relating the meteor brightness and other observable quantities to the meteoroid mass, the influx of meteoroids of various masses can be computed. By adding the information on interplanetary dust and NEAR-EARTH ASTEROIDS, this could be done for the mass range 10^{-21}–10^{15} kg. On average, 1.5×10^8 kg of cosmic material hits the Earth per year. However, in a typical year only half of this mass arrives. The second half comes from the bodies with masses of the order of 10^{14}–10^{15} kg (asteroids several km in diameter) which impact only once in 10^7 years. The second most important bodies for the mass influx are those in the mass range 10^5–10^8 kg (mostly cometary bodies ≈10 m in diameter) with several impacts per year.

The distribution of meteoroids with mass is unequal and no single population index (or magnitude distribution index) can be applied to the whole interval (figure 3). This suggests that several sources of sporadic meteoroids are present. The third most important source is the dust. Meteors in the visual range represent only a minor constituent in terms of mass influx. This may change during short periods of meteor showers and storms.

Evolution of meteoroid streams

Although the parent body of the Geminid meteoroid stream, Phaeton, does not show any cometary activity, typical meteoroid streams are formed by comets. An asteroidal stream can be produced by a collision among asteroids but a powerful collision is rare event and only minor streams are usually formed by asteroidal collisions. A cometary stream can be formed by a complete disintegration of a comet (like COMET BIELA formed the Andromedids) but most streams have been formed less dramatically during the normal cometary activity.

Cometary nuclei are composed by ices and dust grains. Solar radiation causes the ices to sublime, especially near the comet perihelion. The released gas flow also carries solid grains. The grains achieve a speed up to tens of meters per second relative to the nucleus. They then move independently on their own heliocentric orbits. However, since the relative speed is much lower than the comet orbital velocity, the meteoroid orbits remain similar

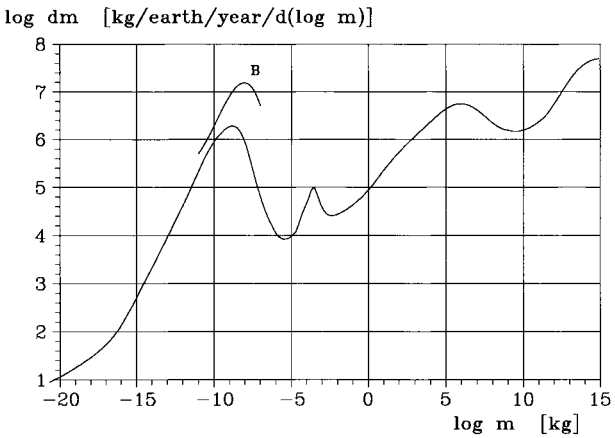

Figure 3. Influx of sporadic meteoroids given in terms of mass per order of mass interval per entire Earth's surface per year as a function of the mass. The four maxima correspond (from the left to the right) to dust, visual meteors, 10 m cometary bodies and km sized asteroids. A newer but unconfirmed calibration for dust is given as curve B. Courtesy: Z Ceplecha.

to the orbit of the parent comet and a well-defined stream is formed. Because of small differences in semimajor axes and thus in the orbital periods, the meteoroids gradually spread along the cometary orbit.

The sizes of particles in a stream formed this way are limited. Small particles are subject to solar radiation pressure. Grains of the size of the order of 0.1 μm are expelled from the solar system. The orbits of somewhat larger dust particles are modified by the RADIATION PRESSURE and by the POYNTING–ROBERTSON EFFECT and a mass segregation within the stream may occur this way. On the other hand, meteoroids larger than several centimeters are too heavy to be carried by the gas outflow against the comet's gravity and are therefore not present in streams formed this way.

In addition to the radiation pressure, both the meteoroids and the parent comet are subject to gravitational perturbations by planets. This leads to gradual dispersion of the stream into sporadic background. The age of the current meteoroid streams is of the order of 10^4 yr only. Their masses are comparable with the masses of the parent comets. Mutual collisions among meteoroids are another effect which leads to the stream dispersion.

The precession of the whole stream can shift the ascending and descending nodes. Any associated meteor showers may then appear or disappear in course of several centuries. This is the case of Geminids which evolve very rapidly. If the orbital evolution of the parent body is complicated, a whole complex of streams can be formed leading to several showers with quite different orbits. This scenario was proposed for comet Machholz 1 with eight possible showers associated, including the Quadrantids.

Classification of meteors

One possible classification is into sporadic and shower meteors. However, meteors differ also in their physical aspects. The most rigorous physical classification is based on the ablation coefficient σ (for definition see the section 'Meteor physics'), fragmentation events or spectra. However, simple quantities such as meteor beginning and end heights can be also used to reveal meteoroid structural classes.

The photographic and television meteors of normal brightness (meteoroids up to about 0.1 kg) have been classified according to the height of the beginning of the luminous trajectory. The height, when normalized to the same initial velocity and incidence angle, shows differences up to 30 km, corresponding to a factor of 50 in the air density. This reflects the differences in the material properties (heat conductivity, heat capacity, density, radiation emissivity). For larger meteoroids (i.e. fireballs), the end height, normalized to the same velocity, angle and mass, proved to be a better discrimination factor. The penetration ability differences are up to a factor of several hundreds when expressed in terms of the air density.

Four main types of fireballs can be recognized. Their typical heights, ablation coefficients and densities are given in table 3. The ablation coefficient can be derived directly for sufficiently well-observed fireballs. The meteoroid bulk density is more difficult to derive and the values given in table 3 are only statistical. The assignment of stones (ordinary chondrites) to the most compact type I was confirmed by the photographed falls of three meteorites. ACHONDRITES may also belong to this type. The connection between types III and comets is confirmed by the fact that the members of typical cometary meteor showers belong to these types. There is no special type for iron meteoroids. Because of their high thermal conductivity, iron meteoroids have high ablation coefficients (between types II and IIIA). This is partly compensated by higher density and the end heights are therefore comparable with those of type II fireballs.

Iron meteoroids are best recognized from meteor spectra. Also achondrites can be distinguished by their spectra. On the other hand, chondrites and cometary meteoroids show similar spectra because they have similar chemical composition despite their very different structure.

Meteor physics

In this section we review the basics of the so-called physical theory of meteors. The theory is mainly used to derive meteoroid properties, such as initial velocity and mass, ablation properties, composition etc, from observations. The observations provide meteor position and brightness as a function of time and, in some cases, the spectrum of the radiation, the intensity and duration of a radar echo or other data. Another approach is numerical modeling of meteors using hydrocodes. Because of the complexity of the problem, these methods provided only partial success and are not discussed here in more detail.

Table 3. Classification of fireballs.

Type	h_B (km)	h_E (km)	σ (s^2 km^{-2})	ρ_d (g cm^{-3})	Assigned material
I	80	30	0.015	3.7	Stony
II	90	45	0.04	2.0	Carbonaceous
IIIA	100	60	0.10	≈0.8	Cometary
IIIB	110	70	0.25	≈0.3	Soft cometary

h_B, beginning height of meteors ($v_\infty = 25$ km s^{-1}); h_E, end height of fireballs ($v_\infty = 25$ km s^{-1}, $m_\infty = 10$ kg); σ, ablation coefficient; ρ_d, bulk density.

Dynamics and fragmentation

We start with a brief description of the theory of motion of a single ablating body. The body (meteoroid) is characterized at each point of the trajectory by its mass m, head cross-section S, density ρ_d and velocity v. The density of the atmosphere at that point is ρ, t is time. The motion and ablation of the body are governed by two equations, the drag equation,

$$m\frac{\mathrm{d}v}{\mathrm{d}t} = -\Gamma S\rho v^2 \tag{1}$$

and the mass-loss equation

$$\frac{\mathrm{d}m}{\mathrm{d}t} = -\Lambda\frac{S\rho v^3}{2Q}. \tag{2}$$

Here Γ is the drag coefficient, Q is the energy necessary for ablation of a unit mass of the meteoroid ($Q \approx$ (2–8) $\times 10^6$ J kg^{-1}) and Λ is the heat transfer coefficient. In principle Γ can be greater than unity owing to the reactive impulse of reflected and evaporated molecules. Λ is always less than unity, because the energy is consumed also for other purposes, such as heating of the surrounding atmosphere and the evaporated material, radiation, ionization, sonic waves etc. The acceleration due to Earth's gravity is neglected in the above equations.

To solve the equations, new quantities are introduced: the ablation coefficient $\sigma = \Lambda/2\Gamma Q$, the shape factor $A = S/V^{2/3} = Sm^{-2/3}\rho_d^{2/3}$ (A is a dimensionless quantity; for a sphere $A = 1.21$) and the shape-density coefficient $K = \Gamma A\rho_d^{-2/3}$. The drag and mass-loss equations can be then rewritten:

$$\frac{\mathrm{d}v}{\mathrm{d}t} = -K\rho m^{-1/3}v^2 \tag{3}$$

$$\frac{\mathrm{d}m}{\mathrm{d}t} = -K\sigma\rho m^{2/3}v^3. \tag{4}$$

The solution is obtained by assuming constant σ and K. One integral is obtained by dividing both equations and integrating:

$$m = m_\infty\,\mathrm{e}^{-(1/2)\sigma(v_\infty^2 - v^2)} \tag{5}$$

where m_∞, v_∞ are the mass and velocity at the beginning of the ablation phase. The ablation coefficient σ is an important parameter describing the meteoroid mass-loss ability.

Equation (5) relates mass to velocity but does not tell us anything about the change of velocity with time. The complete solution can be obtained by means of exponential integral functions and can be found in the specialist literature. The solution is important because observational data (length as a function of time) can be fitted to the resulting functions by optimizing four free parameters. The most important parameters obtained are the ablation coefficient, σ, the initial velocity, v_∞, and the combination $Km_\infty^{-1/3}$. Assuming a typical value for ΓA (≈1.1) and density ρ_d, the initial mass m_∞ can be estimated. Equation (5) can be used to compute mass change during the flight. The mass determined this way is called dynamic mass. Alternatively, if mass is determined from photometry, the density ρ_d can be computed also independently.

The single-body theory is only an approximation. There is much observational evidence that meteoroids are subject to severe fragmentation during their atmospheric penetration. In the case of the Peekskill fireball, 70 fragments are directly visible on one still photograph. More than 1000 meteorites were recovered from a single fireball in Mbale, Uganda, in 1992.

A sudden fragmentation changes the dynamics abruptly because of abrupt change of mass. The single-body theory cannot be used. Nevertheless, one fragmentation point can be found by a sophisticated procedure. It was found that fragmentation occurs in most cases under a dynamic pressure less than 1.2 MPa. In contrast, the mechanical strength of most meteorites is higher than 10 MPa. The structure of meteoroids seems therefore to be strongly affected by the collisions in interplanetary space causing large-scale inhomogeneities.

As well as sudden fragmentation events, continuous fragmentation prevails in some meteoroids, especially of types IIIA, IIIB. Continuous fragmentation can be considered as a mode of ablation and is included in the ablation coefficient. In fact, fragmentation is the most effective ablation process.

Flow regimes

From the aerodynamic point of view three basic flow regimes can be distinguished. They are classified according to the Knudsen number Kn, which is the ratio

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of the mean free path of molecules in the vicinity of a meteoroid, L, and the characteristic dimensions of the meteoroid, R: $\mathrm{Kn} = L/R$. In the free molecule regime ($\mathrm{Kn} \gg 1$) the body suffers direct impacts of individual molecules and the collisions among molecules are negligible. In the transition flow regime ($\mathrm{Kn} \approx 1$) the molecular collisions are non-negligible and a shock wave is formed in front of the meteoroid. In the continuum flow regime ($\mathrm{Kn} \ll 1$) air behaves as a continuum, the shock wave is strong and sonic booms are produced.

Radiation and spectra

During the meteoroid interaction with the atmosphere, part of its kinetic energy is transformed into radiation. This statement leads to the conventional luminous equation:

$$I = -\tau \frac{v^2}{2} \frac{\mathrm{d}m}{\mathrm{d}t}. \tag{6}$$

Here I is the meteor luminosity and τ is the luminous efficiency, i.e. the quantity expressing which part of the energy is transformed into radiation. Only the energy loss due to mass loss is considered; the equation neglects the loss of kinetic energy due to $\mathrm{d}v/\mathrm{d}t$, which is smaller in most cases.

The units of I and τ represent some problem. If I is given in absolute units (erg s^{-1} or W), τ is dimensionless. If the meteor brightness is measured in magnitudes M, the intensity is defined as $I = 10^{-0.4M}$ and the commonly used units for τ are 0 mag erg^{-1} s.

The luminous efficiency depends on meteoroid velocity and mass. The actual values are still uncertain. The preferred values for 100 kg bodies are about 4% for $v = 20$ km s^{-1} and about 2% for $v = 10$ km s^{-1}. For smaller bodies the efficiencies are significantly lower. For high velocities the efficiencies are even more uncertain. Usually it is assumed that τ is directly proportional to v. A zero magnitude meteor may be produced by a 0.5 g meteoroid at 20 km s^{-1} or a 0.02 g meteoroid at 60 km s^{-1}.

The integration of meteor light curves using the luminous equation provides the initial meteoroid photometric mass. In some cases the dynamic and photometric masses do not agree, indicating that our knowledge of fragmentation processes and radiation mechanisms is not complete.

More insight into meteor radiation is provided by meteor spectroscopy. Meteor spectra consist primarily of emission lines and molecular bands. Most of them belong to hot vapors of the meteoroid. The strongest lines are usually those of Na, Mg, Ca, Fe, Mn, Cr, Si and atmospheric N and O. The continuous thermal radiation of the meteoroid surface is negligible in most cases. In extremely bright fireballs (mag −20), thermal continuous radiation of the vapors becomes significant.

In the first approximation, meteor spectra can be fitted by a model assuming local thermal equilibrium in the hot gaseous envelope. However, two spectral components are present, one with excitation temperatures of 3500–5000 K and one of about 10 000 K. The high-temperature component is much stronger in fast meteors. The spectra of meteor wakes are far from thermal equilibrium. Little is known about meteor trains.

Meteor spectra can be used to derive the approximate composition of the vapors. The vapor composition does not always directly reflect the composition of the meteoroid. The refractory elements are not efficiently vaporized, especially in slow meteors. This suggests that melting is the main ablation process. Nevertheless, the main compositional classes of meteoroids can be recognized from meteor spectra. See the section 'Classification of meteors'.

Ionization

The collisions among evaporated meteoric atoms and atmospheric atoms and molecules cause ionization of atoms and molecules. The ionized trail persists for some time after the meteor disappearance. The linear electron density α (cm^{-1}) is supposed to be proportional to the meteoroid mass loss rate:

$$\alpha = -\frac{\beta}{\mu v} \frac{\mathrm{d}m}{\mathrm{d}t}. \tag{7}$$

Here μ is the mean mass of meteoric atoms and β is ionization coefficient which is defined as the number of free electrons produced by one evaporated atom. The ionization coefficient depends strongly on velocity; the dependence $\beta \sim v^{3.5}$ has been derived, with $\beta \approx 0.01$ for $v = 20$ km s^{-1} and $\beta \approx 1$ for $v = 70$ km s^{-1}.

Reflections from ionized trails are observed by meteor radars. The reflection lasts as long as the electron density is larger than some critical value (which is dependent on radar wavelength). Electron density gradually decreases owing to electron diffusion. For long-duration trails (>10 s), other effects are also important, in particular the attachment of free electrons to neutral particles. Direct recombination is slow.

The radar reflection occurs not only from the ionized trail but in exceptional cases also directly from a moving source, probably from the vicinity of the meteoroid. This phenomenon is called head echo and is still unexplained.

Metonic Cycle

An interval of 19 years after which the phases of the Moon recur on the same days of the year, which appears to have been discovered in or around 433 BC by the Greek natural philosopher Meton (*c*. 460 BC–?), and about 50 years later by the Babylonians. This occurs because 235 lunar months is almost exactly equal to 19 tropical years (235 lunar months is equivalent to 6939.689 days, whereas 19 tropical years is equal to 6939.602 days, a discrepancy of about two hours). Meton divided the 19 years into 12 years of 12 months and 7 years of 13 months. The Metonic cycle was used by the Greeks and Babylonians as a reference against which to make adjustments to the calendar and provided the basis of the rules for determining the date of Easter.

Metos of Athens (*c.* 440 BC–?)

Greek astronomer, perhaps born and certainly active in Athens. Made the first recorded attempt to reconcile the lunar and solar calendars. In 432 BC he made observations in Athens of the year and the month. His length for the year was just 1/76 of a day too long. Since the Earth, the Moon and the Sun are independent bodies with quite arbitrary periods, attempts to fit together days (Earth's rotation period), months (the lunar orbital period) and the year (the period of the solar orbit) never quite work, so that for example the year is not a whole number of days. Metos discovered that, over a longer length of time, there almost was a fit between the Moon and the Sun, namely that 235 lunar months (6939.69 days) made up just about 19 tropical years (6939.60 days). This means that after 235 months, the synchronism of the solar and lunar calendars repeats itself and the phases of the Moon recur on the same dates. This became known as the *Metonic cycle* and was adopted from 330 BC as the basis for the Greek calendar until the introduction of the Julian calendar in 46 BC. Since the Metonic cycle is almost equal to 20 eclipse years, 6932.4 days, it is possible for a series (four or five) lunar eclipses to occur on the same dates 19 years apart. CALLIPPUS found an even more exact fit between the lunar and solar calendars after four Metonic cycles.

Michell, John (1724–93)

Cleric, geologist and astronomer, born apparently in Nottingham, England. Cambridge-educated and professor of geology there, invented the idea of black holes in a speculative lecture to the Royal Society in 1783 about the gravitational attraction on light in the vicinity of the Sun, or a body more massive than the Sun. Calculated that a body some 500 times the diameter of the Sun (and the same density, so 100 million solar masses and the size of Jupiter's orbit) would attract light such that it could not escape from the Sun's surface without travelling faster than light did (according to RØMER's value). Michell's calculation was based on the now obsolete corpuscular theory of light (that light is made of particles and can be attracted gravitationally), but his speculation contains all the essential ideas behind black holes. Michell also showed by statistical methods (which he initiated) that many of the double stars cataloged for example by Herschel (see HERSCHEL FAMILY) were truly associated and gravitationally bound together. He proposed the experiment with a torsion balance actually carried out by HENRY CAVENDISH to weigh the Earth by determining the gravitational constant G. Demonstrated the inverse square law between magnetic poles, demonstrated light pressure by the deflection of a thin suspended copper sheet, worked on earthquakes and seismology.

Michelson, Albert (1852–1931)

German-American physicist, invented the *Michelson-Morley interferometer* to detect, with MORLEY, the motion of the Earth through the ether, but found that irrespective of the orientation of the interferometer, no motion could be detected. This was explained by the Fitzgerald–Lorentz contraction, and was a foundation for Einstein's theory of special relativity. Michelson went on to apply interferometry to astronomy by mounting an interferometer on a steel beam on the 100 in Mount Wilson telescope, measuring the diameters of six stars.

Michelson–Morley Experiment

A celebrated experiment carried out by A A Michelson (1852–1931) in 1881 and by Michelson together with Edward Morley (1838–1923) in 1887, which attempted and failed to detect the motion of the Earth through the ether. The basis of the experiment was that if a beam of light traveled a known distance in the direction in which the Earth was supposed to be moving through the ether, and another beam traveled the same distance at right angles to this direction then, if light moved at a constant velocity through the ether, the two beams should take different times to cover the distance. The failure to detect any difference is accounted for by the special theory of relativity.

Michigan Radio Astronomy Observatory

Located in Ann Arbor, close to the University of Michigan campus. The primary instrument at the observatory is a 26 m diameter parabolic reflector with an 11 m focal length. This telescope was constructed in 1958, under contract from the Office of Naval Research. Since 1968, the research and operation of the observatory have been supported jointly by the National Science Foundation and the University of Michigan.

The 26 m telescope is used to study total flux density and linear polarization from active extragalactic objects. The discovery that such objects vary in brightness with time-scales of weeks to a few years was made using the Michigan instrument in 1964–5, and the discovery of variability in polarization followed in 1966.

Current research at the observatory is focused on understanding the physical conditions in the relativistic flows in jets and on investigating the relationship between variations in the radio wavelength and the behavior of the radiation in other regions of the electromagnetic spectrum.

Microchannel Plate Detectors

Microchannel plates (MCPs) are imaging electron multipliers of high gain which have been widely used in space astronomy from the visible to the x-ray and in space plasma analysis. MCPs are, in fact, the archetypal detectors for space science: fast, compact, low-mass, low-power devices with a wavelength response extending from the optical to the x-ray, coupled with high sensitivity to ions and electrons.

Technology

The origin of these detectors can be traced to 1930, to P T Farnsworth's US patent for a continuous-dynode electron multiplier—an evacuated hollow tube whose internal surface is coated with a resistive material of high secondary electron yield and along which a large (∼kV) potential difference is applied. When ionizing radiation strikes the inside wall of the tube, low-energy (∼eV) electrons emitted from the surface are accelerated down the channel by the applied electric field. If these electrons gain sufficient energy from the field before next striking the wall, they may each promote more than one secondary electron into the vacuum and an avalanche may develop.

The first practical embodiments of this concept were in the US, UK and USSR in the early 1960s. Single-channel channel electron multipliers (CEMs) with ∼1 mm bores were fabricated from, among other materials, reduced lead (or lead–bismuth) silicate glasses containing significant weight fractions of the alkali metals (Cs, K, Na, Li). The channels of these CEMs were curved in order to give high electron gains (10^7–10^8 for bias voltages of 3 kV) while suppressing unwanted afterpulses from positive ion feedback. The operating pressure for CEMs and MCPs is typically 10^{-6} mbar. With the addition of an input cone to increase collecting area, CEMs were very rapidly adopted for use in space science—as detectors at the foci of paraboloidal x-ray and EUV concentrators on the COPERNICUS (1972) and Apollo–Soyuz (1976) missions and, in particular, as detectors for positive ion and electron analyzers, an instrumental niche they occupy to the present day.

The first MCPs were simply arrays of straight-channel CEMs bonded together using a low-melting point solder glass. By the late 1960s, however, in a development driven by the military need for night vision image intensifiers, the modern 'two-draw' etchable core process, with its similarity to fiber optic production technology, had evolved (variants on this process include 'hollow' and 'triple' drawing). A bar of acid-soluble core glass is inserted into a hollow tube of cladding glass and the composite billet pulled down through a vertical oven heated above the softening point of the glasses. The billet (and hence the final microchannel) is usually circular in cross-section, although square channels are required for MCP optics (below). The ∼1 mm fiber emerging from the bottom of the oven is cut into lengths which are then stacked into a hexagonal or square former to create a multifiber. This multifiber is again drawn down, cut, stacked and pressure fused at high temperature to produce a boule or block from which MCP blanks of the appropriate thickness can be sliced. The blanks are then acid etched to produce the open channel structure. The embryonic channel plate is then chemically treated in order to establish the appropriate channel resistivity and secondary electron yield coefficient and, finally, nickel alloy (Nichrome or Inconel) electrodes are vacuum evaporated onto the front and rear faces, connecting all $\sim 10^7$ channels—each one capable of acting as an independent photomultiplier tube—in parallel. The finished channel walls have a glass composition which varies with depth: in particular, a silica-like surface layer some 100–500 Å thick overlays a thicker semiconducting lead-rich layer. The former layer controls the secondary electron yield and, hence, the quantum efficiency and gain; the latter layer, in which conduction takes place by a hopping mechanism, controls the multiplier current supply and, hence, the gain-versus-count rate characteristic. The very small volume of the active layer also makes MCPs intrinsically radiation hard in a space environment.

Since the linear gain in a continuous-dynode multiplier depends only on the length-to-diameter ratio of the channels (typically 40:1 in night vision MCPs), not explicitly on channel diameter, MCPs can be fabricated with very small pores—leading to imaging detectors of very high spatial resolution. Since the pulse transit time in a 0.5 mm long channel, biased to 1000 V, is of order 100 ps, MCP detectors are also intrinsically fast, a property used to great advantage in time-of-flight space plasma analyzers. The pore diameter in state-of-the-art MCPs is 6 μm, while the open area fraction is typically around 65%. The imaging area of an MCP may now approach 100 cm^2—as in the CHANDRA High Resolution Camera (see table 1). Formats include circular, square, rectangular and annular (for readout of hemispherical charged particle analysers). MCPs with either convex or concave surface profiles have been produced to match the focal surfaces of EUV and UV telescopes and spectrometers. Radioisotope-free 'low-noise' MCP glasses have been formulated, which lack the internal beta-induced background of standard compositions containing K and/or Rb. By varying the production process, the resistance of a 25 mm diameter MCP can be as high as 1 GΩ or as low as 100 kΩ. Low-resistance (high-current) MCPs are of great interest for high count rate applications but, because MCP glass has the negative temperature coefficient (around $-1\%\,^{\circ}C^{-1}$) characteristic of a semiconductor, low-resistance plates are susceptible to 'thermal runaway' which may lead to the local melting of the channel matrix. Very-low-resistance MCPs must be heat-sunk to a conducting anode if they are to be operated stably. Despite its flexibility, however, the two-draw process is costly, complex and close to the end of its technical evolution: for example, the production of large-area glass MCPs with channels much smaller in diameter than 6 μm will be extremely

challenging. The long-term future of MCP fabrication may well lie in micromachining, using reactive ion etching or other techniques to produce precisely dimensioned arrays of small channels in Si wafers. Micromachining would provide, in principle, better control of resistivity, better high-vacuum compatibility (new glass MCPs copiously outgas water vapor) and the ability to provide 'one-off' formats at relatively low cost. The first attempt to fabricate such 'alternative technology' Si MCPs was, however, as long ago as 1977; alternative CEM technologies have been successfully based on both ceramics and conducting polymers.

Photocathodes

The intrinsic quantum efficiency of bare glass MCPs in the 'open window' soft x-ray and EUV bands is rather low (∼5–15%) and varies strongly with angle of photon incidence to the channel axis. Alkali halides such as CsI or KBr are therefore thermally evaporated onto the input surface of the MCP to produce substantial enhancements in efficiency. At 120 Å, the detection efficiency may reach 70% for a CsI-coated plate preceded by an open mesh biased slightly more negative than the input face itself. This 'repeller grid' allows events from the interchannel web to be counted by returning low-energy secondary electrons to their plane of emission, where they may enter a channel and initiate an avalanche. Alkali halide coatings may also be used to increase the electron or positive ion detection efficiency of MCP detectors for use in plasma analyzers.

In the optical and far-ultraviolet (FUV) bands, MCP-based detectors are sealed vacuum tubes. The semitransparent photocathode is deposited on a transparent substrate (borosilicate glass or fiber optic faceplate for the optical band; quartz or sapphire for the FUV). Photoelectrons emitted from the cathode are accelerated towards the MCP, which acts as an electron detector, not as a direct photon detector. Photocathodes for the optical are generally antimonized multialkalis such as S20 (Na_2KCsSb) with a peak efficiency of 20% and a response extending out to a wavelength of 0.9 μm. CsTe is also employed in sealed intensifiers for the blue end of the visible spectrum. Negative electron affinity materials such as GaInAs or GaAs, with an extended infrared response but very severe tube vacuum requirements, have found limited use in ground-based astronomy.

Readout

In space astronomy, MCP detectors are usually based on the ion-feedback-free chevron (two MCPs with offset channel axes and an interplate gap between them—an arrangement first developed c 1970 (see figure 1)) or Z-stack (three plates in contact) configurations. The output pulse height distribution (PHD) of a single MCP is generally quasi-exponential, placing a severe requirement on the dynamic range of subsequent processing electronics. The PHD of a multi-stage detector composed of plates with individual length-to-diameter ratio of 80:1 or 120:1, however, is peaked with a modal gain of $\sim 10^7$ (0.625 pC/pulse). A large number of signal location techniques have been developed to encode the position of the MCP charge cloud at the output of the final plate in the stack. Readout methods may be either electrically or optically coupled. In the latter category, commonly used in detectors for visible wavelengths, the output charge cloud is accelerated through a large potential difference and allowed to strike a phosphor screen. The light spot from the phosphor is then channelled via a fiber optic faceplate onto a silicon charge coupled device (CCD) or charge injection device (CID). By using a fiber optic with a suitable taper ratio, a small CCD can be used to encode a much larger MCP input surface. Suitable interpolation algorithms allow the centroid of the light flash (and hence the photon arrival position) to be found to much better than one CCD pixel width, allowing images to be formed which clearly show the microchannel pore structure.

Electrical readout elements are generally based on (a) charge division in a resistive sheet, as in the EXOSAT CMA and ROSAT Wide Field Camera detectors, (b) charge partition among a pattern of conducting elements, for example the wedge-and-strip anodes used in the MCP

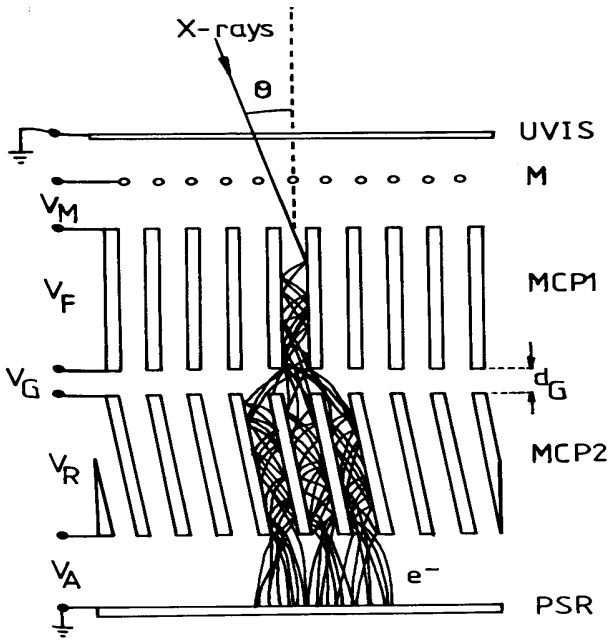

Figure 1. Schematic view of avalanche propagation in a two-stage 'chevron' MCP x-ray detector. The channels of the rear plate (MCP2) are biased at an angle (6°–15°) to those of the front plate (MCP1) in order to stop positive ions generated at the output end propagating back to the entrance surface and initiating afterpulses. PSR, position-sensitive readout; UVIS, UV–ion shield composed of metalized plastic; M, mesh. Typically, the applied potential differences V_F and V_R are ∼1500 V. For electron detection, the front plate input face is held at ground and the PSR at high positive potential.

detectors on the EUVE satellite, or (c) timing of the charge pulses at the ends of a delay line, as in the detectors on the FUSE mission. Because, crudely, it is simpler to measure a time interval to high precision than it is to digitize a charge to the same precision, delay line readout generally delivers higher spatial resolution (<10 μm) at higher count rates (>100 kHz). More complex position encoding methods use the coincidence counting of pulses on orthogonal strips, as in the Multi Anode Microchannel Array (MAMA) detector in the STIS instrument on the HUBBLE SPACE TELESCOPE. Here, $2M$ amplifier–discriminator chains encode M^2 pixel addresses. The crossed grid charge collector used on the Chandra High Resolution Camera detectors uses orthogonal grids of fine wires to intercept the charge cloud emanating from the rear MCP of a chevron pair. The wires of each grid are terminated by a resistive line subdivided by many (64 per axis) preamplifier inputs. The x or y location of the x-ray interaction is found by taking appropriate ratios of the charges measured by neighboring preamplifier 'taps'. M-fold partitioning of the encoder axis means that the position signal executes its full dynamic range over a distance L/M, where L is the side length of the image field, allowing high resolution (<25 μm) to be obtained over large (L = 10 cm) image areas for modest levels of signal digitization.

Flight instruments

Table 1 describes a number of MCP detectors flown on major space astronomy missions for the UV, EUV and x-ray wavebands.

Microchannel plate x-ray optics

Uniquely, MCP structures can function not only as detectors but also as focusing optics for the UV, EUV and x-ray bands. The operation of MCP x-ray optics was first described by researchers at CSIRO and the University of Melbourne in 1989 and the first images with square-pore MCPs were reported by the University of Leicester in 1993. MCP optics operate by grazing incidence reflection from the internal channel walls. Currently, the best angular resolution for the central component of the cruciform focus is about 5 arcmin. MCPs potentially provide important advantages over conventional x-ray optics because of their very low mass-to-effective area ratio and very large (in principle, 4π sr) fields of view. Applications now being studied include an imaging all-sky monitor (the so-called *lobster eye* telescope) for the 0.1–3 keV band, a hard x-ray telescope for the 2–60 keV band, imaging x-ray fluorescence spectrometers for the surface geochemistry of airless inner solar system bodies and a wide field-of-view aurora imager for the 1300–1600 Å band.

Microlensing

Microlensing refers to the special case of GRAVITATIONAL LENSING where the multiple images produced are too close together on the sky to be observed as separate images. However, the lensing can still be detected because these multiple images appear as a single object of increased apparent brightness. Although this is not detectable in a one-off observation (since we do not know the 'normal' brightness of the source), with the passage of time the lens moves across the Earth–source line and the amount of brightening changes. Typically the source will appear to brighten, reach a maximum and then fade symmetrically back to normal over the course of a few weeks or months; this is called a 'microlensing event'.

The major application of microlensing, suggested by Paczynski in 1986, is in the search for the DARK MATTER which is strongly believed to exist from rotation curves of spiral galaxies etc. Since the lensing effect depends only on lens mass, it can be used to search for very faint or invisible objects such as brown dwarfs, neutron stars, old white dwarfs or black holes, which might make up the dark matter. These are collectively known as massive compact halo objects or MACHOs, in contrast to the hypothetical weakly interacting massive particles or WIMPs.

To understand the basics of microlensing, consider a small massive object (the lens) situated exactly on the line of sight from Earth to a background star and consider a number of light rays radiating from the star passing the lens at different distances and being bent towards the lens. Since the bending angle for a light ray increases with decreasing distance from the lens, it is clear that there is a unique 'miss distance' such that the ray will be deflected just enough to hit the Earth; this distance is called the Einstein radius. By rotational symmetry about the Earth–star axis, an observer on Earth with perfect resolution would see the star lensed into an annulus centered on its 'true' position, called an Einstein ring. As the lens is moved slightly off the line of sight (e.g. by 0.1 Einstein ring radii), the Einstein ring splits into two banana-shaped arcs, one on the same side of the lens as the source, one on the opposite side. As the lens moves further off (more than 1 Einstein radius), the arcs become more circular, the 'opposite-side' arc fades very rapidly and the 'same-side' arc turns into a slightly deflected and nearly circular image of the star. Figure 1 illustrates a sequence of such images for a typical microlensing event.

Although the perfect alignment giving the Einstein ring will rarely occur in practice, it is still a very important concept because the size of the hypothetical Einstein ring sets the length scale over which substantial brightening will occur. As we will see, for a typical lens in our Galaxy the radius of the Einstein ring $r_{\rm E}$ is roughly $8(M/M_\odot)^{1/2}$ AU (astronomical units), where M is the lens mass. Knowing this scale allows us to understand most of the general characteristics of microlensing: it is extremely small compared with the typical distance to a lens, so the angular separation of the two images will be too small to resolve, hence the 'micro'lensing. However, it is considerably larger than either the size of a star or the size of a MACHO, so we can usually approximate the lens and source as pointlike, which leads to a simple prediction for the lightcurve shape. Also, $r_{\rm E}$ is very small compared with the typical separation of objects in the Galaxy, which implies that microlensing will be a very rare phenomenon. Another notable feature is that $r_{\rm E}$ is proportional to the square root of the lens mass. This means that the area of sky 'covered' by a lens (at fixed distance) is proportional to its mass, so the total fraction of sky covered depends only on the total mass density in lenses, not the individual lens masses. This fraction is called the 'optical depth' τ, and is $\sim 10^{-6}$ for Galactic microlensing. The duration for a microlensing event is given by the time for the lens to move by $2r_{\rm E}$ relative to the Earth–star line; for typical Galactic speeds of 200 km s^{-1}, this is $\sim$130 days $\times (M/M_\odot)^{1/2}$.

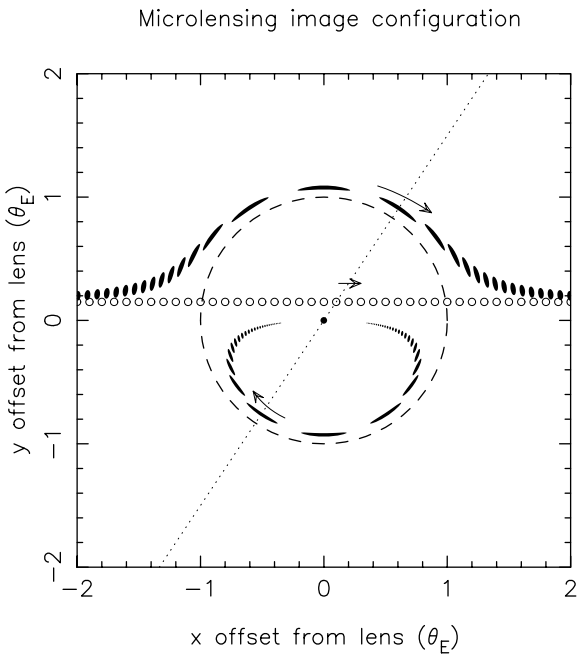

Figure 1. A microlensing event seen at 'perfect' resolution. The axes show angular offsets on the sky from the lens (central dot) in units of the Einstein angle; the dashed circle is the Einstein ring. The series of small open circles shows the 'true' source position at successive timesteps. For each source position, there are two images (solid blobs) collinear with the lens and source, as indicated by the dotted line; the arrows illustrate their motion.

For perfect alignment, simple geometry gives the (small) deflection angle of the light ray meeting Earth as $\alpha = r_{\rm E}/D_{\rm ol} + r_{\rm E}/D_{\rm ls}$, where $D_{\rm ol}$ is the observer–lens distance, $D_{\rm ls}$ is the lens–source distance etc. Requiring this to equal the general relativity deflection, $\alpha = 4GM/c^2 r_{\rm E}$, we obtain

$$r_{\rm E} = \left(\frac{4GM}{c^2}\,\frac{D_{\rm ol}D_{\rm ls}}{D_{\rm os}}\right)^{0.5}.$$

The angular Einstein radius is just $\theta_{\rm E} \equiv r_{\rm E}/D_{\rm ol}$. If we now introduce a small offset of the lens by a distance b from

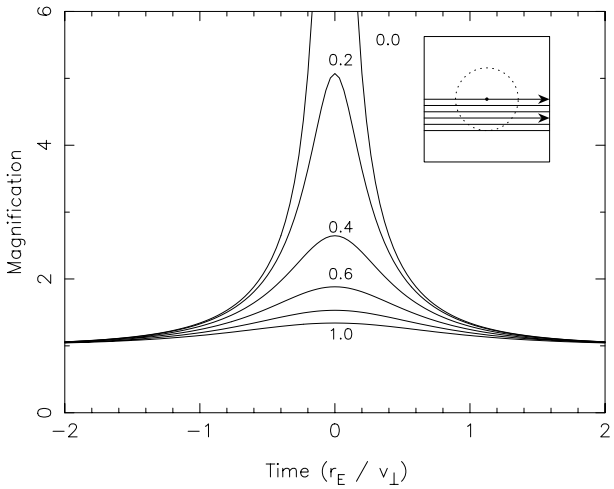

Figure 2. Microlensing event lightcurves (magnification versus time) for six values of the impact parameter $u_{\min} = 0.0, 0.2, \ldots, 1.0$ as labelled. Time is in units of the Einstein radius crossing time $r_E/v_\perp$. The inset illustrates the Einstein ring (dotted circle) and the source paths relative to the lens (dot) for the six curves.

the Earth–source line, i.e. an angle $\beta \equiv b/D_{ol}$, a simple generalization gives the two image angular positions (relative to the lens) as

$$\theta_\pm = 0.5[\beta \pm (\beta^2 + 4\theta_E^2)^{1/2}].$$

Since lensing preserves surface brightness, the magnification A_i of each image is given by the ratio of image to source areas, which for a 'small' source and any axisymmetric lens is just

$$A_i = \left| \frac{\theta_i}{\beta} \frac{\mathrm{d}\theta_i}{\mathrm{d}\beta} \right|.$$

For a point lens, this leads to a total observed magnification as the sum of the two image magnifications,

$$A = A_+ + A_- = \frac{u^2 + 2}{u(u^2+4)^{1/2}} \qquad (1)$$

where $u \equiv \beta/\theta_E = b/r_E$ is the misalignment in units of the Einstein radius. This behaves as $A \approx u^{-1}$ for $u \lesssim 0.5$, so the magnification may be large, but as $A \approx 1 + 2u^{-4}$ for $u \gtrsim 2$, so the magnification rapidly becomes negligible at large u. For uniform motions, we will have $u(t) = \{u_{\min}^2 + [v_\perp(t-t_0)/r_E]^2\}^{1/2}$ where $v_\perp$ is the transverse velocity of the lens relative to the line of sight and $u_{\min}$ is the value of u at closest approach, which occurs at time t_0. Substituting this into equation (1) gives the lightcurve $A(t)$; some examples are shown in figure 2.

Observations of microlensing

To search for microlensing by MACHOs, since it is so rare we need millions of source stars and they should be far enough away to give a good path length for lensing, but not so far away that the individual stars are faint. The obvious targets for dark-matter lenses are the LARGE MAGELLANIC CLOUD (LMC) and SMALL MAGELLANIC CLOUD (SMC), the largest of our Milky Way's many satellite galaxies, since the sight line to them passes mainly through the Galactic halo. The Galactic bulge is also an interesting target, although here because of the high stellar density the microlensing should be mainly due to intervening faint stars rather than dark matter. Around 1991, several teams of astronomers called MACHO, EROS and OGLE began large projects using wide-field 1 m class telescopes to search for microlensing events. The novel feature of these experiments is their massive data volume, requiring large amounts of disk and tape storage and special high-speed photometry programs. The expected number of microlensing events is much smaller than the fraction of intrinsic variable stars, but fortunately microlensing has many strong 'signatures' that are distinct from all previously known types of variable star: the most important is the 'uniqueness', i.e. any given star should be microlensed at most once in a human lifetime, while almost all variable stars are periodic or quasi-periodic. Also, most events should have a symmetrical shape as in figure 2, and they should be achromatic (the source's color should not change during the event), since lensing is independent of wavelength.

The MACHO, EROS and OGLE teams announced their first candidate microlensing events near simultaneously in late 1993 (figure 3). Since then, they have accumulated much more extensive datasets, and completed detailed calculations of their microlensing detection efficiency as a function of event duration; thus a number of general results have become clear.

(i) Hundreds of events have been observed towards the Galactic bulge. They are distributed 'randomly' across the color–magnitude diagram, and their distribution of peak magnifications matches the theoretical prediction, which provides a very convincing check that microlensing works as predicted and that the experiments can detect it. The event rate towards the bulge is greater than initially predicted by Galactic models, favoring a barred structure for the Galaxy. The distribution of timescales is consistent with most of the lenses being low-mass stars as expected and can provide constraints on the stellar mass function at low masses.

(ii) Towards the Magellanic Clouds, no 'short' events (timescales from a few hours up to 20 days) have been seen by any group. This places strong limits on 'Jupiters' in the dark halo: specifically, compact objects in the mass range 10^{-6}–0.05 solar masses contribute less than 10% of the dark matter around our Galaxy. This is a very important result, as these objects were previously thought to be the most plausible form of baryonic dark matter, and (for masses below 0.01 solar masses) they would have been virtually impossible to detect directly.

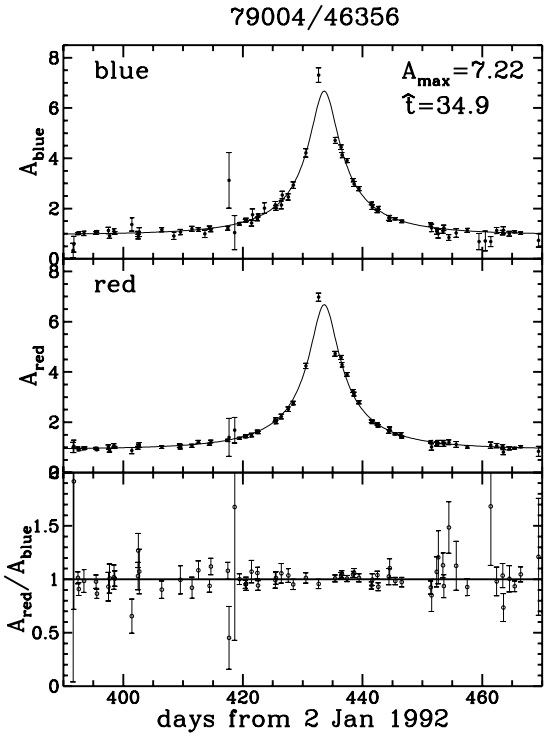

Figure 3. The first LMC microlensing candidate from the MACHO project. (Expanded view: 6 yr of constant data are outside the plot). Upper and middle panels show brightness versus time in blue and red passbands respectively, in units of the baseline value. Points with error bars are observations, the curve is the best microlensing fit. The lower panel shows the ratio of red/blue flux, illustrating the lack of color change.

(iii) Approximately 18 events with durations 30–200 days have been observed towards the Magellanic Clouds. The implied optical depth is well above expectation from 'known' stars, and is roughly 1/3 of the value expected ($\tau \approx 5 \times 10^{-7}$) for an all-MACHO dark halo. The relatively long durations imply lens masses of roughly 0.3–0.7 solar mass, which is a puzzle as discussed below.

(iv) Many events are now detected in real time and announced on the world-wide web. This enables more frequent monitoring of ongoing events, giving more precise tests of the shape. This has attracted considerable interest since, where the lens is a low-mass star (probably the case for most of the events towards the Galactic bulge), a planet around the lens star may give rise to a short-duration 'blip' superimposed on the smooth microlensing lightcurve: this method is potentially sensitive to low-mass planets down to a few Earth masses, below the range accessible to radial-velocity planet searches. Two groups called PLANET and MPS are now searching for this effect.

Current questions in microlensing

The nature of the objects giving rise to the lensing towards the Magellanic Clouds is a significant puzzle at present; the inferred lens masses are well above $0.1M_{\odot}$, which means that they cannot be ordinary hydrogen-burning stars in a spherical halo, as these would be visible in large numbers in deep images, e.g. the Hubble Deep Field. There are two classes of solution: either the lenses are in the halo but are much fainter, e.g. old white dwarfs or possibly primordial black holes, or they are low-mass stars but in a non-halo population, i.e. preferentially concentrated in the foreground of the LMC. The white-dwarf solution has significant problems associated with early metal production but has received some support recently from a possible detection of proper motions of faint objects in the HUBBLE DEEP FIELD. Various classes of non-halo population have been proposed, e.g. a 'thick' LMC disk, a small dwarf galaxy projected in front of the LMC, a warped Milky Way disk etc, but several searches for such populations have been negative.

There are several ways of testing these possibilities: one is to measure distances to individual lenses. In a 'standard' microlensing event as in figure 2 it is impossible to measure the lens distance since the one physical parameter (event duration) depends on three unknowns, the lens mass, distance and transverse velocity. However, as proposed by Gould and others, a small fraction of observed events should deviate from the standard shape for one of several reasons: the non-uniform motion of the Earth, the finite size of the source, a binary lens etc. In these cases we can obtain an additional observable which constrains the location of the lens. At present there are only one or two such cases for Magellanic Cloud lensing. Future satellite observations may help to measure lens distances, either by measuring the 'parallax' effect or the small centroid shift during the event.

Another active area is the search for microlensing towards the ANDROMEDA GALAXY, M31. This is considerably more challenging since the greater distance means that there are multiple unresolved stars per resolution element, and sophisticated image differencing techniques are necessary. However, it has the advantage that microlensing from M31's own halo will produce substantially more events towards the far side of M31's disk than towards the near side, owing to the nearly edge-on inclination. Two groups called AGAPE and MEGA have done pilot studies and are currently undertaking large-scale searches towards M31.

Cosmological microlensing

Although microlensing within the LOCAL GROUP is the main application at present, microlensing of 'point' sources at cosmological distances (e.g. quasars, supernovae or gamma-ray bursts) may also be observable. In the case of a quasar lensed into multiple images by a foreground galaxy, the individual stars in the galaxy may act as microlenses. Here the microlensing appears as brightness changes unique to one image of the multiplet (after correcting for

the time delay); in this case the optical depth is typically close to unity (because the surface density must be of order the 'critical' surface density to produce multiple imaging), so the interpretation of the lightcurve is complex. Other searches are in progress for microlensing of quasars behind the VIRGO CLUSTER by dark objects in the cluster, and the Next Generation Space Telescope should be easily able to detect microlensing of stars in the Virgo galaxy M87.

Micrometeorite

An interplanetary dust particle or a particle ablated from a meteoroid during its passage through the Earth's atmosphere that has not itself burnt up in the atmosphere as a meteor. Particles below a mass of around 1 μg are slowed by collisions with molecules in the upper atmosphere to a speed at which further collisions impart insufficient energy for ablation to occur. Such particles drift down and eventually settle on the surface. Micrometeorites have been recovered from cores of sediments drilled from the ocean floor and from the Antarctic ice, and from rainwater. They can also be collected before they reach the ground by high-flying airplanes. Interplanetary dust particles recovered from the atmosphere are sometimes called *Brownlee particles* after Donald E Brownlee, who was the first to investigate them systematically.

Microscopium

(the Microscope; abbrev. Mic, gen. Microscopii; area 210 sq. deg.) A southern constellation which lies between Sagittarius and Piscis Austrinus/Grus, and culminates at midnight in early August. It was introduced by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2.

A small, inconspicuous constellation, the brightest stars in Microscopium are γ and ε Microscopii, both of magnitude 4.7. Interesting objects include α Microscopii, magnitude 4.9, which has a fainter companion, magnitude 9.8, separation 20.5″, and NGC 6925, an eleventh-magnitude spiral galaxy.

Mid-Infrared Instrumentation

These astronomical instruments are designed to sense radiation at mid-infrared (also known as thermal) wavelengths (5–30 μm). Mid-infrared instruments operating from ground-based telescopes are limited in sensitivity by the large thermal background from the sky and also the telescope itself but enjoy the spatial resolution benefits provided by large ground-based telescopes. Space-based mid-infrared instruments are not limited by the atmospheric background but can suffer from lack of spatial resolution owing to the smaller telescope apertures available to these instruments.

The mid-infrared spectral region

The infrared (IR) region of the radiation spectrum covers the wavelengths longward of the visible region ($\sim$0.7 μm) and short of the microwave region. The infrared region is further subdivided into three regions: the near-infrared (0.7–5 μm) the mid-infrared (5–30 μm) and the far infrared (30–few hundred μm). In some applications (particularly military infrared devices) the infrared region is divided into the short-wave infrared (SWIR, 1–2 μm), mid-wave infrared (MWIR, 3–5 μm) and long-wave infrared (LWIR, 8–12 μm).

The mid-infrared region is largely synonymous with the thermal infrared, meaning the spectral region where thermal radiation from room temperature type bodies (around 300 K) dominates. The thermal radiation is the radiation emitted by all bodies, because of their own heat, and is characterized by the Planck function. For objects of temperatures around 300 K, the peak of the black body curve (see BLACK-BODY RADIATION) lies at 10 μm in wavelength.

Atmospheric bands and transmission

The transparency of the atmosphere defines a number of bands. This is because atmospheric gases, especially H_2O and CO_2, are efficient absorbers of infrared radiation at certain wavelengths. These absorption bands define 'windows' of relative transparency through the atmosphere. In the mid-infrared region these bands lie at 3–5 μm, 8–13 μm and 16–22 μm, although the 8–13 μm band is by far the 'cleanest', i.e. most free from extra absorption bands. From a high, dry mountain observatory the best part of the 8–13 μm window, near 10.5 μm is about 95% transparent. At the edges of the window it is closer to 50–70%, before falling to 0% transmission outside of the windows.

Thermal backgrounds

At mid-infrared wavelengths, all terrestrial bodies are radiating copiously. This is true of the sky and also the telescope and instrument itself. The fact that the sky is 50–95% transmissive in the atmospheric windows also means that the sky is between 50% and 5% emissive. Similarly, the aluminized mirrors of the telescope emit between 1% and 5% of a black body at the telescope temperature. The dirtier the mirror, the larger the emission. The spider vanes and any part of the telescope structure 'visible' to the instrument radiate as near-perfect black bodies. All these sources combine to provide a large background flux of infrared photons on the infrared detector. The photon shot noise arising from this background radiation sets the background limit to the detector sensitivity. Except at very high resolutions the background 'noise' dominates all other sources of noise such as detector read noise and dark current.

To reduce the background emission from the telescope itself, INFRARED TELESCOPES typically have no optical baffling (which radiates at thermal wavelengths), they maintain a low emissivity mirror surface by regular cleaning and aluminizing, and employ an undersized secondary mirror so that no part of the telescope structure is visible to the infrared detector.

For a typical broad-band imaging situation, using a 4 m class telescope, clear and cold sky, and a pixel field of view of 1 arcsec, then the background from sky and telescope is around 10^9–10^{10} photoelectrons s^{-1}. The astronomical source, however, will be many orders of magnitude (around 10^{-5}) fainter than the background. Extraction of the signal from the background and the background photon shot noise is the key problem for ground-based mid-INFRARED ASTRONOMY.

Observatories

To minimize the sky background, the best mid-infrared observing sites are located atop high, dry mountains (see also OBSERVATORIES AND THEIR LOCATION). Probably the best mid-infrared site in the world is the Mauna Kea observatory in Hawaii, at 4200 m elevation. Here the telescope is above a significant fraction of the Earth's atmosphere and IR-absorbing gases, and in particular it is above 90% of the atmospheric water vapor. The reduced atmospheric temperature and background and improved transmission mean that system sensitivities are significantly improved. Comparable sites are also found in the Atacama desert in Chile, although they are not quite as high.

Chopping

With the advent of large-format, staring detectors at near-infrared wavelengths the practice of chopping has largely disappeared from such instruments, but at mid-infrared wavelengths the background is sufficiently large and the background due to the sky is sufficiently variable that 'sky chopping' is still generally necessary. Chopping provides a form of background subtraction that is very effective and particularly removes the effect of high-frequency fluctuations in the sky background. These fluctuations generally take the form of turbulence which presents regions of slightly different temperature and/or transparency to the detector on very short timescales (i.e. subhertz rates).

Chopping involves wobbling the secondary mirror of the telescope to present alternate views to the detector,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

firstly with source plus background, and then with background alone. The difference of these two images leaves source only.

As the background flux compared with the source is reduced, the requirement for chopping diminishes. So for observations involving very high spectral resolutions, or where the sky is very clear and temperatures low (e.g. South Pole or space), background chopping is usually not required.

Diffraction limit and seeing

At mid-infrared wavelengths the spatial resolution we can obtain with current-generation telescopes (i.e. up to 10 m diameter) is limited not so much by atmospheric SEEING as in the visible and near-infrared regions but rather by the diffraction limit of the telescope itself. The diffraction limit at 10 μm for a 4 m telescope is on the order of half an arcsecond. For most instruments the diffraction limit determines the pixel scale so as to just sample the point spread function (PSF). This means that the point source sensitivity increases as the square of the aperture (D^2) in the critically sampled diffraction limited case, but in the seeing limited case increases as the diameter (D) only.

At 10 μm the seeing is about one-half of that at visible wavelengths. At the best observing sites the median seeing is typically half an arcsecond in the visible, or one-quarter arcsecond in the mid-infrared. So, except for the largest telescopes or the lesser observing sites, the atmospheric seeing is usually dominated by the diffraction limit.

Detector sensitivity

It is very difficult to quote system sensitivities, because the actual sensitivity achieved depends so much on the operating configurations (spectral resolution, pixel size, detector type, telescope size and emissivity, atmospheric background and temperature, weather etc). If we adopt a fairly standard imaging format, however, it is possible to provide some indicative numbers, from which different situations can be scaled. Using a 4 m IR optimized telescope at a good observatory site, a good detector with quantum efficiency around 25%, a pixel size of 0.25 arcsec^2 and a broad-band filter 8–13 μm then a sensitivity figure of around 1–2 mJy arcsec^{-2} $(1\sigma)^{-1}$ h^{-1} should be achievable (the flux density unit Jansky is defined by 1 Jy $= 10^{-26}$ W m^{-2} Hz^{-1}). Sensitivity limits for various mid-infrared instruments available at large observatories are usually available at the observatory web site.

Detectors for use in the mid-infrared

Si photon detectors

The majority of detectors used for mid-infrared astronomy fall into the class of doped-silicon photon detectors. In these devices an incident photon causes an electron to shift from the valence band to the conduction band of the semiconductor, leaving a mobile electron in the conduction band and hole in the valence band. The electron–hole pair can then be sensed using a suitable bias circuit. The efficiency with which the detector layer converts incident photons to photoelectrons is called the detector quantum efficiency (η). The quantum efficiency is dependent on the detector material, its doping and also thickness, and is typically in the range 10–25%.

The drawback with these detectors is that the band-gap energy is low enough that thermally generated electrons (dark current) in the detector itself are excited into the conduction band. At room temperature the dark current would swamp photoelectrons, and so the detector has to be cooled. The longer the wavelength to which the detector needs to operate the colder it needs to be, and temperatures of 4–12 K are typical.

As in the visible and near-infrared wavelength regions, mid-infrared astronomy is being revolutionized by the advent of large format staring focal plane arrays (FPAs). The background from the sky and telescope is large enough that detectors, even with well depths of 10^6–10^7 electrons, still need to be read out at frame rates between 200 and 400 frames s^{-1} for broad-band imaging. These high readout rates and the low required operating temperatures have served to limit detector sizes to just a few hundred pixels square. The most common detectors today have 128 × 128 pixels, generally with between two and four readout channels. Currently under development, or shipping in limited quantities for testing, are 256 × 256 element and 320 × 240 element arrays.

As of today there are only two major manufacturers of astronomy-grade large-format mid-INFRARED ARRAYS, Boeing (until recently made by Rockwell International) and the Santa Barbara Research Center (SBRC, formerly owned by Hughes, but recently acquired by Raytheon). A small number of detectors are also made by LETI of France, Amber Engineering, USA, Aerojet, USA, and some others, but these detectors are rarely competitive for astronomical applications compared with the SBRC and Boeing offerings.

Bolometers

Bolometers are devices that respond to changes in heat, rather than directly detecting the photoelectron. To do this the bolometer has a load that absorbs the incident radiation and a sensing circuit that detects the change in a physical property of the load (e.g. conductivity) as the temperature changes. These detectors have the advantage of operating over a very wide wavelength range but the response times of these detectors tends to be slow. In principle these devices do not require cooling to operate (cf photon detectors) although in practice some cooling is almost always employed in astronomical applications to improve the sensitivity. In spite of some difficulties these detectors can be extremely sensitive and were the mainstay of mid-infrared astronomy before the development of photon detectors and focal plane arrays.

Instruments

While instruments for use at mid-infrared wavelengths are varied they all have some common aspects. Most mid-infrared instruments cool the detector to temperatures

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

between 4 and 20 K. In addition, however, most instruments also cool their complete optical assembly to reduce background emission from the optics themselves. This is taken to the extreme for space- and airborne instruments where the telescope itself is also cooled. Traditionally these instruments were cooled with liquid nitrogen (77 K) and liquid helium (4.2 K). Lately, however, two-stage closed-cycle coolers have become more readily available and for many applications have become the cooling system of choice.

Mid-infrared instruments also use reflective optics in preference to refractive optics wherever possible. This is because reflective optics are achromatic and have high reflectivities compared with the transmission of refractive optics. This is not to say that refractive optics are never used, but reflective are preferable.

In the past mid-infrared instruments have usually been single-purpose instruments for imaging (see INFRARED IMAGERS), low-resolution spectroscopy, high-resolution spectroscopy or polarimetry. As the large observatories have begun to provide facility mid-infrared instruments, however, very sophisticated multifunction instruments have been developed. The most ambitious of these programs are probably the VISIR instrument for the European Southern Observatory, Very large Telescope (ESO VLT 8 m) and Michelle for the United Kingdom Infrared Telescope (UKIRT 4 m) which will later be used on the Gemini 8 m North telescope. Each of these instruments combines broad- and narrow-band imaging with low-, medium- and high-resolution echelle spectroscopy. In each case these instruments also provide polarimetry capabilities.

Space-based and airborne mid-infrared instruments

Ground-based infrared astronomy is severely limited by the background emission produced by the atmosphere. These problems can be completely circumvented by placing the telescope and instrument in Earth orbit. If the telescope itself is cooled, then the sensitivity of the system is limited only by the size of the telescope that can be launched into orbit and the natural scene background. For space-based instruments the sensitivity limit is generally provided by the emission from small interplanetary dust grains heated by the Sun in our own solar system. To achieve the ultimate in sensitivity one needs to place a mid-infrared instrument beyond the orbit of Jupiter where the emission from interplanetary dust grains becomes negligible. Without the limitation of the atmosphere, mid-infrared instruments in space are not restricted to the atmospheric bands as are instruments on the ground, and whole new regions of the spectrum become available for study.

Major contributions to the progress of mid-infrared astronomy were made by the INFRARED ASTRONOMY SATELLITE (IRAS) launched in 1983 and the Infrared Space Observatory (ISO) launched in 1995. IRAS performed an all-sky survey at mid–far-infrared wavelengths while ISO acted as a space observatory facility providing imaging and spectroscopic capability from around 2.5 μm to 240 μm. The next major space facility will be the SPACE INFRARED TELESCOPE FACILITY (SIRTF), currently scheduled for launch in 2001. The Next Generation Space Telescope (NGST) scheduled for launch in 2007 may also carry some mid-infrared instruments (see SPACE INSTRUMENTATION: NEXT GENERATION SPACE TELESCOPE).

One problem for space-based mid-infrared astronomy is that the need to cool instruments (using liquid cryogens) means that mission lifetimes tend to be limited to between 1 and 2 yr depending on the amount of cryogen carried. The limited launch weight, size and cooling requirements limit the aperture size of the infrared telescope (IRAS and ISO both used 60 cm class telescopes). The smaller telescope limits light-gathering power, but in addition the diffraction limit of such telescopes is large (3–4 arcsec at 10 μm and 35 arcsec at 100 μm). This means that the spatial resolution that can be achieved with such instruments is comparatively low. So space-based and ground-based instruments will always be complementary: space-based observations provide access to the full spectrum, without the troublesome effects of the atmosphere, whereas ground-based instruments provide spatial resolution and sometimes sensitivity owing to their large apertures, but in their limited operating regions.

As a compromise between ground- and space-based mid-infrared astronomy, there is the option to place the infrared telescope at high altitude. This can be done by balloon (up to 100 000 ft) or aircraft which reach up to 40 000 ft. At these altitudes the environment is much like that for space instruments, but at a lower cost and with more versatility. Although balloon-borne instruments were common in the early days of IR astronomy, the cost, short flight duration and high risk of such ventures has seen a decline in their use in favour of aircraft. The NASA Kuiper Airborne Observatory (KAO) was a 90 cm cryogenically cooled telescope mounted in a Lockheed C141 Starlifter. It operated very successfully with a variety of mid- and far-infrared instruments until 1995 when the aircraft was decommissioned. The KAO is soon to be replaced by the Stratospheric Observatory for Infrared Astronomy (SOFIA), which will carry a 2.5 m telescope aboard a Boeing 747 jet.

Milankovitch, [Milankovič] Milutin (1879–1958)

Yugoslav mathematician and astronomer who, starting in 1912, showed how the radiation received by the Earth varies cyclically as the Earth's orbit varies. There are three significant *Milankovitch cycles*: the eccentricity of the Earth's orbit varies from more elliptical to more circular with a period of the order of 100 000 years; the obliquity of the Earth's axis oscillates between two extremes with a period of 41 000 years; and the spin axis precesses with a 23 000 year cycle. Palaeoclimatic oscillations with these periods have been discovered in data from deep sea cores dating back 6 million years, which measured global ice volume (indicated by oxygen isotopes in fossil organisms) and fluctuating productivity in surface waters (indicated by calcium carbonate sedimentation), and which thus correlate with the Ice Ages. Although Milankovitch cycles are named after Milankovitch, his ideas were pre-dated by Joseph Adhemar (1842) and James Croll (1875).

Milky Way Galaxy

The galaxy (i.e. assemblage of stars, gas and dust) of which the Sun is a member. Also known as the Galaxy, it is a disk-shaped system, with a diameter of between 80 000 and 100 000 light-years and a thickness of about 2000 light-years, that contains more than a hundred billion (10^{11}) stars. The core, or nucleus, of the Galaxy is surrounded by an ellipsoidal central bulge, containing relatively closely spaced stars, that measures some 15 000 light-years in diameter and about 6000 light-years in the direction perpendicular to the plane of the disk. Surrounding the bulge and extending in a near spherical distribution above and below the galactic plane (the plane of the disk) is the galactic halo. The halo contains about 200 globular clusters (near-spherical clusters that contain between 10 000 and 1 000 000 stars) and an extremely thinly scattered population of individual stars.

The Sun is located just over half way out from the center to the edge of the disk, estimates of its distance from the center ranging from about 22 000 to about 29 000 light-years, with 25 000 light-years being a reasonable working value. In common with other stars, the Sun revolves round the galactic center. The orbital velocity of the Sun is about 220 km s^{-1} and its orbital period is about 225 million years. Overall, the Galaxy exhibits differential rotation, stars and gas clouds closer to the center having shorter orbital periods than those that are located further out.

Stars in the Galaxy are divided into two principal categories, or populations, Population II stars being old stars that formed early in the history of the Galaxy and population I stars being second, or later, generation stars that formed from gas clouds that had been seeded with heavier elements generated in, and expelled from, earlier generations of stars. The halo is composed of Population II objects and the disk, where clouds of gas and dust are concentrated and where ongoing star formation is taking place, is dominated by Population I objects. The central bulge contains both populations but its light output is dominated by radiation from old red giants.

Clouds of dust in the galactic plane absorb starlight and prevent optical astronomers from seeing the galactic center, but infrared and radio wavelengths are largely unaffected. Near-infrared observations have shown that the stars in the central bulge are arranged in an elongated bar, about twice as long as it is wide, that is seen nearly end on from the present location of the solar system. The exact center, or nucleus, of the Galaxy coincides with a strong source of radio emission, called Sagittarius A*, that is less than 15 astronomical units in diameter (i.e. is smaller than the diameter of the orbit of Saturn). Observations of the speeds at which clouds of ionized gas are revolving round the galactic center imply that several million solar masses of material are concentrated within a region of about one light-year in radius. Since only about half of this mass can be accounted for by stars, it seems likely that the balance (about 2.5 million solar masses) is contained in a central black hole and that accretion onto this black hole is the underlying source of the energy radiated by Sagittarius A*.

In 2001, NASA's Chandra X-ray Observatory, detected a sudden x-ray flare while observing Sgr A*. In a few minutes, the source brightened dramatically, eventually reaching a level 45 times brighter than before the flare. After about three hours, the x-ray intensity rapidly declined to the pre-flare level. The rapid rise and fall of the x-rays from this outburst are compelling evidence that the x-ray emission is coming from matter falling into a supermassive black hole. Given the extremely accurate position, it is highly unlikely that the flare is due to an unrelated contaminating source such as an x-ray binary system.

Like many other galaxies, the Milky Way Galaxy has a spiral structure. Within its disk, bright young stars, nebulae, and clouds of gas and dust are concentrated into curved 'arms' that appear to radiate from the central bulge in a spiral pattern. The Galaxy's spiral pattern consists of several major arms and a number of shorter segments, one of which—the Orion arm, or 'spur'—contains the Sun and the Orion star-forming region.

The Milky Way Galaxy derives its name from the Milky Way, a misty band of starlight that stretches across the sky and which may be seen with the unaided eye on a clear dark night. The Milky Way represents the combined light of millions upon millions of stars concentrated close to the galactic plane.

Millimeter and Submillimeter Astronomy

The millimeter wavelength band extends from $\lambda = 4$ mm ($\nu = 75$ GHz) to 1 mm (300 GHz) while the submillimeter band extends from 1 mm to 100 μm (3 THz). The sub-mm band is rather unexplored because of the need to construct large efficient telescopes and sensitive detectors. It is equally important to select excellent sites to reduce the pervasive absorption by the Earth's atmosphere. To a lesser degree, these challenges also affect mm astronomy. Usually the emission from astronomical objects in the mm and sub-mm wavelength range is small compared with that in the meter and centimeter wavelength ranges where intense non-thermal synchrotron emission is common or in the mid- and near-infrared or optical wavelength ranges, where thermal radiation from hot sources is found. Studies in the mm and sub-mm ranges cover a wide range of topics: (1) the physics and chemistry of the interstellar medium (ISM), especially the structure and content of INTERSTELLAR MOLECULAR CLOUDS, (2) star formation, (3) the interaction of stars with molecular clouds, especially during the very early and very late phases of stellar evolution, (4) the distribution of molecular clouds (and neutral carbon) in external galaxies and high-redshift objects and (5) studies of solar system objects. Investigations of the 2.73 K background are also important but specialized.

Spectral line radiation from molecular hydrogen is rare since H_2 has no permanent dipole moment. Thus, extraordinary excitation conditions are needed. The properties of molecular clouds are traced using abundant polar molecules such as carbon monoxide, CO. In the mm and sub-mm wavelength ranges, small linear molecules have rotational transitions, while atomic and ionized carbon have fine-structure lines. In addition to gas, clouds contain dust grains which contain much of the silicon and carbon. Dust grains emit broadband thermal emission which increases at shorter wavelengths where these grains radiate more efficiently. The surfaces of cold grains are covered with condensed atoms and molecules.

There is a sudden transition from neutral atomic hydrogen, H I to H_2 from competition between destruction by the interstellar radiation field and production on grain surfaces. The envelopes of molecular clouds consist of neutral hydrogen, H I, and ionized or neutral carbon, with molecules in cloud cores.

A short history

Observations started with broadband continuum measurements of emission from the Sun, planets and a few quasi-stellar objects. Molecular spectroscopy provided a great impetus for mm and sub-mm astronomy. Radio spectroscopy of molecules began with the detection of the OH radical at a wavelength of $\lambda = 18$ cm in 1963. These molecules were thought to exist in H I REGIONS. In 1968 the detection of ammonia, NH_3, and water vapor, both at 1.3 cm, was made with the Berkeley 6 m telescope. In 1969, formaldehyde, H_2CO, was discovered with the National Radio Astronomy Observatory's (NRAO's) 140 ft telescope at 6 cm. The structures of H_2CO and NH_3 are rather complex, and the abundances are rather small. The most widespread polar molecule, CO, was detected at 2.6 mm in 1970 with the NRAO's 36 ft telescope. After the discovery of CO, there was a rapid increase in the number of interstellar molecules, because radiation processes are more efficient at shorter wavelengths and because there are a larger number of spectral lines in the millimeter and submillimeter wavelength ranges. As of 1999, 120 molecules have been found in the ISM; the heaviest molecule is $HC_{11}N$.

Technical considerations

From diffraction theory, the angular resolution, θ, is

$$\theta = 1.2\lambda/D$$

where D is the telescope size and λ the wavelength. For a 10 m diameter telescope, at $\lambda = 3$ mm, $\theta = 80''$. Intensities are expressed in terms of temperatures, in the Rayleigh–Jeans limit:

$$T = \frac{\lambda^2 I_\nu}{2k} \tag{1}$$

where k is Boltzmann's constant. I_ν is the intensity at frequency ν in units of W Hz^{-1} m^{-2} sr^{-1} and T is the 'brightness temperature'. For thermal emission from planets, T is the surface temperature diluted by the ratio of source to beam size broadened by the source. In most cases, T is not related to a physical source temperature. In terms of I, the flux density is

$$S_\nu = \int I_\nu \, \mathrm{d}\Omega. \tag{2}$$

The solid-angle integration is usually over the beam; if the source size exceeds the telescope beam size, the integration is over the source. Combining equations (1) and (2), we have

$$S_\nu = \frac{2k}{c^2} T \nu^2 \, \Delta\Omega. \tag{3}$$

The power received is

$$P_\nu = \tfrac{1}{2} S_\nu A_{\mathrm{eff}} B \tag{4}$$

where A_{eff} is the effective area and B is the bandwidth.

Receivers

For $\lambda > 0.3$ mm, the most efficient receivers for spectral lines are heterodyne systems. In such coherent receivers, the signal is converted from the sky wavelength to a longer wavelength at which the signal is amplified. Such systems have a wavelength resolution, $\lambda/\Delta\lambda \gg 10^6$. In the 1960s, receiver noise temperatures, T_{rx}, were $\sim$5000 K at 3 mm; now, typical values are <100 K. The ultimate limit for noise in a coherent receiver is $h\nu/k$; practical limits are a few times larger. The first conversion is usually performed

in a mixer. The first mixers were uncooled Schottky devices. Since the 1980s, mixers have junctions which are quantum mechanical superconducting–insulating–superconducting (SIS) sandwiches. SIS mixers are much more sensitive and require less local oscillator power than classical Schottky devices; SIS mixers must be cooled to 4 K. All such receivers are tunable over a large wavelength range. The development of SIS RECEIVERS in the millimeter and sub-mm range has been led by the Caltech Sub-mm Observatory (CSO) and in the millimeter range by NRAO. Other active SIS development groups are at Harvard-Smithsonian Center for Astrophysics (CfA), IRAM and Köln University. From the physics of junction materials, there is a short-wavelength limit to the operation of SIS devices. For spectral line measurements at wavelengths at $\lambda < 0.3$ mm, a new device, the hot-electron bolometer, which has no such limit, has been developed. The first successful astronomical measurements with HEBs were carried out by the CfA group on the Heinrich Hertz 10 m Sub-mm Telescope (HHT) in 1998. At $\lambda > 3$ mm high electron mobility transistors are becoming standard, while, at $\lambda > 2.6$ mm, monolithic indium phosphide microwave transistor amplifiers are now being used on the 16-beam receiver array (SEQUOIA) installed on the University of Massachusetts 14 m telescope. Only SEQUOIA and the eight-beam SIS array installed on the NRAO 12 m telescope have thus far produced published results; all other millimeter heterodyne systems with competitive noise temperatures are single-beam devices.

Bolometers are incoherent receivers; these are preferred for single-dish measurements of broadband continuum radiation at $\lambda < 2$ mm. As with heterodyne receivers, the sensitivity of bolometers has improved greatly since the 1960s. Bolometer sensitivity is given as noise equivalent power (NEP) in W $Hz^{-1/2}$. For practical bolometer systems, background noise, including noise from warm telescope surfaces, the ground and atmosphere, is the limiting factor. A good value of NEP is 3×10^{-17} W $Hz^{-1/2}$. For $\lambda < 0.3$ mm, a combination of bolometer detectors and Fabry–Pérot filters can be effectively used for spectroscopy. In contrast to heterodyne systems, a number of bolometer array receivers are installed on telescopes. The largest is SCUBA, an 81-beam system on the James Clerk Maxwell 15 m Telescope (JCMT) in Hawaii.

The RMS receiver noise in kelvins is

$$\Delta T_{\rm RMS} = \frac{A T_{\rm sys}}{(Bt)^{1/2}} = \frac{A\,{\rm NEP}}{2kBt^{1/2}}. \qquad (5)$$

The constant A is a function of system and data-taking parameters (usually $A \sim 2$), B is the bandwidth in Hz and t is integration time in s. The value of B is limited to one-third of the linewidth for spectral line measurements. For continuum measurements, B can be much larger. The value used for $T_{\rm sys}$ is corrected for absorption of the signal in the Earth's atmosphere and the emission from the Earth's atmosphere and telescope losses. Depending on weather, the value of $T_{\rm sys}$ can exceed the receiver noise temperature, $T_{\rm rx}$, by large factors.

Telescopes

For a RADIO TELESCOPE to be effective, the surface accuracy must be <0.1 of the shortest wavelength measured. Larger radio telescopes have surfaces consisting of individual panels which must be adjusted. The limit to the effective operation of all single telescopes is set by surface deformations and pointing errors. Some of the mm telescopes, with diameters of 14 m and one with 20 m, were built in radomes. The two largest millimeter telescopes, the 30 m, operated by IRAM, and the 45 m in Nobeyama, Japan, are in the open, as will be the 50 m 'Large Millimeter Telescope' (LMT) being constructed near Mexico City. The LMT is designed to be the most advanced single-dish design, useful up to 345 GHz. The construction of open-air telescopes is in part economic; enclosures could cost as much as the telescope itself. The most important improvement in the design of large single dishes has been homology, a scheme in which a paraboloid freely deforms but the shape is maintained. The remaining systematic effects are the influence of wind and temperature gradients in the structure which give rise to differential thermal expansion in the structure. The first radio large telescopes built with high accuracy surfaces of low-expansion material, carbon-fiber-reinforced plastic, were the IRAM 15 m interferometer antennas on Plateauations Bure, I Telescope (SEST) telescope, at La Silla, Chile, and the HHT. The surface accuracy of the HHT shows that RMS surface accuracies of 12 μm are possible. The 10.4 m diameter telescope of the CSO and the 15 m JCMT are sub-mm telescopes on Mauma Kea, Hawaii, an excellent site. The CSO and JCMT were put into operation in the late 1980s and have produced a great deal of science. Both are constructed of aluminum and are housed in astronomical dome-like shelters.

Sub-mm measurements are also made from aircraft. The Kuiper Airborne Observatory provided such an opportunity with a 91 cm diameter paraboloid. The follow-up facility, SOFIA, will have a 2.5 m diameter mirror. At normal flight altitude, 14 km, the water vapor content is extremely low. Thus, SOFIA can be used for measurements at wavelengths at which the atmosphere is opaque from ground-based sites. The Sub-mm Wavelength Astronomy Satellite has detected emission from the ground-state transition of H

$_2$O, at 0.55 mm, but has not detected emission from O_2. In the future are the Far-Infra-Red-Satellite-Telescope and Satellite-Infra-Red-Telescope-Facility.

Single telescopes have a fixed relation of $A_{\rm eff}$ and θ whereas interferometer systems do not (see equations (1)–(4)). Present interferometer systems consist of $n < 11$ elements, each of a moderate diameter. INTERFEROMETERS consist of a number of parabolic antennas, each equipped with one or more coherent receivers. The receiver outputs are combined to produce a response corresponding to the maximum angular resolution determined by the ratio of the wavelength to the largest separation of the elements, projected in the source direction. Emission

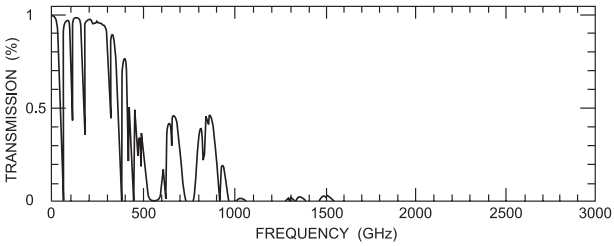

Figure 1. A plot of the transmission through the Earth's atmosphere for the mm and sub-mm wavelength ranges, for a column density of atmospheric water vapor of 1 mm. For an atmospheric optical depth τ, the transmission is $e^{-\tau}$. (Adapted from Phillips and Keene (1992).)

from structures with angular sizes larger than the angle corresponding to the closest separation of the antennas is not recorded. This is the 'smooth structure' in a source. Such information can be recovered by combining the interferometer output with data taken using a large single telescope. Interferometers provide higher angular resolutions and positional accuracies than single-dish telescopes. For a fixed collecting area bandwidth, and ν, the temperature (but not the flux density) uncertainty of an interferometer is worse than that for a single telescope with the same angular resolution. The first mm-wave interferometer, at the Berkeley Radio Astronomy Laboratory, consisted of two 6 m antennas. In the mm range, there are four systems: The Berkeley–Illinois–Maryland association (BIMA) array near Hat Creek, CA, the Caltech Owens Valley Interferometer (OVRO) near Bishop, CA, the Nobeyama Array in Japan and the IRAM array on Plateau de Bure, France. A number of high dynamic range, high-sensitivity images have been produced by the BIMA, OVRO and IRAM arrays. In addition, the 10 m CSO and 15 m JCMT telescopes are occasionally used as a sub-mm interferometer. To obtain even higher angular resolutions, experiments have been carried out using the technique of very long baseline interferometry at 3 mm and 1.3 mm. Finally, a dedicated sub-mm array consisting of eight 6 m dishes has been under construction by the Smithsonian Astrophysical Observatory and the Academica Sinica Institute for Astronomy and Astrophysics, Taiwan, on Mauna Kea, Hawaii. The sensitivity and imaging quality of interferometer systems can be improved by an array with many large antennas on an excellent site. This is the rationale of the Atacama Large Millimeter Array (ALMA) project, to be built in Chile at 5 km elevation, by NRAO and ESO. ALMA is planned to have $n > 60$ elements and a total $A_{\rm eff} > 10^4$ m^2. The results to be obtained with ALMA may revolutionize all of astronomy.

Atmospheric effects

Millimeter and especially sub-mm observing sites are selected to minimize the effect of weather on the observations. Signals are absorbed by O_2 and H_2O vapor. The scale height of H_2O vapor is $\sim$2 km, while that of O_2 is $\sim$8 km, so the influence of H_2O should be reduced at high altitudes. See figure 1 for a plot of transmissions. At 860 GHz ($\lambda = 0.35$ mm), even the very best sites on Earth are useful only a small percentage of the time.

Observing techniques

Because the signal levels are small compared with atmospheric or receiver noise, all measurements must be made by taking the difference of two signals. For spectral line measurements, one uses compared data taken at two different positions or frequencies; for continuum measurements there is a rapid switching by movements of the telescope subreflector or by wobbling a flat mirror. The time intervals are determined by instabilities in the receiver and atmosphere. A technique of slow scanning of the telescope is the normal data-taking mode for continuum measurements. For spectral line measurements this has been called 'on-the-fly' mapping. The data are taken rapidly, before weather or telescope characteristics can change. This greatly increases the reliability of spectral line images and efficiency of data taking.

'Chopper wheel' calibrations are the norm for spectral line measurements. In the simplest version of this method, measurements are made of a room-temperature absorber and the atmosphere; with models, these allow an estimate of the atmospheric emission and hence the absorption. A more complete characterization of the atmosphere requires a 'tipping curve', which involves measurements at a number of elevations. The data are corrected for the absorption and usually for telescope efficiencies to give intensities (usually in the form of temperatures) for a perfect telescope outside the atmosphere. Additional calibration steps involve measurements of sources of known intensity, then scaling the data taken. For interferometry, the measurements of a source and known source or 'calibrator' are interspersed in time. It is assumed that the system performance varies smoothly between calibrations and the corrections obtained are applied to the source measurements.

Astronomical considerations

Spectral lines

In figure 2 we show the energy level diagrams for CO, neutral carbon, C I, and ionized carbon, C II; the energy, E, above the ground state is in kelvins, from $E = kT$. Allowed dipole transitions occur with a unit change in the angular momentum quantum number $\Delta J = \pm 1$. For the CO molecule low-J transitions are frequently thermalized, so the kinetic temperature, $T_{\rm k}$, characterizes the populations. Measurements of CO allow good estimates of the column density of H_2, since CO can be excited at low H_2 densities, since the excitation is close to local thermodynamic equilibrium (LTE) and since there is a large abundance relative to H_2.

If the radiation arises from an isothermal layer much larger than the telescope beam, one can obtain a fairly realistic estimate of kinetic temperatures and

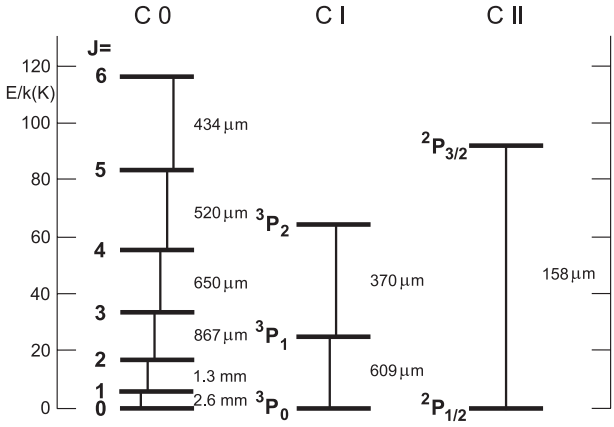

Figure 2. The first few rotational energy levels of selected species. In the ISM, carbon monoxide, CO, is the most abundant molecule with a permanent dipole moment. Also shown are fine-structure transitions of neutral carbon, C I, and ionized carbon, C II.

CO column densities using an LTE analysis. Rotational lines of $^{12}C^{16}O$ are usually optically thick; then peak line temperature T equals T_k, the kinetic temperature. To obtain column densities without models of molecular clouds, one must use rarer, stable isotopes of CO. In LTE, the total population, N, can be obtained from the (optically thin) $J = 1$–0 line of $^{13}C^{16}O$:

$$N(\text{total})^{^{13}\text{CO}} = 2.6 \times 10^{14} \frac{T \int \tau^{13}(v)\, \mathrm{d}v}{1 - \exp(-5.3/T)} \qquad (6)$$

where the column density $N(\text{total})^{^{13}\text{CO}}$ is in cm^{-2}, the linewidth v in km s^{-1} and T in K. If the line optical depth, $\tau^{13} \ll 1$, $T\tau^{13} = T_L^{13}$. If $\tau^{13} \gg 1$, we must use the line of $C^{18}O$; the expression is very nearly the same. Such estimates are usually realistic for cooler clouds ($T_k < 20$ K). To obtain the column density of H_2, one assumes an isotopic ratio and that the CO-to-H_2 ratio is 10^{-4}; the latter value is usually reasonable.

In addition to estimates of column densities, one can estimate local H_2 densities, $n(H_2)$, from the ratio of column density to cloud size to obtain the local density. This leads to a lower limit for $n(H_2)$ since clouds have small-scale structure or 'clumping'. If energy levels are populated by collisions with H_2 molecules, the density needed to balance decay out of a level is n^*. Setting the collision rate equal to the decay rate, we have $n^*\sigma\bar{v} = A$. If the optical depth of the line is $\tau \gg 1$, the analysis becomes more complex. In the Sobolev or large velocity gradient (LVG) approximation, one assumes that the molecular cloud has a velocity gradient $V \sim r$. In the LVG model, the value of the A coefficient is replaced by A/τ. For a multiline analysis of a species, including the fall-off above and below the maximum intensity, one can solve for both T_k and H_2 density (see figure 3).

From LVG calculations applied to optically thin transitions of carbon monoxide, there is a simple relation between total column density and the $J = 2$–1 line, which is valid for a wide range of kinetic temperatures and H_2 densities. Large-scale surveys of ^{13}CO and CO $J = 1 \rightarrow 0$ lines in the disk of our Galaxy show that line shapes and intensity ratios along lines of sight are remarkably similar. Since ^{13}CO lines are optically thin, the CO integrated line intensities must measure mass, even though $\tau^{12} \gg 1$. This can be explained if clouds are in virial equilibrium and consist of a large number of small subthermally excited clumps. An exact relation between the integrated intensity of the $J = 1 \rightarrow 0$ line and column density of H_2 has been determined empirically for the disk. This approach has been often used for molecular mass determinations in external galaxies. However, there are exceptions to this relation: the conversion factor for the galactic center is 1/7 of the factor used for the disk, and the conversion factor appears to differ from galaxy to galaxy.

Dust emission

Another method to determine H_2 column densities is to use broadband dust emission. The dust intensities rise rapidly with frequency, and measurements made with large bandwidths lead to very small values of ΔT_{RMS} (see equation (5)). One drawback to continuum measurements is line-of-sight confusion, since there is no velocity information. The quantitative relation between τ_{dust} and $N(H_2)$ is calibrated by the measurement of emission and extinction toward NGC 7023. The optical extinction has been converted into a column density of hydrogen using the standard gas-to-dust relation (see Mathis 1990). If $h\nu \ll kT$,

$$N(\text{H}) = 1.93 \times 10^{15} \frac{S_\nu}{\theta^2} \frac{\lambda^4}{(Z/Z_\odot) b T_{\text{dust}}}. \qquad (7)$$

S_ν is in Jy, source FWHP size, θ, in arcseconds and λ in μm. $N(\text{H})$ is the column density of hydrogen in all forms, in cm^{-2}. The value of metallicity is Z (for the Sun, $Z_\odot$). The factor b accounts for changes in grain sizes. For moderate densities, $b = 1.9$; for very dense gas, $b = 3.4$, but a wider range is likely. If the uncertainties in equation (7) can be reduced, dust measurements could rival molecular line determinations of mass estimates. Images of dust emission show more structure than images of spectral lines; the explanation for this is not clear, thus far.

A summary of scientific results

It is estimated that there are ~5000 giant molecular clouds in our galaxy. These each have masses of $\sim 10^6 M_\odot$; these are probably cloud complexes with, on average, $n(H_2) \approx 10^2$ cm^{-3} and $T_k \approx 20$ K. Dark dust clouds have larger densities and $T_k = 10$ K. Clouds are assumed to be gravitationally stable and may have a fractal structure. For the Galactic disk inside the solar circle, the masses in H I and H_2 are about equal. Outside the solar circle, the mass of H I is ~6 times that of H_2.

In most clouds, $\Delta v_{1/2}$, the FWHP linewidths, are found to be supersonic. There are some exceptions,

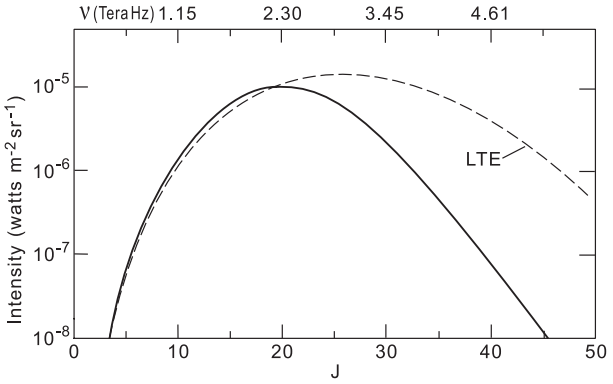

Figure 3. A plot of CO line intensities for the Orion KL source. The dashed curve is a plot of populations for LTE, while the solid curve is an LVG calculation for $T_k = 750$ K, $N(H_2) = 2.8 \times 10^{21}$ cm^{-2}, $n(H_2) = 2.7 \times 10^6$ cm^{-3}. The difference in the curves is caused by the faster decays from higher J levels. With measurements at frequencies above and below the maximum, one can determine both $n(H_2)$ and T_k (Watson *et al* 1985 *Astrophys. J.* **298** 316).

such as the denser cores of dark clouds. Large-scale organized motions, such as rotation, or large-scale collapse are ruled out from observations. It is unlikely that magnetohydrodynamic waves cause most of the line broadening. The linewidths could be caused by outflows from embedded objects, such as young stars, or by the conversion of large-scale motions such as galactic rotation into smaller-scale turbulence. These motions cause shock waves which give rise to broader lines. Theoretical studies show that there are two types of shocks: 'J' or jump shocks and 'C' or continuous shocks. J-shocks locally heat the gas and this leads to the dissociation of molecules. This will change the chemistry of the cloud greatly. C-shocks are cushioned by larger magnetic fields and cause less dissociation. Sub-mm line ratios provide a diagnostic which allows one to differentiate between these types of shocks. For J-shocks, there is a large amount of emission from ions. For C-shocks, the emission is primarily molecular and neutral carbon, but little ionic emission. For a complete understanding, studies of CO, C I and C II are needed (energy level diagrams in figure 2).

The most well-studied Galactic sources are as follows: (1) IRC+10216, a circumstellar envelope of the red giant star CW Leo, ∼150 pc from the Sun; (2) the Orion KL region, at 500 pc, 45″ NW of the Trapezium cluster of stars which ionize the Orion H II region, with FWHP 10″, $T_{kin} = 165$ K and $n(H_2) = 10^7$ cm^{-3}; (3) the dark cloud center TMC-1 in Taurus, with $T_{kin} = 10$ K and $n(H_2) \sim 10^4$ cm^{-3} at 160 pc; (4) Sgr B2, a complex of dense H_2 clouds and H II regions at 8.2 kpc, near the center of our Galaxy; (5) Sgr A, the galactic center itself. In addition, there are a number of well-studied external galaxies. The group is inhomogeneous for a number of observational reasons; the objects are Arp 220, IC342, M82, M51 and NGC 253. In the mm range, all of these were first mapped to a resolution of ∼12″ in a number of lines with single dishes. Later the brighter lines were imaged with interferometers down to resolutions of ∼2″. References to data are given in the bibliography. See especially references in the *Protostars and Planets* series.

INTERSTELLAR CHEMISTRY involves non-equilibrium, non-terrestrial processes. At typical densities, neutral–neutral gas-phase reactions are too slow to form complex molecules in $\sim 10^6$ yr. Rather, the formation involves ion–molecule chemistry. Hydrogen and helium ions are produced by cosmic rays. The H^+ forms H_3^+ or charge exchanges with C or O atoms. The reaction rates for ion–molecule reactions are $>10^3$ times faster than neutral reactions. This explains the abundance of molecules such as CO or OH in dark clouds. Ion–molecule reactions also play a large role in the formation of molecules in the envelopes of low-mass stars in the red giant phase. As a rule of thumb, hydrogen-poor molecules with unsaturated bonds are gas-phase, ion–molecule products, while molecules with saturated bonds are thought to be produced on grains and released into the ISM.

Important goals of mm and sub-mm astronomy are to determine collapse criteria for molecular clouds and to search for individual collapse objects. Stars must form from molecular clouds, because of the close spatial and physical associations. Models for collapse begin with sizes of 10^{16} cm, continuing to pre-planetary disk sizes 10^{14} cm around the resulting star. At present, mm and sub-mm instrumentation limits us to nearby objects which could be imaged on scales $<10^{16}$ cm. After many searches, a number of candidate objects have been found. These are mostly in dark dust clouds where low-mass stars are expected to form. The collapse signature is based on a model where the cloud center has higher temperature and density and where the collapse motions exceed the thermal motions. The measurements of optically thick lines, such as carbon monosulfide, $^{12}C^{32}S$, will show a narrow absorption feature (from gas in the outer part of region). This locates the center of the emission profile. If the cloud is collapsing, the blueshifted portion of this profile has a larger intensity than the redshifted portion, since the radiation from hotter blueshifted gas passes through the redshifted gas without being absorbed. The redshifted radiation from equally hot gas is absorbed by cooler gas at nearly the same velocity. Thus the blue wing arises closer to the warmer gas. If the cloud is expanding, the redshifted portion is more intense. A measurement of the rarer isotope $^{13}C^{32}S$ must show no narrow absorption feature or asymmetry.

An important aspect of molecular cloud physics involves cooling. There are theoretical models, but these are complex even in idealized cases. Surveys of mm and sub-mm spectral line data allow direct tests of the cooling processes by mapping the intensities of the lines of CO, which dominates cooling at lower densities, and H_2O, which should dominate at higher densities. At the highest densities, one expects that hydrides will provide most of the cooling. Measurements of the CO lines from $J = 1$

to 20, H_2O transitions and lines from the more abundant hydrides are needed to experimentally determine the heat flow from clouds.

Fundamental to the STAR-FORMATION process is the outflow phase. This occurs shortly after the core of the star forms. Excess material is expelled in the form of a bipolar high-velocity stream of material which is mainly molecular. Such outflowing material has been traced in mm wavelength lines of CO and other molecules. The central object in this phase is a YOUNG STELLAR OBJECT (YSO). Surrounding the YSO is usually a dense disk of material, perpendicular to the direction of the bipolar outflow; outflows may be driven by magnetic forces.

A completely different type of outflow occurs at the end of the main sequence life of stars of roughly a few solar masses. These asymptotic giant branch stars or red giants are referred to as mass loss stars. Many have been traced in CO lines. The outflow velocities are $\sim$30 km s^{-1}. The mass loss mechanism is thought to be radiation pressure on dust grains, which drags the gas. The moderate velocity flows are sometimes accompanied by flows with velocities larger than 100 km s^{-1}. This material should be hotter and may be atomic rather than molecular. If so, atomic lines of carbon or oxygen might supplement the information based on CO or shock tracers such as SiO to trace these flows.

In PHOTODISSOCIATION REGIONS, the molecules are close to a source of ultraviolet radiation which alters the chemistry and heat balance. The most obvious change is that C II and C I become much more abundant. The layer containing C I may extend to a depth which is a significant fraction of the width of the PDR. The most well known PDR is the 'Orion bar', to the SE of the Orion H II region.

Sub-mm spectroscopy of galaxies is likely to reveal warmer regions of exceptional star-forming or shock activity. Since most galaxies are compact, high angular resolution is needed. Some have moderately intense lines, so can be imaged with interferometers. For most, the emission is usually weak, so lower-resolution data are taken with single telescopes, so far. The most studied galaxy in the mm and sub-mm is Messier 82. It has long since been established that M82 has warm molecular gas; there are HHT maps over a few arcminutes in the $J = 7$–6 line of CO which arises from an energy level 156 K above ground. Thus, there must be very widespread emission from warm molecular gas; details of the heating processes are not fully understood. Another interesting object is the galaxy Centaurus A (see NGC 5128/CENTAURUS A). The nucleus is an intense continuum emitter even in the sub-mm wavelength range, so that species such as hydrides might be detected in absorption. Another fruitful case study is the face-on spiral IC342, thought to be an analog of our Milky Way. Studies will allow a comparison of global properties of these sources. At redshifts >4, CO lines have been detected in the mm wavelength range. In the future, the detection of redshifted lines of molecules, C II and O I would extend chemistry studies to the early universe. See the results summarized by Combes and Wiklind (1998).

Mills, Bernard Yarnton (1920–)

Australian engineer and astronomer, born near Sydney, and worked with the Australian CSIR Division of Radiophysics. He measured the position of Cygnus A and identified a faint nebulosity as its origin, confirmed by a more accurate position by F. G. Smith and 200 in photographs by W BAADE and R MINKOWSKI showing Cygnus A as a peculiar galaxy. Mills built a cross-type radio interferometer at the Fleurs Field Station: the two arrays in the N–S and E–W arms produced intersecting fan beams which were switched in and out of phase and made a narrow pencil beam at their intersection which could position radio sources accurately. He constructed the *Mills cross* (1954) which operated at 85 MHz and had 1500 foot arms, with which he mapped the Magellanic clouds and conducted source surveys. Mills led the group that constructed the Molonglo Cross, an instrument with one mile arms operating at 408 MHz, built in 1967 and converted in 1981 to a synthesis telescope. Mills discovered the Vela pulsar at the center of the Vela supernova remnant.

Milne, Edward Arthur (1896–1950)

Astrophysicist, born in Hull, Yorkshire, England, became Rouse Ball Professor at Oxford. Milne's theoretical work on stellar atmospheres led to the determination of the temperatures of stars of the different spectral classes and the calculation of limb darkening (the decrease of brightness across the face of a star from center to edge). Milne also showed how molecules escape from stellar and planetary atmospheres. He developed a new form of relativity called kinematic relativity, based on attractive general philosphical ideas. He also suggested that the 'constants' of physics (such as G) changed over the life of the universe. Neither of these propositions is accepted.

Mimas

The innermost of Saturn's mid-sized icy satellites, discovered in 1789 by William Herschel. It orbits the planet at a distance of 186 000 km, within the tenuous E ring and near its inner boundary. Mimas is a heavily cratered world, with many craters overlapping. With one exception they are less than 30 km across. The exception is Herschel (named to honor the satellite's discoverer), whose diameter of 130 km is nearly a third of the satellite's diameter, 400 km. Like other mid-sized satellites of Saturn, Mimas may have been destroyed and reassembled itself in the era of heavy bombardment 4 billion years ago. Its density of 1200 kg m^{-3} indicates that its composition is largely of water ice. Mimas's proximity to Saturn's ring system gives it a controlling influence: it keeps the Cassini Division clear, for example, and is responsible for 'corrugations' in the A ring.

Mineur, Henri (1899–1954)

Born in Lille, France, worked at the Paris Observatory, discovered the retrograde rotation of the system of globular clusters around the Galaxy, due to the fact that they are stationary while the Sun moves prograde. Discovered the error in the period–luminosity law for Cepheid variable stars, on which the cosmological distance scale is based. Mineur founded and was the first director of the Institute d'Astrophysique in Paris.

Minkowski, Hermann (1864–1909)

Born in Alexotas, Russian Empire (now Kaunas, Lithuania), became professor at the University of Göttingen, worked on the mathematics of the theory of relativity. Using tensor calculus he cast the work of LORENTZ and EINSTEIN into the form of a four-dimensional non-Euclidean space, now known as *Minkowski space*. This 'space-time continuum' provided the framework on which Einstein developed the general theory of relativity.

Minkowski, Rudolph Leo Bernhard (1895–1976)

Born in Strassburg, Germany, worked on atomic spectroscopy at Hamburg and had to flee the Nazi persecution, joined WALTER BAADE on the Mount Wilson Observatory staff, where he began to apply spectroscopy to astronomy. He investigated nebulae, including supernova remnants, especially the Crab nebula. He classified supernovae into Types I and II, leading to their identification as two similar implosions in different kinds of stars. He headed the National Geographic Society-Palomar Observatory Sky Survey (POSS) which photographed the entire northern sky with the Palomar 48 in Schmidt Telescope. With Walter Baade he optically identified many of the early radio sources, including Cygnus A. In 1960, on his very last observing night with the 200 in Palomar Telescope, he found a galaxy (3C 295) with the then highest redshift, a record which stood for 15 years. After he made the discovery, the night was declared overcast and the occasion toasted in whisky. He discovered Comet 1950b and a small, faint, provocatively shaped nebula is named *Minkowski's footprint*.

Mira

The star o Ceti, a red giant, is believed to have been the first variable star ever discovered. It is the type-star of the most common class of long-period pulsating variables, which are usually described as Mira-type stars. Its variability was first recorded by the German theologian David Fabricius (1564–1617) in 1596, and was first studied in detail about 40 years later. It is visible to the unaided eye for only about four months around each maximum, and is a telescopic object for the next seven months—hence Fabricius initially believing it to be a nova. This was of course before the invention of the telescope, so Mira was a star which was then invisible for some two-thirds of the time. It was for many years the only known case of a star varying in brightness. This behavior gave rise to the name Mira ('Wonderful'), which is attributed to Johann Hevelius (1611–87). Despite its long absences it was recorded by Johann Bayer (1572–1625), who showed it as a fourth-magnitude star in his *Uranometria* star atlas of 1603.

Mira's period is variable, but averages 331.96 days (about 11 months). The rise from minimum to maximum is significantly faster than the fall, usually taking about 110 days. There is some evidence from speckle interferometry that Mira is subject to sudden large variations in diameter at particular wavelengths. The spectral type varies during the light-cycle, between M5e and M9e. Its apparent magnitude at maximum is typically 3.0, but can be anywhere in the range 2.0–5.0; minima usually lie between 8.5 and 9.5, but can be as low as 10.1. The star has a parallax of 0.008″, and is at a distance of about 420 light-years. Its absolute magnitude is difficult to calculate with any precision, but is probably about 1.0.

Mira has a close binary companion, the white dwarf VZ Ceti, which is believed to accrete material from Mira's stellar wind. The existence of this faint (thirteenth-magnitude) companion was predicted in 1920 by J H Joy (1882–1973) of the Mount Wilson Observatory, from periodic variations in Mira's spectrum. VZ Ceti is visible only at times when Mira itself is very faint; it was first detected optically with the 36 inch refractor at the Lick Observatory in 1923 by the great double-star observer R G Aitken (1864–1951); the separation was then about 0.9″.

Mira is probably the most thoroughly observed of all variable stars; every maximum since 1638 has been recorded. More than 4000 Mira-type variables are now known.

Mira Variables

Mira variables are cool, giant, pulsating stars with periods in the range ∼100 to ∼500 days. The range extends to ∼2000 days if we include OH/IR variables which are generally too faint (due to their low temperatures and to dust shell obscuration) to be readily detected at optical wavelengths and have been mainly found either from their OH-maser emission at radio wavelengths or in the infrared where they are bright. One reason for the importance of Miras in modern astrophysics is that they are low-mass stars in the last, and most luminous, phase of their evolution, before they eject their outer layers as planetary nebula shells (see also STELLAR EVOLUTION). Miras are also important as standard candles for estimating distances within our Galaxy (e.g. the distance from the Sun to center of the Galaxy) and also the distances to nearby galaxies (e.g. the Magellanic Clouds). Matter is being lost from the surfaces of Miras into space in a way that is not yet fully understood. Nor do we precisely understand how the solid grains present in this outflow are formed.

o Ceti, known as 'Mira' (the wonderful), was the first star to have been recorded as variable other than novae or supernovae. It was first noted by David FABRICIUS in 1596, though the fact that it varies in light with a period of about 332 days was not known until the mid-seventeenth century. Its period and light range are typical of this type of star. In the mean it varies from a visual magnitude of 3.4 at maximum, to 9.3 at minimum but the light curve does not repeat exactly from cycle to cycle and it can at times rise to a magnitude of 2.0 and decline as faint as 10.1 mag.

Red (i.e. cool) giant and supergiant variables constitute a large and rather heterogeneous group of objects. The Mira class is restricted to cool stars (surface temperatures lower than ∼3500 to 3000 K) with well defined periods and with visual light ranges of 2.5 mag or more (light ranges of 6 mag or more, as in o Cet itself, are common). Whilst the minimum light amplitude for membership of this class is rather arbitrary it does in fact result in the selection of a group of objects with relatively well defined physical properties. The large light range in the visual region is partly due to the low surface temperatures of the stars. For most Miras the maximum in the energy distribution is in the infrared near 1.6 μm. At such wavelengths the light range is usually much less (typically 1.0 mag or less). Since the visual region is in the short-wavelength tail of the energy distribution, a small change in the surface temperature makes a large difference to the visual brightness. In addition the molecular absorption bands, which dominate the visual region of Mira spectra, strengthen as the surface temperature periodically decreases during the pulsation cycle and their blocking effect further increases the visual light range. Because most of the energy of normal Miras is radiated in the near infrared between 1.0 and 3.0 μm, measurements in this region of the spectrum can be used to estimate the bolometric (i.e. the total) luminosity of the star. There are nearly 6000 Miras or probable Miras currently listed in the *General Catalogue of Variable Stars* (4th edition 1985–1990). But in most parts of the sky only the relatively bright Miras have been so far discovered.

Mira atmospheres

Miras can be grouped into three broad classes according to the chemical composition of their atmospheres. In the largest class (M-type Miras), the spectrum in the optical region is dominated by absorption bands of the TiO molecule. In the S-type Miras absorption bands of ZrO dominate the optical spectrum, though often with strong TiO bands as well. These two classes are grouped together as O-rich Miras (or O-Miras). In the third class (C-type or C-Miras) the spectra are dominated by molecules containing carbon (C_2 etc). Most of the carbon and oxygen in the atmospheres of all these stars is locked up in the stable molecule CO. If there is an excess of oxygen in the atmosphere, the Mira is O-type, if there is an excess of carbon it is of C-type. Both this difference and the difference between the two classes of O-Miras are due to differing amounts of 'dredge-up' that the stars have undergone. 'Dredge-up' is the convective mixing into the upper atmosphere of the star of material that has undergone nuclear processing in its interior. Atomic absorption lines due to the unstable element technetium, which does not occur naturally on the Earth and was first produced in the laboratory in 1937, were found in some S-type Miras in 1951. The half-life of its most stable isotope is 4×10^6 years and the isotope produced by the nuclear s-process (^{99}Tc), the predicted production mechanism in these stars, has a half-life of only 2×10^5 years. This was an important early indication that nuclear processing and the production of complex nuclei take place in some stars, with the processed material being dredged up into the atmosphere. Technetium lines have been subsequently found in many O- and C-Miras and semiregular variables.

Lines of the absorption bands of the CO molecule can be observed in infrared spectra of Miras. The variation in the radial velocity of CO lines of relatively high excitation potential which are formed deep in the atmosphere of the star demonstrates that once per pulsation cycle a shock wave is generated which moves outwards through the stellar atmosphere. Doubling of these absorption lines at certain pulsation phases shows that as one such shock wave is dying out in the higher atmosphere another is being generated lower down. These observations strongly indicate that the variation of Mira stars is due to a pulsation mechanism of some kind. For self-sustaining pulsation one requires there to be a layer in the star which will act as an 'Eddington' valve, absorbing energy when the star contracts and releasing it when the star expands. In the case of Miras this is probably a region in which hydrogen is ionized on compression, recombination and release of energy taking place on expansion.

A characteristic of Mira variables as distinct from most lower-amplitude red variables is that they have emission lines of the hydrogen Balmer series in their spectra (see HYDROGEN SPECTRUM). The intensity of these

lines varies systematically in the pulsation period of the star. Most workers believe that the lines are excited by the shock waves just discussed. When first observed, as the brightness of the star increases towards maximum light, the lines have very unusual relative intensities (Hδ much stronger than Hγ for instance). This is due to the emission being excited by the shock deep in the stellar atmosphere. The line strengths are thus greatly modified by absorption in the outer atmosphere (e.g. by molecules of TiO). As the pulsation cycle proceeds, the shock wave moves outwards through the atmosphere and the emission lines which are generated suffer less from the effects of overlying absorption. Many of the well studied Miras also show, at certain phases in their pulsation cycle, emission lines of neutral and ionized metals (e.g. lines of Fe I, Fe II, Mg I, Si I, In I) and even forbidden lines (i.e. lines with very low transition probabilities) of ionized iron ([Fe II] lines). The relative intensities of the metallic emission lines in Mira spectra are quite unlike that seen in other astronomical or laboratory sources. Certain lines of Fe I, Ti I and Zr I, for instance, are abnormally strong compared with other lines of the same element. These lines are excited by fluorescence. This depends on the chance coincidence of a resonance line (that is one whose lower energy level is the ground state) of the element concerned with a strong emission line of another element. Most of the relevant coincidences are in the ultraviolet. Thus long before it was possible to observe Miras from above the Earth's atmosphere it was clear from observations of the fluorescent lines of other elements, seen in the optical region, that the lines of ionized magnesium (Mg II) at 2800 Å must be strongly in emission in some Miras.

The atmospheres of Miras are very extended. A clear indication of this came when the angular diameters of Miras measured in the visual and in the infrared by lunar occultation techniques were compared. For a given O-Mira such as R Leo the diameter at $\sim$2 μm is about half that in the visual. Later it became possible to measure the variation of the angular diameters of Miras with wavelength using interferometric techniques. In the visible region, the angular diameter of o Cet was then found to vary by large amounts (up to a factor of two) depending on whether the observation was made at the wavelength of a strong absorption band of the TiO molecule where the opacity of the atmosphere is very high or just outside the band where the opacity is much lower and where, therefore, we are seeing much deeper into the atmosphere. Thus whilst for most stars the depth of the atmosphere is only a small fraction of the stellar diameter, in the case of Miras the atmosphere occupies most of the star. Evidently the whole concept of 'a diameter' becomes rather vague in these circumstances and different values may well be appropriate for different purposes. Diameters are needed to compare Miras with the theoretical models of these stars and for a discussion of Mira pulsations. In both these cases the diameter is taken to be that measured in the wavelength range in which most of the energy of the star is being radiated (in the infrared at about 1.6 μm). At this wavelength, models suggest that one is measuring the diameter of the stellar photosphere. From Miras with measured angular diameters and parallaxes one can estimate that a Mira of period 300 days has a linear diameter of $\sim 400 R_{\odot}$ (about the distance of Mars from the Sun). The diameters are even larger at longer periods.

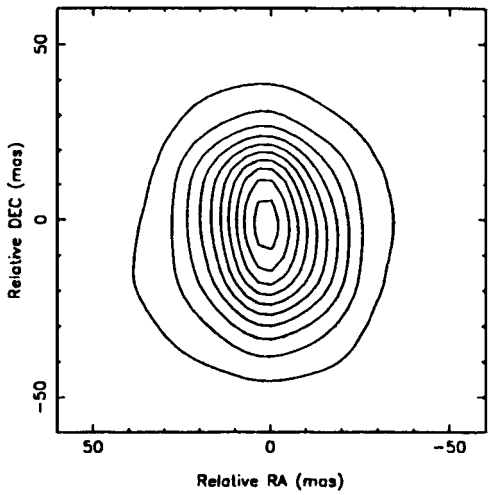

Figure 1. An aperture synthesis image of R Cas showing its non-circular profile (from Haniff 1995).

In recent years it has become possible to reconstruct the images of Miras from interferometric (aperture synthesis) measurements. In several cases (e.g. figure 1) the reconstructed image at optical wavelengths is non-circular. This result applies to the outer region of the atmosphere which, as just discussed, is the region seen at optical wavelengths. It is not yet clear whether it also applies to deeper layers such as seen in the infrared. Three possibilities have been suggested to explain this result: (a) flattening of the outer atmosphere due to rotation; (b) non-radial pulsation of the star; (c) large star spots on the stellar surface which are not fully resolved with current instrumentation and lead to an apparent non-circular profile for the star. The last of these possibilities has generally been favored, mainly because the atmospheres of cool red giants, in general, are expected to contain large convection cells and in these circumstances large over-hot or over-cool regions on the surface might be anticipated. The limited amount of work that has so far been carried out also indicates that the diameter of the outer regions (as seen in the visible) can vary in a manner unconnected with pulsation. In attempting to explain these results it has to be borne in mind that the outer regions are very tenuous and possibly consist of rising and falling clouds with little or no material between them.

The circumstellar region, mass loss, grain formation

One reason why the structure of the outer atmosphere of Miras is of importance is that it is relevant to understanding the process by which Miras lose mass.

Mass loss is clearly a key factor in attempting to understand this stage of stellar evolution, and, when properly understood it will lead to a full understanding of how solid grains are formed in the circumstellar environment. At the present time we have only a rudimentary idea of how this process takes place. Remarkably, laboratory studies of small inclusions in some meteorites show them to have the same relative abundances of certain isotopes as those predicted for Mira atmospheres, suggesting that some grains in these meteorites come from Mira outflows.

Miras are losing mass at rates which are typically in the range from $\sim 10^{-7}$ to $\sim 3 \times 10^{-5} M_{\odot}$ yr^{-1}. For extreme OH/IR Miras the rate can be as high as $\sim 10^{-4} M_{\odot}$ yr^{-1}. It has not yet been possible to predict mass-loss rates theoretically. However, observations indicate that the rate is related to the star's pulsation since it is correlated with both the period and the pulsation amplitude. It is generally believed that pulsation raises (gaseous) matter sufficiently above the star that condensation into grains can take place. The concentration of matter into clouds in the atmosphere as mentioned above will clearly aid the process of grain formation. Once formed, the grains are then driven from the star by radiation pressure, dragging gas with them.

The dust round O-Miras is probably composed mainly of silicates whilst that around C-Miras is, probably, generally composed of carbon or carbon-rich compounds. Some C-Miras show large decreases in visual and near-infrared brightnesses on time scales of some thousands of days (i.e. in a time long compared with the pulsation period). These declines in brightness may be similar to dust obscuration events of the RCB type. Thus the dust formation process may be episodic or non-uniform over the stellar surface, possibly connected with clouds in the stellar atmosphere. It seems likely that similar, non-uniform dust formation takes place in the circumstellar envelopes of O-Miras. In this case, though, it is likely to be less obvious in optical observations since, mass for mass, silicate grains of a given size have a much lower opacity in this region than carbon grains. However, temporal changes in the dust shell of o Cet itself are known from interferometric studies in the infrared (at 11 μm) and strongly suggest that the circumstellar dust is concentrated into clouds.

The full complexity of the circumstellar environment of Miras is best seen in the OH/IR stars. These are long-period O-rich Miras many of which were first detected in surveys for objects showing the 18 cm emission lines of the OH molecule. Such lines are emitted by maser action. These objects are usually very faint at optical wavelengths due to heavy circumstellar dust obscuration and probably also to the low temperature of the central star. They tend to be bright at far-infrared wavelengths (at 10 μm and longer wavelengths). This infrared radiation comes from the circumstellar dust heated by the underlying star whose periodic light variations it therefore tends to follow. Besides thermal emission from dust, these objects also show thermal emission from some molecules (e.g. mm and sub-mm lines of CO and SiO) and maser emission from others (H_2O, OH, SiO).

Interferometric studies of Mira itself in the infrared (11 μm) show that dust formation takes place within about two stellar radii of the surface of the star (with the photospheric (infrared) diameter of the star defined as above). Observations of other Miras show that SiO masers are also excited at about this distance from the star's surface—that is, in a shell whose radius is only about 50 per cent greater than that of the outer radius of the star's atmosphere as observed at visual wavelengths. Since a typical Mira of period 350 days has a photospheric radius of $\sim$450 solar radii ($\sim 3 \times 10^{13}$ cm), the inner radius of the dust shell and the radius of the ring of SiO masers is of order 10^{14} cm. H_2O masers are typically of order 10^{15} cm from the center of the star and the OH masers another factor of about ten further away. CO is formed deep in the atmosphere of the star, and provided one has sufficient sensitivity, thermal emission from this molecule can be detected in the outflowing gas and dust mixture up to the point where all the CO has been photodissociated by interstellar ultraviolet radiation. This extent will evidently depend on the mass loss rate and on the speed of the outflow. Observed outer radii of the thermal CO emission around Miras are typically 10^{16} to 10^{17} cm and thus have large angular extent for the nearer Miras, e.g. an angular diameter of $\sim$14 arcsec for o Cet.

OH masers have been detected from a large number of Miras and OH/IR Miras. The lines are generally double peaked. The two peaks come from the front and back of a (presumed) spherical shell expanding at $\sim$10 to 20 km s^{-1}. The OH emission is stimulated by infrared radiation from the heated dust and so varies in the period of the star. There is a time delay (typically 10 to 100 days) between the intensity variations of the two peaks in the spectrum line due to the light travel time across the shell. Since in some cases this shell can also be resolved as a ring in the plane of the sky, one can use the time delay together with the angular diameter of the ring to determine the distance of the source, provided one assumes spherical symmetry.

Circumstellar masers of most extreme OH/IR Miras project on the sky as circular rings and thus do suggest overall spherical symmetry for these objects. For less extreme Miras there is considerable evidence that the outflow from the star can be aspherical and also that the outflowing matter is concentrated into clouds. For instance the fluorescent emission of the KI resonance line 7699 Å is highly asymmetrical around Miras, as is the CO thermal emission. Optical polarization measurements indicate that there must be asymmetrical scattering by the grains in the dust shell. In O-Miras the H_2O maser distribution on the plane of the sky can be asymmetric and in an O-Mira such as R Cas the individual OH masers show that the mass loss is clumped on a scale small compared with the OH shell radius and is intrinsically chaotic with the clumps retaining their identity as they move outwards. These results, together with the apparent non-circular

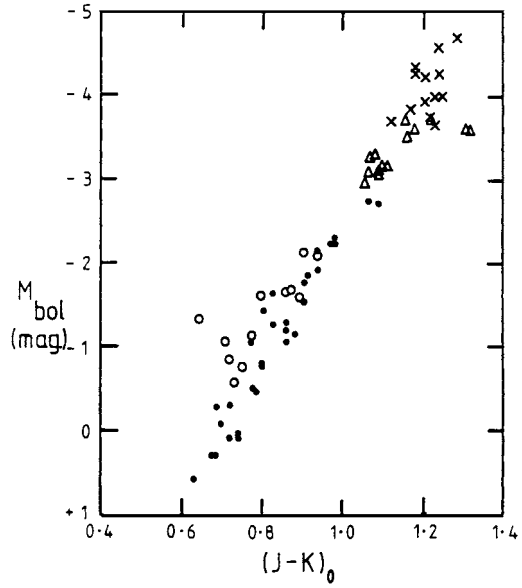

Figure 2. The giant branch of 47 Tuc together with Miras from various clusters; crosses, Miras; triangles, 47 Tuc non-Mira variables; open circles, 47 Tuc AGB stars; filled circles, 47 Tuc RGB stars (from Feast and Whitelock 1987).

profiles of the outer atmosphere of O-Miras, the RCB-like declines of some C-Miras and other evidence, which was mentioned above, suggest that overdense, or unusually cool, regions (clumps, clouds) in the upper atmosphere of the star may be important in the mass-loss and grain formation process.

The circumstellar environment of C-Miras has been somewhat less well studied than that of O-Miras. However, CW Leo, also known as IRC + 10216, a C-Mira with a pulsation period of 630 days, has a shell in which infrared, mm and sub-mm studies have revealed thermal emission lines from more than 40 different chemical compounds. Some of these are quite complex (e.g. HC_9N) and the object is important for our understanding of circumstellar chemistry.

Evolution, pulsation

The evolutionary state of O-Miras is perhaps best shown by those short-period Miras which are members of relatively metal-rich GLOBULAR CLUSTERS. Low-mass stars such as those in globular clusters evolve off the main sequence and climb the red giant branch (RGB). From the top of the RGB they drop to the horizontal branch and then climb through the red-giant region again on the asymptotic giant branch (AGB). Figure 2 shows a color–magnitude diagram with the known cluster Miras together with the RGB/AGB of 47 Tuc, a globular cluster which contains three Miras. Miras are evidently the brightest and coolest of the stars in the clusters in which they occur. Their luminosities are above the predicted maximum for RGB stars (at least for periods greater than about 160 days). They are thus at the tip of the AGB. After this stage they are expected to eject their atmospheres and become planetary nebulas. Near the top of the AGB, stars begin the process of thermal pulsing during which they burn helium and hydrogen alternately in a nuclear active zone. This zone surrounds an inert core which is essentially a white dwarf of about the same size as the Earth. The Miras belong to this thermal pulsing stage, and it seems likely that stars only manifest Mira characteristics during the brighter phases of each thermal cycle. A star may thus become a Mira several times, although this is not yet certain. Between these times it would probably be a low-amplitude semiregular variable such as can be seen marked in figure 2. A thermal pulse is initiated once every $\sim 10^5$ years in a solar mass star by a helium flash (a thermonuclear runaway) which lasts ~500 years. During this relatively short period the structure of the star changes significantly and one might anticipate changes in the pulsation period due to this. Whilst any long-term changes in the periods of most Miras are very small, a few, e.g. R Hya, R Aql, W Dra and BH Cru, show good evidence for significant changes. Thus the period of R Hya has changed from ~500 days in 1700 to 388 days at the present time. It seems likely that these rare objects are currently undergoing helium flashes.

The occurrence of short-period Miras in globular clusters (e.g. three Miras with periods near 200 days in 47 Tuc) shows that Miras at these periods must be old objects with initial masses near solar. The data from globular clusters are limited but they indicate that when there is more than one Mira in a cluster their periods are close to one another. There is also a relation between the periods of Miras in clusters and the cluster metallicity, the period being longer in higher-metallicity clusters. Unfortunately it has not been possible to test this period–metallicity relation for Miras in the general field. The reason for this is that although it is possible to classify Miras spectroscopically into the three broad chemical groups (M, S and C) noted above, their atmospheres are so complex that so far no satisfactory detailed analyses for chemical abundance have been made. However, the galactic kinematics of Miras in the general field are correlated with their periods allowing a classification according to POPULATION. The short period ~200 day stars belong to an old, thick disk or intermediate-halo population as expected since some Miras of this period occur in relatively metal-rich globular clusters. Longer period Miras belong to populations which are more metal-rich and/or younger. Thus the sequence of Mira periods is a sequence of the end points of AGB branches of different ages and/or chemical abundances. It seems likely that the 1000–2000 day OH/IR Miras simply continue this sequence to larger mass stars (perhaps to stars of initial mass $\sim 4 M_\odot$). This is, however, still uncertain, partly because the central stars of these objects are obscured from view by their thick circumstellar shells and so cannot be adequately studied.

The above discussion refers to O-Miras. The place of C-Miras in stellar evolution is less certain. Some at least

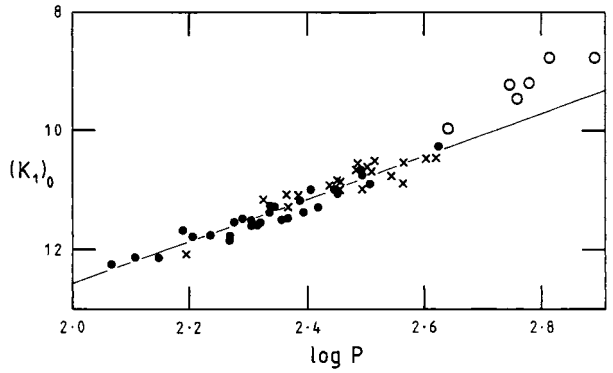

Figure 3. The period–luminosity relation for Miras in the LMC. Ordinate, apparent magnitude at K (2.2 μm); abscissa, log of the period in days; filled circles, O-Miras; crosses, C-Miras: open circles, long-period Miras of uncertain status (from Feast *et al* 1989).

probably evolve from O-rich Miras as a result of dredge-up processes without a significant change of period.

Miras in the LARGE MAGELLANIC CLOUD (LMC), where they are all at closely the same distance from us, show well defined linear relations between bolometric or infrared magnitude and log P for periods between ∼100 days and ∼400 days. The relations for O- and C-Miras are almost the same at 2.2 μm (K-band) (figure 3) and only slightly different in bolometric luminosity. The scatter about the relations is very small (only 0.13 mag about the O-Mira relation at K). This small scatter is a reason for suggesting that Miras may occur only at the brighter phases of a thermal pulse. The absolute magnitudes of the Miras (i.e. the zero point of the Mira period–luminosity (PL) relation) can be obtained in the following ways: by adopting a distance to the LMC (e.g. as derived from Cepheid variables); by using the distance of globular clusters which contain Miras; by using the absolute magnitudes of main-sequence companions to Miras in visual binary systems; or by using the trigonometrical parallaxes of Miras (the Hipparcos astrometry satellite has provided a set of such measures). Infrared color differences between O-Miras of the same period in the LMC and the Galaxy suggest that the period–metallicity relation may not be the same everywhere and such a difference may imply slight differences in luminosity at the same period. The bolometric luminosity of a Mira with a period of 200 days is about 4000 times that of the Sun and that of a 400 day Mira about 9000 times the Sun's.

Once the absolute magnitude, and hence the distance, of a Mira is known this can be combined with an angular diameter to give a linear diameter. The presence of short-period O-Miras in globular clusters as well as the galactic kinematics of O-Miras show that at least those with periods of about a year or less have masses near that of the Sun. One can then use this fact together with the linear diameter and the period to deduce the mode in which Miras pulsate. Good agreement is found in this way with the theoretical predictions for pulsation in the first overtone. This, however, remains a controversial result, mainly because theoretical predictions of shock waves strong enough to excite the observed emission lines discussed above seem to require a smaller, hotter star and this would then be pulsating in the fundamental mode. That the topic has remained controversial is partly due to uncertainties in the definition of the diameter, as discussed earlier, and also to uncertainty in the theoretical predictions of both pulsation and shock wave production. There is evidence for multimode behavior in a few Miras. In such cases the light curve shows evidence of the superposition of two or more periodicities. In principle the period ratios of the excited modes allow mode identification but the theoretical predictions depend on the model of the atmosphere which is adopted. The resolution of these problems will no doubt lead to a deeper understanding of the complex atmospheres of Miras.

The progenitors of Miras are clear in the case of the shorter period Miras that occur in globular clusters, at least if we adopt the standard picture of stars evolving along the AGB to higher luminosities and lower surface temperatures. As figure 2 shows, variability sets in as one ascends the AGB, first as irregular or low-amplitude semiregular variations and then as Mira-type pulsations. In a period–absolute magnitude diagram the low-amplitude semiregular variables evolve along the 'Whitelock' relation of figure 4 with increasing luminosity, period and pulsation amplitude, finally reaching the top of the AGB as Miras on the Mira PL relation. It is presumed that longer-period Miras which evolve from more massive or more metal-rich stars do so in an analogous way. Neither the mass loss of Miras nor their further evolution is fully understood, though the stars are widely believed to eject their outer layers as planetary nebulae.

Mira binaries, red supergiant variables

A number of Miras are known in interacting binary systems. SYMBIOTIC STARS generally show a rich emission spectrum of relatively high excitation, believed to be energized by the infall of gas from the Mira onto a disk round a compact companion. The nearest such system contains the Mira R Aqr (period = 387 days) and is resolved as a bipolar nebula on the plane of the sky. In some symbiotics (e.g. RR Tel, period = 387 days) the presence of a Mira in the system is not obvious from optical observations but the variable dominates the light of the system in the infrared. o Cet itself is transferring mass to a white dwarf companion and this variable should perhaps be regarded as a marginal member of the symbiotic class. QX Pup (also denoted by OH0739 − 14 or OH231.8 + 4.2, depending on whether one specifies the star by equatorial or galactic coordinates) is a 700 day Mira in a complex bipolar nebula showing high-velocity outflows (at ∼200 km s^{-1}). It does not show the characteristic symbiotic emission line spectrum, but this Mira too seems likely to be part of an interacting binary system. The QX Pup system is sometimes known as the

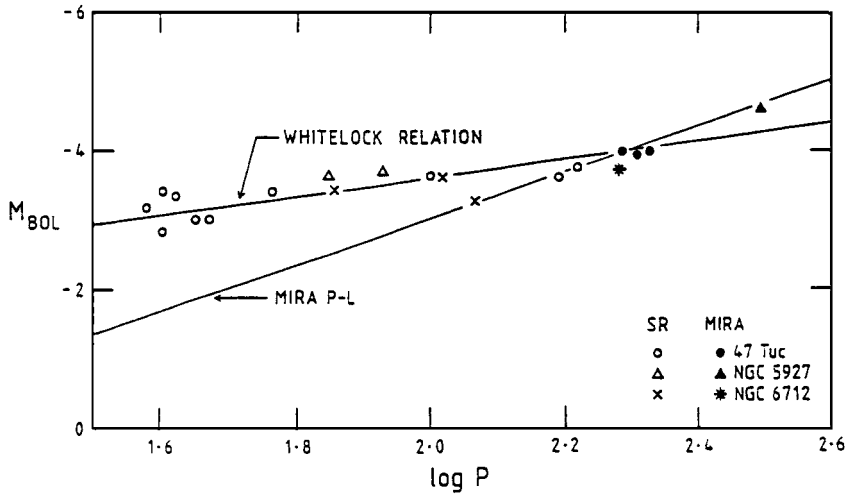

Figure 4. The absolute bolometric magnitude plotted against log period in days for semiregular (SR) and Mira variables in metal-rich globular clusters. The Mira PL relation is shown. The SRs define a line of shallower slope (the Whitelock relation) (from Feast 1989).

Calabash Nebula (from its shape) or the Rotten Egg Nebula (from the great strength of emission lines of H_2S and other sulfur compounds in its mm spectrum).

There is a rare class of supergiant red variables which like the Miras show a rather regular periodicity in their light variations and these are sometimes confused with the Miras. They tend to have periods greater than about 400 days and lower light amplitudes than the Miras. They are also about two magnitudes brighter than Miras but have been much less well investigated. They are known in our Galaxy, the Magellanic Clouds and some have been found in the spiral galaxy M33. Evidence for a period–luminosity relation has been found. These objects are believed to be massive (progenitor mass $\geq 9M_{\odot}$), core helium-burning stars. It is conventional to refer to such objects as supergiants whilst Miras and other stars on the AGB are termed giants. This convention holds even though the spectra of some Miras place them in luminosity classes II or I (i.e. they are spectroscopically classed as supergiants.).

Current research

Infrared, radio and interferometric techniques are currently leading to an understanding of the complex atmospheres of Miras, their circumstellar environment, and the way these are related to stellar pulsation. One aim is to determine the mechanisms of mass loss and grain formation, neither of which are properly understood at present. The final ejection of the outer layers of a Mira, probably as a planetary nebula, is a crucial phase of stellar evolution about which even less is known.

The importance of Miras as distance indicators within our own Galaxy and in extragalactic systems is being increasingly realized. For instance Miras are present in large numbers in the central bulge of our Galaxy and studies of these stars at optical, infrared and radio wavelengths have already made important contributions to our understanding of the composition, kinematics and structure of the bulge, including its bar-like shape. They have also enabled an estimate to be made of the distance to the galactic center. Since Mira periods are related to the stellar population to which they belong, they are valuable indicators of galactic evolution.

Miras are very luminous in the near infrared and it is anticipated that large numbers of them will be found in infrared sky surveys such as that of the European consortium DENIS and of the American consortium 2MASS, both of which began in the late 1990s. The colors of Miras measured in the infrared are distinctive and allow such stars to be recognized even before variability studies are made. Follow-up studies of Miras discovered in the surveys should lead to major improvements in our understanding of both stellar and galactic evolution.

Miranda

Miranda is the smallest of URANUS' five major satellites and one of the most unusual objects in the SOLAR SYSTEM. Miranda is such a small world, only about 470 kilometers (300 miles) in diameter, that it was not discovered until 1948 by the American astronomer GERARD P KUIPER. Very little more could be learned about Miranda until the VOYAGER 2 spacecraft flew through the Uranian system in 1986. Because of navigation requirements to give Voyager 2 the gravitational assist necessary to send it on to Neptune, the spacecraft passed closer to Miranda than any other large object in the Uranian system. The targeting of Voyager 2 near Miranda was viewed by most planetary scientists as an unexciting necessity, since all evidence indicated that Miranda would be only an uninteresting, heavily cratered object.

As it turned out, Miranda became the great surprise of the encounter. It is indeed a small object, but its surface is incredibly diverse. The expected heavily cratered terrain is present, but the surface is also criss-crossed by a network of rift-like canyons more characteristic of a much larger object. And, most intriguingly, set amidst the craters and canyons are three large geologically modified patches called 'coronae', unlike any other feature seen elsewhere in the solar system (figure 1).

All three of the coronae have sharply defined boundaries, with surface topographies and textures quite different from the cratered terrain. All three have very few superposed craters, indicating that they formed later than, and on top of, the heavily cratered terrain. Yet each corona is unique in detail. The largest of the coronae, named Arden, consists of a set of concentric light and dark bands and looks something like a great oval racetrack. The outermost 'lane' in the racetrack is one of the huge canyons. The corona over the South Pole, named Inverness, also has light and dark areas, but the pattern is more rectangular than Arden's. The surface of Inverness is also covered by sets of low, parallel ridges arranged in a roughly rectangular pattern. The third corona, named Elsinore, appears uniformly gray in the images. Its surface is covered by parallel sets of low ridges and troughs like Inverness', but the pattern is oval, like Arden's.

Canyons on Miranda occur over a wide range of sizes, but the most prominent are typically 50–60 km wide, 6–8 km deep and hundreds of km long. A few of the canyons appear smooth and 'softened' by age or overlying material, but most appear rugged and fresh. The walls of many of the fresh canyons consist of a series of steep, smooth slopes arranged like tilted steps from canyon floor to rim. However, some canyon walls, like Verona Rupes off the northeast corner of Inverness, consist of a single magnificent step from floor to rim.

Even the population of CRATERS on Miranda is somewhat unusual. On most objects in the solar system, craters range in appearance from fresh and crisp to old and worn down, with all stages of preservation in between. On Miranda some craters appear fresh and some appear worn, but there are almost none in between. Most of the large craters on the cratered terrain appear worn down while the smaller craters on both the cratered terrain and the coronae are sharp and fresh.

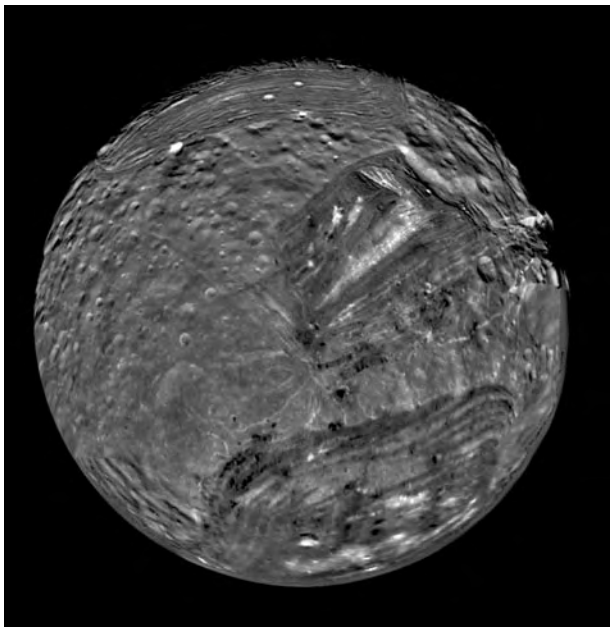

Figure 1. This picture of Miranda is a mosaic of the best images obtained by Voyager 2 in 1986. The projection is orthographic, with the South Pole at the center. The surface shows an incredible variety of features: the heavily cratered terrain at left; large canyons cutting across the surface, including Verona Rupes at right; and the three coronae, Arden at the bottom, Inverness at center, and Elsinore at the top of the image. (NASA photograph.)

The unusual and unexpected collection of features on Miranda has prompted a number of competing explanations for their origin. One early suggestion, based on the theoretical idea that small objects near large planets like Uranus should have been blasted apart many times by incoming PLANETESIMALS, was that Miranda had been catastrophically shattered into many large pieces after it had partially melted into dark rock-rich and light ice-rich layers. The shattered pieces then fell back together in random order, with darker fragments formerly in the deep interior forming the coronae now visible on the surface. An extension on this idea was that the canyons had been formed as rock-rich chunks and had slowly sunk back to Miranda's center, stressing and breaking the surface.

Subsequent detailed analysis of the canyon networks led to their interpretation as cracks or rifts formed by stretching of the surface, which in turn was caused by upwelling of material from below. The appearance of the coronal materials—particularly the different brightness of distinct features (especially in Inverness, see figure 2), the morphology of the surface ridges, and the lobed and flow-like edges—led to their interpretation as huge deposits of lava-like material that flowed out onto the cratered surface, filling low spots and spilling out on top of the

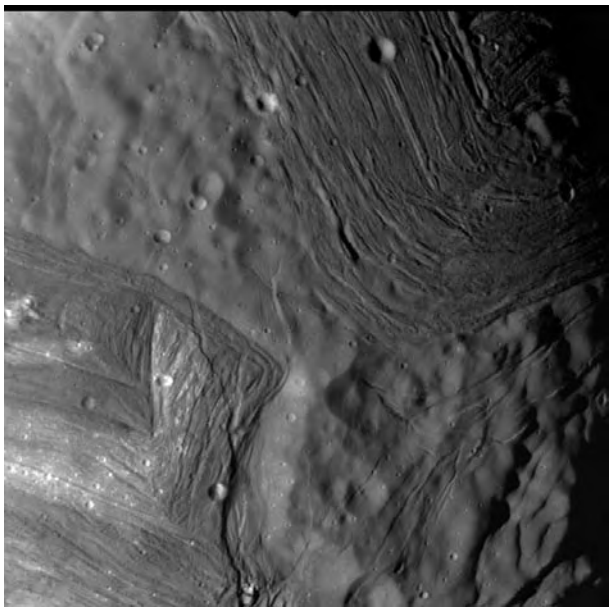

Figure 2. This picture taken by Voyager 2 in 1986 shows portions of Elsinore Corona at upper right, and Inverness Coronae at lower left. A strip of ancient cratered terrain separates them. Note how the coronal materials appear to have flowed over the older cratered surface. (NASA photograph.)

cratered terrain. Both the inferred surface stretching and the volcanism can be accounted for by heating, thermal expansion and partial melting deep in Miranda's interior. The problem is in understanding how sufficiently high temperatures to cause such extensive geologic activity can occur in as small a body as Miranda. Ideas accounting for the apparently excessive heating include episodes of tidal heating, or the presence of an outer layer of material with a very low thermal conductivity, leading to enhanced insulation of the normal internal radioactive heat source. This interpretation does not exclude the idea that Miranda had been blasted apart early in its history, but the present surface features do not appear to result from such an event.

Miranda is an icy body. Spectral analysis of its reflected light shows the presence of water ice on its surface. Miranda's density of 1.15 g cm^{-3} indicates that its interior is also made mostly of water ice with a small fraction of rocky material. Miranda's density is somewhat smaller than the densities of its sister satellites (see URANUS), implying that Miranda might have a smaller fraction of rocky material in its interior than its neighbors. Alternatively, Miranda's outer layers could be more porous than its larger neighbors'.

If the coronal materials are indeed formed by eruptions of lava-like materials, they indicate the presence of at least small amounts of ices other than water ice. 'Lavas' on Miranda would not be made of liquid rock as on Earth, but of liquid water. However, the putative lava deposits on Miranda are up to a kilometer thick and have surface ridges and curved edges indicative of a lava with high viscosity. Pure water has a low viscosity, but mixtures of water with such compounds as ammonia and methanol do have sufficiently high viscosities to form the coronal features. Such icy mixtures also have very low melting points, making melting on small bodies like Miranda easier. Ices of compounds such as methanol have been detected on other icy bodies in the outer solar system, so they could be present on Miranda (see VOLCANISM IN THE SOLAR SYSTEM). Such icy lava would erupt onto Miranda's surface with temperatures near −120 °C and freeze down to Miranda's average surface temperature near −190 °C. At this temperature, water ice is as stiff as rock on Earth and will form permanent features.

Mirror

An optical component from which light is reflected. Because light is reflected from the front surface of an astronomical mirror, it does not have to travel through the material of which the mirror is made. An astronomical mirror usually consists of a suitably shaped substrate (the body of the mirror) on which a thin layer of highly reflective metal, such as silver or aluminum, is deposited. The substrate is normally a material with a very low coefficient of expansion which, therefore, expands and contracts as little as possible when its temperature changes, typical materials being Pyrex (a low-expansion glass), quartz or ceramics.

Telescopes other than optical telescopes (e.g. for x-rays or radio) use mirrors (or reflectors) in analogous ways; however, the materials of the substrate and reflecting surface are adapted to the properties of the radiation.

In a reflecting telescope, light is collected and brought to a focus by a concave 'primary' mirror, the size of the image formed at its focal plane being proportional to the focal length of the mirror (the distance between the surface of the mirror and the focus). In most reflecting systems, the converging cone of light from the primary is intercepted by a smaller secondary mirror. If the secondary mirror is flat, it reflects the converging cone of light to a different position without changing its angle of convergence and without altering the focal length of the instrument. For example, in the Newtonian design, a flat secondary reflects light to a focal position at the side of the telescope tube. In other designs, the front face of the secondary is curved and changes the angle at which light rays are converging, thereby altering the effective focal length of the telescope. In the Gregorian and Cassegrain designs, the secondary reflects light back down the telescope tube, through a hole in the center of the primary mirror, to a new focal position. The Gregorian uses a concave secondary, the surface of which has an elliptical cross-section, whereas the Cassegrain (and its derivatives) uses a convex secondary with a hyperbolic curve.

If the surface of a mirror has a spherical curve, it will be unable to focus parallel rays striking different parts of its surface to the same focal point (this defect is called 'spherical aberration'). Most reflecting telescopes use paraboloidal primary mirrors (mirrors in which the cross section of the surface is part of a parabola) to overcome this problem. However, paraboloidal mirrors produce crisp, sharp images only in the central parts of their fields of view, images towards the edges of the field suffering from another defect called coma. The Ritchey–Chrétien design (a development of the Cassegrain), which produces good-quality images across most of its field of view, has a hyperboloidal primary and a hyperboloidal secondary.

Mitchell, Maria (1818–89)

First woman astronomer in America, born in Nantucket, MA, became librarian of its Atheneum Library, helped her father in his amateur observatory. In 1847, independently discovered a comet named *Miss Mitchell's Comet*, and became a 'computer' at the US Nautical Almanac Office, calculating the motion of Venus. After a European tour, she was presented with a telescope bought with money collected by American women. Became professor of astronomy and director of the observatory at the newly opened Vassar College in Poughkeepsie, New York, photographing Jupiter, Saturn and the stars, and furthering women's education.

Mizar and Alcor

Mizar (Arabic, 'the Girdle') is the name given to ζ Ursae Majoris, the center star in the handle of the Plough, by J J Scaliger (1540–1609). The star was formerly known as Merak or Mirak, from the Arabic Al Marakk—'the Loin' (of the bear). This duplicated the name given to another star, β Ursae Majoris, which may account for Scaliger's introducing a new name. Mizar is an interesting multiple star system, but is perhaps best known for its pairing with Alcor ('the Rider'). Fourth-magnitude Alcor is separated from second-magnitude Mizar by 11.82′ at position angle 72°, and is thus an easy naked-eye double. In ancient Arabia, where it was often referred to as Suha, 'the Forgotten [or Lost or Neglected] One', it was regarded as a test of acute vision. This suggests that it may have brightened over the past few centuries.

Mizar is a main-sequence star of apparent magnitude 2.23 and spectral type A2V; with a parallax of 0.042″ it is 78 light-years distant. Its absolute magnitude is 0.3. It is believed to be the first binary system ever discovered, in 1650 by Giovanni Riccioli (1598–1671). In 1889 its brighter component also became the first spectroscopic binary to be announced, following the discovery by Anna C Maury (1866–1952) of the Harvard College Observatory that the absorption lines in its spectrum alternately appeared double and single, with a period of 20.5 days. The spectroscopic binary, separation about 0.01″, was first resolved telescopically in 1925 by F G Pease (1881–1938), using a 20 foot beam interferometer attached to the 100 inch reflector at the Mount Wilson Observatory—an epoch-making instrument devised by Albert Michelson (1852–1931), with which the first stellar diameters were also measured. The components of the spectroscopic binary are now designated ζ UMa A and B. The secondary star of the main binary system, designated ζ UMa C, is a similar main-sequence star of spectral type A7Vm and apparent magnitude 3.85. It is separated from ζ UMa AB by 14.4″ at position angle 152°. This component is itself also a spectroscopic binary, with a period of 175.5 days.

Alcor (80 UMa) is a white main-sequence dwarf, spectral type A5V, apparent magnitude 3.99. It is a little more distant than Mizar at 81 light-years (parallax 0.040″), but may be a distant member of the same gravitational system. Its absolute magnitude is 2.0. All these stars are part of the Ursa Major moving cluster, having similar and approximately parallel proper motions.

In 1722 an eighth-magnitude star, between and a little to the south of Mizar and Alcor, was discovered by J G Liebknecht (*fl*. 1720), a little-known German professor of mathematics and theology. He was observing with a simple refracting telescope of poor quality, and his inadequate measurements of the star's position led him to conclude erroneously that the object was a planet, which he named 'Sidus Ludoviciana', after the Landgrave Ludwig of Hessen-Darmstadt. The name was copied in many subsequent atlases, a rare distinction for such a faint and unimportant star.

Molecule

The smallest particle of a chemical compound that can exist by itself and which has all the chemical properties of that compound. A molecule consists of two or more atoms, of the same elements or of different elements, linked together by chemical bonds. It may be described by its molecular formula. For example, O_2 denotes a molecule consisting of two oxygen atoms (this is the form in which most of the oxygen in the Earth's atmosphere exists), and O_3 denotes a molecule consisting of three oxygen atoms (this particular form of oxygen is called ozone). A molecule of water (a compound), which consists of two hydrogen atoms and an oxygen atom bonded together, is denoted by H_2O, a molecule of carbon dioxide (one carbon atom joined to two oxygen atoms) by CO_2, and so on.

The molecular mass (often referred to as 'molecular weight') of a molecule is its mass expressed in atomic mass units and is equivalent to the sum of the atomic masses of all its constituent atoms. In round figures, the molecular mass of a diatomic (two atom) oxygen molecule is 16 (the atomic mass of oxygen being 8), the molecular mass of water is 10 (the atomic mass of hydrogen being 1) and the molecular mass of carbon dioxide is 28 (the atomic mass of carbon being 12). In practice, atomic and molecular masses differ slightly from precise integral values. Molecules range in size and mass from simple diatomic molecules such as H_2 to macromolecules with molecular masses of more than 10 000.

A molecule has a physical size and shape that depends on the separation and relative orientation of its constituent atomic nuclei. Consequently, it exhibits three types of discrete (quantized) energy levels and transitions (changes between levels): electronic transitions, which involve changes between energy states in the shared cloud of electrons that surrounds its constituent atomic nuclei; vibrational transitions between its various permitted states of vibration (these involve the separations between nuclei); and rotational transitions, which involve discrete changes in the way in which the molecule rotates around various axes. Each of these kinds of transition is accompanied by the emission or absorption of radiation of a specific wavelength, the three classes of molecular transition giving rise to large numbers of lines, many of which overlap to produce broad bands in the resulting spectra. Through studies of their emission and absorption spectra, astronomers have identified more than a hundred species of molecule in the interstellar medium.

Molonglo Observatory Synthesis Telescope

Australian radio telescope, located near Canberra and operated by the University of Sydney. A large Mills Cross radio interferometer was built there in 1966. One arm of the cross has been converted into the Molonglo Observatory Synthesis Telescope (MOST).

MOST consists of two cylindrical 778 m $\times$ 12 m paraboloids, 15 m apart and aligned east–west. The telescope is steered by mechanical rotation of the cylindrical paraboloids about their long axis, and by phasing the feed elements along the arms. The resulting system can follow a sky field for ± 6 h if it lies south of declination -30°.

Molyneux, William (1656–98) and Molyneux, Samuel (1689–1728)

William was an optical physicist, born in Dublin, independently wealthy and an English government official in Ireland, studied optics and published *Dioptrica Nova* (1692). He obtained a telescope from FLAMSTEED and made astronomical observations, but while his private correspondence with Flamsteed and HALLEY was extensive he never published in astronomy. His second son, Samuel, a prosperous English amateur astronomer, attempted with JAMES BRADLEY to measure the parallax of Gamma Draconis with a 'zenith sector', i.e. a telescope (in this case mounted on the chimney stack of Molyneux's house) looking at stars directly overhead. They found an impossibly large angular shift (up to 40 arcseconds), with the wrong phase characteristics. This turned out to be not parallax but 'the aberration of light' due to the combination of the Earth's orbital velocity (changing throughout the year) with the incoming velocity of light from the star.

Monoceros

(the Unicorn; abbrev. Mon, gen. Monocerotis; area 482 sq. deg.) An equatorial constellation which lies between Orion and Hydra, and culminates at midnight in early January. It is usually considered to have been introduced by the Dutch theologian and geographer Petrus Plancius, who included it on a celestial globe in 1613, though some authorities regard it as older than this.

An inconspicuous constellation, the brightest star in Monoceros, β Monocerotis (combined magnitude 3.8), is actually a multiple system consisting of three bluish-white (B3) components, magnitudes 4.5, 5.2 and 5.6, separation 7.2″ and 10.1″ from the primary, which also has an unseen companion. Other bright stars are α Monocerotis, magnitude 3.9, and γ Monocerotis, magnitude 4.0. Other interesting stars include Plaskett's Star, a sixth-magnitude spectroscopic binary whose components are among the most massive stars known, the variables U Monocerotis (range 6.1–8.8), an RV Tauri star, and R Monocerotis (range 11.0–13.8), a T Tauri star which is enveloped in and illuminates NGC 2261 (Hubble's Variable Nebula, a Herbig–Haro object), and A0620–00, a possible three-solar-mass black hole.

Monoceros is crossed by the Milky Way and contains several bright open star clusters, including: NGC 2264, a large triangular-shaped cluster of over a 100 stars, including a couple of dozen of eighth or ninth magnitude and also 15 Monocerotis (also known as S Mon., magnitude 4.7v), at the southern end (apex) of which lies the dark Cone Nebula; NGC 2232, a group of a couple of dozen stars, many of sixth to eighth magnitude, surrounding 10 Monocerotis (magnitude 5.1); NGC 2244, another large cluster, including a dozen or so sixth to ninth magnitude stars, embedded in the Rosette Nebula (NGC 2237-9, 2246), a diffuse emission nebula; and M50 (NGC 2323), a rich group of several dozen stars fainter than eighth magnitude. The few galaxies known are relatively small and faint.

Montanari, Geminiano (1633–87)

Italian scientist, born in Modena, practised law in Vienna. Returned to Italy to Modena as court philosopher and mathematician, where he was taught by Count Cornelio Malvasia, with whom he went to Bologna and became professor of mathematics at the university. Montanari made a map of the Moon for Malvasia's ephemeredes of 1662, developing a telescope reticule to make the observations; he published ephemeredes himself in 1665. He studied variable stars (discovering the variability of Algol), observed comets, waged war on astrology, made excellent lenses and developed a machine he called a 'sferologio' that showed all of the movements of the heavenly bodies like an orrery.

Month

A unit of time based on the motion of the Moon around the Earth. The synodic (or lunar) month is the mean time interval between two successive new moons (i.e. the time taken for the Moon to pass through its cycle of phases) and is equal to 29.53059 mean solar days. Because the synodic month (the basis of the lunar calendar) is not equal to a whole number of days, the calendar month is rounded to a whole number of days, as follows: 30 days in April, June, September and November, 28 days in February (29 in a leap year), and 31 days in all other months.

Other definitions of the month include the following. The sidereal month (duration, 27.32166 days) is the time taken for the Moon to move through an angle of 360° relative to the background ('fixed') stars. The anomalistic month is the time interval (27.55455 days) between successive passages of the Moon through perigee. The tropical month (27.32158 days) is the time interval between two successive conjunctions of the Moon with the vernal equinox. The nodical (or draconic) month (27.21222 days) is the time interval between successive passages of the Moon through the ascending node of its orbit.

See also: calendar, equinox, node, orbital elements, sidereal period, synodic period.

Moon

The Moon, our closest neighbor in the universe, has a specific relationship with humanity. It is by far the brightest object of the night sky. The encounter of the Sun and the Moon during solar ECLIPSES strikingly demonstrates the similarity in the angular diameter of these two celestial bodies. As queen of the night, the Moon, together with the Sun, has been integrated into the system of symbols and religions of all early civilizations. Because of the obvious link with biological rhythms, the Moon was nearly everywhere associated with a goddess, the lunar 'yin' providing the balance with the solar 'yang'. It was given a particularly important role in Manichaeism (the 'religion of light', from the 3rd to the 14th century), departing souls migrating from the Earth to the Moon during the waxing phase before being transferred to the Sun during the waning phase. Countless pages have been written on the role of the Moon in art, literature, music and culture in general. Most ancient civilizations had CALENDARS which were either lunar (such as the Jewish or Muslim calendars) or lunisolar (such as the Roman calendar which evolved into the Gregorian calendar now widely in use). Because of the importance of calendars for agricultural societies and that of eclipses as portents of dire events, observations of the Moon and predictions of its motion were central to the early development of astronomy, possibly back to prehistoric times.

The Earth–Moon system is unique in the solar system with its ratio of less than 4 between the sizes of the planet and its satellite, and, as seen from afar by departing space probes, it can indeed be considered as a double planet (figure 1). Pluto with its satellite Charon (a factor of 2 in size) are now considered as the two largest members of the Kuiper belt of small outer solar system bodies, even though the International Astronomical Union has maintained the formal status of Pluto as the ninth planet. Because of the large mass of the Moon and its proximity to the Earth, lunar tides are nearly three times larger than solar tides. The orbit of the Moon is quite different from that of other large satellites (with the exception of Triton, around Neptune), which are nearly circular and lie in the equatorial plane of their primaries. One of the major scientific questions associated with the Moon is therefore that of the origin of the Earth–Moon system, which has only recently made significant progress.

In the first section, the history of lunar astronomy will be presented, concluding with the status of lunar science in the middle of the 20th century, before the beginning of the space era.

Figure 1. The double planetary system of the Earth and the Moon observed by the Galileo spacecraft departing to Jupiter. When compared with the Earth, this image demonstrates that the Moon, which looks so bright in the night sky, is actually quite dark.

The second section will focus on the role of the Moon as the major goal of the first 15 yr of space programs, with the pivotal date of 21 July 1969 when Neil Armstrong was the first human being to set a footprint on another planetary body during the historic flight of Apollo 11. After the last Soviet lunar mission, in 1976, the Moon was left alone for nearly 20 yr. The major breakthroughs in lunar science which resulted from this period of intense activity will be reviewed. The return to Earth of lunar samples has revealed the chronology of the geological history of the Moon, to the extent that, during its first billion years, it is better known than that of the Earth itself.

In the third section, the giant impact model for the origin of the Earth–Moon system will be presented. Its formulation in the early 1980s resulted from combining the wealth of information provided by the space missions with advances in dynamical modelling.

These new ideas contributed to the renewed interest in lunar exploration initiated by the American missions Clementine (1994) and Lunar Prospector (1998–99) and presented in the last section on the recent past and future prospects of lunar science. The future of lunar exploration is yet uncertain, with a series of increasingly ambitious missions which could lead to a permanent manned outpost on the Moon before 2030.

The Moon in the history of astronomy

The Moon was undeniably, together with the Sun, the prime target of NAKED-EYE ASTRONOMY, possibly as

early as the stone age (astronomical relationships have been claimed for most major megalithic monuments, in particular Stonehenge) and definitely from the beginning of historical times, in Chaldea, Egypt, China or Mesoamerica. It was immediately evident that the Moon always turns the same side towards the Earth, which means that both its rotation period and its orbital period are tidally locked at 27.3 days. The variations of the orbital velocity along the slightly elliptical lunar orbit lead to an apparent back and forth rotation of the Moon as seen from the Earth which is called the libration. When taking into account the inclination of the rotation axis, slightly less than 60% of the lunar surface can be observed from the Earth. The familiar cycle of PHASES OF THE MOON (new Moon, first quarter, full Moon, last quarter) is linked to the angle between the directions of the Moon and the Sun, which repeats every 29.53 days (the lunar month). With the naked eye, one can readily distinguish the bright zones (the highlands) from the dark zones (the mare), the latter covering less than 35% of the visible regions. In central and eastern regions, the dark zones appear nearly circular, with diameters of up to 1100 km (Mare Imbrium). On the western side, they merge into the vast Oceanus Procellarum.

The Moon was the first celestial body observed by Galileo with a telescope in 1609, an event which marked the beginning of modern ground-based astronomy. He immediately identified countless round features, the lunar CRATERS. Forty years later, the major features of the near side had been revealed with the names which are still in use today (figure 2). Ray craters such as Tycho had been observed, with bright lines extending radially over thousands of kilometers. The nearly instantaneous disappearance of occulted stars demonstrated that the Moon has no atmosphere. Spatial resolution for lunar observations is essentially limited by atmospheric turbulence to a few km at ground level, down to 1 km at high altitudes. The Moon, a bright extended source, did not benefit from the race to larger and larger mirrors which was essential in the development of galactic and extragalactic astronomy. The major advances of the 19th century were the identification of tectonic features and lava flows on MARE.

Figure 2. Map of the visible face drawn by Grimaldi and Riccioli in 1651, a bare 40 yr after the first telescope observations by Galileo. The two circles mark the limits of the regions which can be observed owing to the lunar librations.

Table 1. Orbital and physical characteristics of the Moon.

Semimajor axis	384 400 km
Eccentricity	0.0549
Inclination on the ecliptic	5.15º
Radius	1740 km
Density	3.34
Mass ratio with respect to the Earth	1/81

The dynamical characteristics of the Moon were in the forefront of the development of celestial dynamics in the 18th and 19th centuries, with applications to astronomical navigation. The characteristics of the orbit of the Moon (table 1) were determined with an accuracy which made possible the development of the theory of perturbations. The influence of the Sun slowly modifies the position of the nodes (intersections of the lunar orbit plane with the orbit plane of the Earth) as well as that of the pericenter. The angular size of the Moon is 10% smaller at apogee than at perigee, where it can completely mask the Sun (total eclipse) if they are on the same line (hence with the Moon at one of the nodes). There is a remarkable triple coincidence between 223 lunar months, 239 returns to the pericenter and 242 returns to the ascending node, all within half an hour of 6585.33 days. This explains the repetition of eclipses with similar characteristics over an 18 yr cycle, with a shift in longitude of 120º (one-third of a day). The eclipse cycle is called the SAROS, a Chaldean word, even though it is now considered unlikely that it was recognized at such an early stage. Tidal dissipation within the Earth's mantle and oceans leads to a long-term evolution of the orbit of the Moon, which slowly drifts away from the Earth. The present and past rate of this long-term motion was a critical missing parameter when attempts were made to retrace this evolution backwards, so as to address the issue of the origin of the Earth–Moon system.

The major questions of lunar science were still open in the middle of the 20th century. Even the origin of ubiquitous features such as the lunar craters was a matter of controversy between proponents of volcanic and impact processes. Theories on the origin of the Moon covered all possibilities (or so it seemed at that time): ejection of a liquid 'droplet' from a rapidly rotating young Earth (fission theory), capture of the Moon by the Earth or accretion of the Moon from PLANETESIMALS orbiting the Earth. All three had critical flaws.

- Hydrodynamic instability of the Earth before the fission requires a total angular momentum of the Earth–Moon system twice as large as that which is observed and does not lead to extremely asymmetric partitions (1:81) as demonstrated by the nuclear fission 'liquid drop' analog (uranium splits into daughter nuclei with mass ratios of at most 2 to 1). Furthermore, the initial orbit would have been equatorial, with no plausible evolution path to the present orbit.
- No plausible dissipation process was proposed to shed the excess energy of a proto-Moon approaching the Earth, which constitutes a major difficulty for the capture hypothesis.
- Accretion in orbit, a smaller-scale version of the Kant–Laplace condensation theory, results in the so-called 'regular' satellite systems (such as that of Jupiter and Saturn), in the equatorial plane of their primaries and with very small eccentricities, which is not the case of the Moon. The low density of the Moon when compared with the Earth represented a major problem if these two bodies formed from the same reservoir of planetesimals.

There was also no information on the ages of lunar features. No transient events were observed, and, because of its small size and density, it was widely considered that the Moon cooled more rapidly than the Earth and was now a dead world. This hypothesis was to be proven correct by lunar sample geochronology.

The Moon and the early phases of exploration of the solar system

The Moon, with its proximity and public appeal, was the obvious first target for spaceflight beyond low Earth orbit. Indeed, only 2 yr elapsed from the first Sputnik to the Soviet lunar probe which crashed on the lunar surface. A major breakthrough was obtained with the first lunar fly-by by Lunar 3, in 1959, which revealed a far side almost entirely covered by highlands (figure 3). The pace of events became quite frantic after the decision by J F Kennedy in 1961 to land a man on the Moon in less than 10 yr. This initiated the 'race to the Moon' as a way to demonstrate the American technological leadership. Only 3 yr separate the first soft lander (Luna 9, a Soviet mission, in 1966) from the historic landing of Apollo 11, in July 1969 (table 2). In 1972, the last of the six Apollo flights left the Moon, and this intensive phase of lunar exploration came to a halt in 1976, when the last automated Soviet sample return mission left Mare Crisium. The science results from this gigantic effort have provided a quantum jump in our understanding of the Moon and its history.

A global photographic coverage was obtained with polar orbiters, with high-resolution images of the potential landing sites. This demonstrated the impact origin of most, if not all, lunar craters, from the similarity to explosion craters and the circular 'ripples' around major basins such as ORIENTALE BASIN. The observation of craters at all scales from basins down to a few micrometers explained the formation of a ubiquitous layer of debris 5–10 m thick, the lunar REGOLITH (figure 4), mainly constituted of very small grains (a few 10 μm)

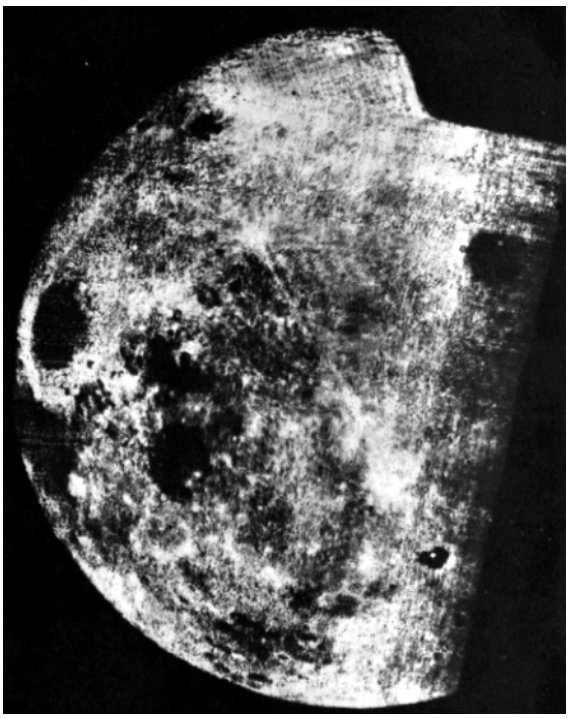

Figure 3. This historic image obtained by the Luna 3 probe in 1959 revealed a far side dominated by highlands (bright regions).

Table 2. Main lunar exploration missions from 1959 to 1976.

Luna 3 (USSR)	October 1959	First images of the far side
Luna 9 (USSR)	January 1966	First soft lander
Lunar Orbiter 4 (USA)	May 1967	Photocartography from a polar orbit
Surveyor 1, 5, 6 (USA)	1966–68	Soft landers
Lunokhod 1, 2 (USSR)	1970, 1973	Remotely controlled rovers (10–40 km)
Luna 16 (USSR)	September 1970	Automated sample return (Mare Fecunditatis)
Luna 20 (USSR)	February 1972	Automated sample return (Apollonius highlands)
Luna 24 (USSR)	August 1976	Automated sample return (Mare Crisium); 2 m deep drill core
The Apollo program (USA)		
Apollo 11	July 1969	First manned landing (Mare Tranquilitatis)
Apollo 12	November 1969	Oceanus Procellarum
Apollo 14	January 1971	Fra Mauro formation (SE of Procellarum)
Apollo 15	July 1971	Hadley (Mare–highland contact zone); First deep drill core, first manned rover (20 km)
Apollo 16	April 1972	Descartes (highlands); deep drill core, rover
Apollo 17	December 1972	Taurus–Littrow (Mare–highland contact zone); field geology (H Schmitt), 35 km explored, deepest drill core (3.2 m)

but also including rocks of all sizes. The accurate determination of the gravity field and altimetry over the low-latitude regions combined with the seismic active and passive experiments provided information on the internal structure of the Moon: either no core or a very small core (at most a few hundred km in radius), a thick mantle and then a crust which is much thinner on the near side (60 km) than on the far side (100 km). The minor contribution of the core to the total mass means that the Moon has about half as much iron as the Earth, a major constraint on formation models. Positive gravity anomalies below basins, the mascons, confirmed the impact origin hypothesis. Magnetometers revealed that the Moon had no dipolar field but observed local crustal fields with widely varying orientations. The origin of these fossil fields is still controversial (frozen ancient dipolar field, induction) and this question is linked to the existence and actual size of a possible lunar core.

The major justification for the large Apollo budgets (up to several per cent of the US GIP in the peak years) was definitely political with military undertones. The goal of the first Apollo flights was quite literally to display the flag, not to do science, and the first astronauts had little or no scientific training. As a result, many samples from Apollo 11 and 12 were collected without adequate documentation, such as taking a photograph before picking up a rock, to know which face was exposed to space. After the political goals had been

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

reached, and after the scientists pointed out the consequences of mishandling the sampling process, a science team was put together for the Apollo 13 flight to instruct and support the astronauts. Of course, this mission is more widely known for its dramatic rescue effort after an explosion in the service module half-way to the Moon than as a breakthrough for the role of science in the program. The last four Apollo flights were science oriented, with much larger and better-documented sets of samples. Apart from sampling, the astronauts performed a wide range of scientific investigations, including the first European space experiment, a solar wind collector. The set of instruments left on the surface remained operational years after the departure of the astronauts. One can quote the important results from seismometers on the internal structure or the heat flux experiment, which provided the global content of long-lived radionuclides (potassium, uranium and thorium) in the lunar interior after nearly 4 yr of integration to screen out the diurnal and annual cycles.

Overall, nearly 400 kg of samples were obtained from nine different sites: the six Apollo sites, but also three automated Soviet sample return missions, which brought back a few hundred grams of samples, a technological feat which is only now being planned for Mars. Lunar sample analyses played a key role in a revolution in analytical techniques which not only benefited planetary sciences but had important technological spin-offs: textural, elemental and isotopic analyses which required grams were performed on micrograms with the development of the electron microscopes, ion probes, mass spectrometers and x-ray analysers. When applied to METEORITES, these new techniques revealed the isotopic anomalies which provide the basis for the most recent theories of the formation of the solar system.

The lunar geologic history

The determination of an absolute age scale for the lunar geologic history was the most important result of sample analyses. Chronometers were developed on the basis of the radioactive decay of uranium to lead, rubidium to strontium and potassium to argon. Argon is a gas, so that the latter age fixes the last shock event in the history of the sample, which can be different from the age of formation of the rock. These analyses demonstrated that the formation of the Moon was nearly simultaneous with that of the Earth, 4.55 billion years ago. After at most 200 million years, the differentiation between a possible small core, a mantle and a crust was complete. Over nearly 500 million years, the Moon (and hence also the Earth) was submitted to an intense bombardment as the newly formed planetary bodies swept out the left-over planetesimals in the inner solar system. This period resulted in the formation of giant impact basins, hundreds of km in diameter and tens of km in depth, with fractures in the underlying crust, while the surface was thoroughly pockmarked by overlapping craters. All the 'mountains' on the Moon (up to 8 km high) result from the accumulation of debris or the rebound of the lunar crust associated with the formation of basins. The far side, still dominated by highlands, gives a good idea of what the whole lunar surface looked like 4 billion years ago (figure 5).

In the meantime, heat from radioactive decay was accumulating slowly in the lunar interior. From 4 to 3 billion years ago, melted mantle material was able to escape through the fractures of the crust as gigantic lava flows to fill out the basins and form the lunar maria. This was much easier on the near side than on the far side, where the crust was twice as thick, which explains the near absence of maria on the far side. As on the Earth, the lava flows from the mantle are much darker than crustal material, which explains why mare are darker than highlands (which are already rather dark, with a maximum albedo of 20%). The cooling of lava flows led to the formation of specific features such as faults, domes and valleys (figure 6).

Another important result of high-precision isotopic analyses was the discovery that the Earth and Moon were formed from a single isotopic reservoir, different from that of the parent bodies of meteorites. The minerals constituting the Moon also show similarities to those of corresponding units on the Earth. However, the content of volatile elements is much lower: hydrogen is nearly absent (the Moon is most likely the driest place in the solar system) and potassium, abundant in terrestrial granites, is replaced in the lunar crust by calcium, a much more refractory element.

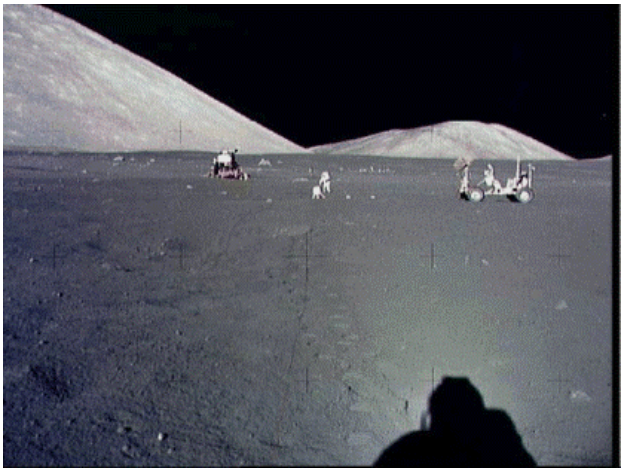

Figure 4. The Apollo 17 landing site. The fine-grained lunar regolith has a very smooth relief and contains only a small fraction of rocks. The footprints of the astronaut (forefront) will remain visible for millions of years. The tiny figure of the astronaut in this profoundly alien landscape is a striking illustration of the magnitude of the Apollo endeavor as well as the true scale of humanity in the universe.

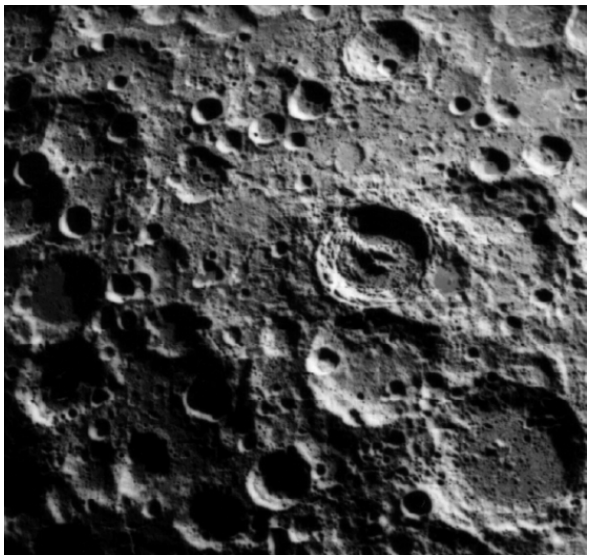

Figure 5. The highlands (here on the far side) have a chaotic landscape resulting from superimposed craters of all sizes. Complex structures such as terraces and central peaks can be observed in the youngest of these craters, such as crater King (right of center, with the lobster-shaped central peak).

Figure 6. The Apollo 15 landing site lies at the eastern edge of the Imbrium basin. Lavas from the center of Imbrium (upper left) filled out the basin up to the first concentric ridges of the rim of the basin (lower right). The sinuous Hadley rille (valley) most likely resulted from the collapse of an oversize lava tube. Tectonic features such as faults were formed by the cooling and relaxation of the lava fills.

Over the last 3 billion years, the role of internal processes was very small. At that stage, there were no planetesimals left in the inner solar system. Later impacts resulted from a small steady-state influx of impactors from the ASTEROID BELT and the KUIPER BELT due to gravitational perturbations. The surface of lunar maria has therefore remained very flat (the mean slope is only a few degrees). The main outcome of this secondary bombardment has been the formation of sparse fresh craters (the most recent large one is TYCHO, a few hundred million years old) and that of the lunar regolith from the slow grinding effect of small micrometeoroids. The relative age of surface units can be determined from crater counts, calibrating on the age of the nine sampled regions. The resulting evolution is extremely slow: the footprints left by the Apollo astronauts may well outlast humanity with a lifetime of a few million years. The absence of an atmosphere means that the main alteration effects of the surface result from the implantation of solar particles and micrometeoroid impacts. This slow evolution is called 'maturity', with an increase in glass content (up to 50%) and a decrease of the albedo. Rays are formed by the bright fresh material thrown out by recent craters and they slowly fade out as maturity increases.

The mare regolith constitutes an invaluable source of information on the history of dust and particle fluxes in the inner solar system. As there is no atmosphere, the surface is directly exposed to the interplanetary medium. The solidifying lavas provided a clean plate more than 3 billion years ago, which registered the effects of particle fluxes and micrometeoroids in a dust layer only 5–10 m thick. The 3.2 m deep drill core obtained during the Apollo 17 mission gives access to 1.7 billion years of history of the interplanetary medium (solar activity, asteroidal and cometary dust, galactic cosmic rays). For comparison, a 4 km deep ice core in the Antarctic corresponds to a few 100 000 yr of history. This unique lunar record should be fully exploited in the future with dedicated new cores extending to the base of the regolith.

The origin of the Earth–Moon system

The tremendous leap in knowledge of the Apollo period did not immediately lead to a widely accepted model for the formation of the Moon. The similarity between the Earth and Moon in terms of trace element and isotopic compositions was considered by geochemists as overwhelming evidence in favor of the fission hypothesis. However, laser echoes using corner reflectors on surface modules allowed the recession rate of the Moon to be measured with precision (4 cm yr^{-1}). Isotopic analysis techniques were also used to follow the growth pattern of corals over time, which constrains the number of days and lunar months per year in the distant past. Integrating this evolution backwards in time led to a highly elliptic and inclined orbit, totally incompatible with fission.

The major breakthrough occurred in the early 1980s:

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

- the development of chaotic dynamics showed that the orbits of planetary bodies can be stable for millions of years and then evolve rapidly as a result of perturbations by Jupiter and Saturn, hence making possible giant collisions in the early solar system;
- 3D hydrodynamic simulations which became possible with supercomputers demonstrated that a likely outcome of the off-center impact of a Mars-sized body with the Earth was the ejection of part of the mantles of the impactor and the proto-Earth into orbit, while the iron-rich cores fused.

This 'giant impact' model combines elements of all three of the original models: It involves a body formed somewhere else in the solar system (capture), then ejection of part of the outer layers of the transiently merged impactor and proto-Earth (fission), then accretion in orbit of the ejected material. When compared with the fission model, the giant impact model leads naturally to a highly inclined and eccentric early orbit, providing for the first time a dynamical solution consistent with the geochemical evidence. A few years later, numerical models for the condensation of the solar nebula resulted in 20 or more large planetary bodies, so that giant impacts are actually needed to trim down the number of planets. The giant impact model is now widely accepted, even though numerous details have to be sorted out (e.g. possible intermediate stages with smaller objects orbiting the Earth). This is a true Sherlock Holmes outcome, the far-fetched becoming plausible after all the obvious candidates had been eliminated.

Recent simulations (Canup and Asphaug 2001) of potential moon-forming impacts have identified a class of impacts that yield an iron-poor Moon, as well as the current masses and angular momentum of the Earth–Moon system. This class of impacts involves a smaller—and thus more likely—object than previously considered viable, and suggests that the Moon formed near the very end of Earth's accumulation, in contrast to previous simulations that required the impact to occur when the Earth was only about half formed.

Chaotic dynamical behaviors have another important implication for the Earth–Moon system: the inclination of the rotation axis of the Earth could increase to 60º or more if the Moon was not there to stabilize its evolution, with devastating consequences for the weather, each pole alternately facing the Sun. It can therefore be argued that the apparition of life on our planet required the presence of a large satellite such as the Moon.

The renewed interest in the Moon and the future of the lunar exploration program

During nearly 20 yr, the Moon was left aside by PLANETARY EXPLORATION. This led to a paradox: the Moon is indeed the only planetary body other than the Earth for which the complete sequence leading from reconnaissance to complete mapping, surface stations and rovers and eventually sample returns had been achieved. However, the very short timescale and the focus on a manned landing resulted in major gaps in the remote sensing and sampling programs, with a major bias in favor of the maria in the central regions of the near side, the most logical landing sites. Only two of the nine sampling sites (Apollo 16 and Luna 20) are in highlands, which cover nearly 80% of the lunar surface. For obvious communication reasons, all the Apollo sites are close to the center of the near side, and the highest latitude which was reached is 25º (Apollo 15). Only a few per cent of the surface were imaged at high resolution or were observed with chemical and mineralogical remote sensing analysis techniques. Furthermore, these techniques made major advances from 1970 to 1990, with improved detectors in the infrared, x-ray and gamma-ray regions of the electromagnetic spectrum.

The developments on the origin of the Moon confirmed the need for a better understanding of the global composition, a critical parameter for fine-tuning the giant impact model. This requires determining the contribution of a possible core to the total iron content and the chemical and mineralogical composition over the whole surface. Constraints can then be obtained by running petrological models which test how a given initial composition can lead to the observed abundances of minerals.

This renewed scientific interest benefited from two factors. By the early 1990s, missions to other planetary bodies had reduced the gap in knowledge, so that the Moon no longer appeared as the privileged child of the solar system family. More importantly, there was a major shift of policy within NASA, from highly complex and costly programs such as Galileo (Jupiter) and Cassini–Huygens (Saturn and Titan) to much smaller and more frequent missions, which could benefit from the major advances in miniaturization resulting from the 'Star Wars' program. The Moon was an ideal target for this so-called 'faster, better, cheaper' approach, with its small launcher requirements, short travel time and easy communications with the Earth. Similar strategies have been initiated by the European Space Agency (ESA) and Japan (unfortunately, the collapse of the Soviet Union led to a stand-by of the Russian planetary exploration program).

The lunar exploration program restarted on this new basis in 1994, with the CLEMENTINE mission (USA), which was to a large extent a spin-off of a militarily oriented technological effort. This small satellite (100 kg) carried three cameras with 11 channels from the visible to the near infrared and a laser altimeter. Its scientific return is quite significant. Clementine discovered the largest lunar basin, Aitken, covering most of the southern far side (figure 7). It provided the first multicolor database

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

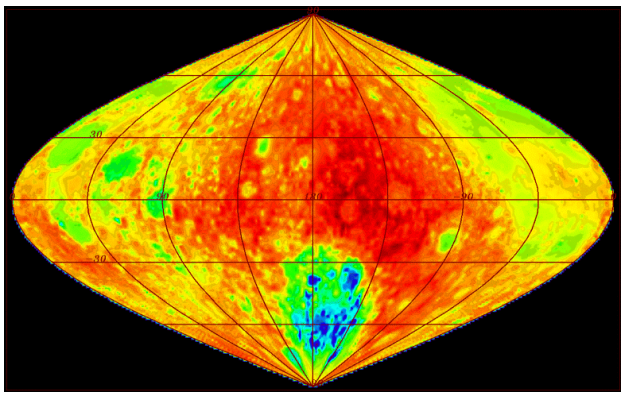

Figure 7. Topographic map of the Moon obtained by the laser altimeter of Clementine. Altitudes range from −12 km (dark blue) to +10 km (red). This map is centered on the far side (longitude 180º), which has a higher elevation and thicker crust than the near side. These observations revealed the largest lunar basin, Aitken, 1800 km in diameter, covering a large fraction of the southern far side. The thick far side crust prevented lavas from filling up this enormous basin, contrarily to similar features on the near side.

for the whole lunar surface, showing that the 'dry' basins of the far side were slightly contaminated by basaltic minerals: lava flows have indeed occurred, but were not quite able to reach the surface, expanding within and below the crust. Clementine also observed polar regions which are always in shadow, providing possible cold traps for volatile species such as water.

A second small polar satellite, LUNAR PROSPECTOR, was launched in early 1998. It provided the first complete coverage with a gamma-ray and neutron spectrometer as well as a state-of-the-art magnetometer. The observation of hydrogen trapped near the lunar poles may be linked to deposits of ice crystals in the permanently shadowed polar craters, although this interpretation is still controversial. If this is confirmed (e.g. by radar sounding) it opens important scientific prospects: such water deposits would then be likely to be provided by cometary impacts on the Moon, so that a core in the polar regolith could give access to the isotopic composition of volatiles from thousands of comets. In the final stage of the Lunar Prospector mission, the orbit was lowered to an altitude of 10 km, which gave unprecendented information on the gravity field. At this altitude, the orbit is not stable, and the inevitable impact was targeted near the south pole. This failed to give direct evidence for water deposits, but the expected signal was extremely marginal.

These discoveries showed that the Moon has quite a few surprises still in store. The next approved mission is LUNAR A, a Japanese mission with two penetrators equipped with seismometers dedicated to the question of the lunar core. This mission was originally planned for 1996, but development problems have delayed it until 2001 or 2002. The Japanese are also planning a very ambitious mission, SELENE, which was scheduled for 2003, but the problems with Lunar A may lead to a shift to a later date. A small ESA mission, SMART-1, will be launched in 2002, mainly as a technological test for a new ion propulsion system. It will provide new high-resolution images, the first comprehensive coverage with an x-ray spectrometer, a chemical analysis instrument which has a better spatial resolution than the gamma-ray spectrometer of Lunar Prospector, and the first medium-resolution IR spectra from lunar orbit, a key constraint on the mineralogical composition.

No discussion of the future of lunar exploration would be complete without mentioning the lunar base issue. The Moon is the obvious stepping stone for human exploration of the solar system, and countless studies have been made on establishing and maintaining a permanent habitat on the lunar surface. Such an endeavor is within reach of present technology, but it requires financial commitments in the scale of those of the Apollo program or the International Space Station. Similarly to these two programs, a lunar base can only be decided on a political basis, with science as a fringe benefit. Many scientific objectives can be reached much more cheaply by automated missions, with capabilities enhanced by the advances in on-board autonomy. The main potential benefit of a lunar base is a new lunar sampling program from medium to high latitudes, highlands or the far side, with deeper drill cores (10 m) giving access to 4 billion years of history of solar activity and the interplanetary medium. Samples from permanently shadowed polar regions would provide the final answer to the question of polar ices, so as to address the diversity and evolution over time of cometary impacts in the inner solar system. The timescale for a lunar base program is still highly uncertain. However, it would be surprising if it was not initiated before 2030, if space exploration worldwide is to retain any momentum.

Moon Maps

The MOON is our closest natural neighbor in space. Its mean distance from us is a mere 239 000 miles, and it has to all intents and purposes no atmosphere, so that there is nothing to veil its surface. Even with the naked eye a great deal can be seen, and it is easy to make out the broad dark plains, still known— misleadingly—as seas (maria). So far as is known, the first map of the Moon was drawn early in the 17th century by WILLIAM GILBERT, physician to Queen Elizabeth I, who is best remembered today as a pioneer investigator of magnetic phenomena. Of course he had no telescope, but the main maria can be identified easily enough.

The next map—and the first to be produced with telescopic aid—was drawn in 1609 by THOMAS HARRIOT, in England. Harriot, one-time tutor to Sir Walter Raleigh, was one of the first to use a telescope for astronomical work, and certainly he preceded Galileo, even though he never followed it up (he died in 1621). Harriot showed not only the principal maria, but also some of the craters and mountain ranges. One of his contemporaries was Sir William Lower, a Welsh baronet who seems to have obtained one of the early telescopes and looked at the Moon. His description of the lunar world was certainly graphic: he compared it with a tart which his cook had made—'there some bright stuffe, there some dark, and so confused lie all over'.

GALILEO began his telescopic work in the winter of 1609–1610, and used his primitive optick tube to make a whole series of dramatic discoveries. The Moon, he wrote, was 'full of inequalitie, uneven, full of hollows and protuberances, just like the surface of the Earth itself, which is varied everywhere by lofty mountains and deep valleys'. Frankly, his lunar map was not as good as Harriot's, but he did make a scientific effort to measure the heights of the lunar mountains, and his results were of the right order.

The next major advance came in 1647, and was due to HEVELIUS, a city councillor of Danzig (the modern Gdańsk) in Poland. Hevelius built an observatory on the roof of his house, and equipped it with the best telescopes available. He compiled a lunar map, showing considerable detail, and made the first attempt to name the lunar features. For example, the crater which we now call Copernicus was his 'Etna', while the dark-floored crater Plato was 'the Greater Black Lake'. The system never became popular, and was soon superseded by that of Giovanni RICCIOLI, who drew a new lunar map in 1651—based largely on the observations of his pupil, Grimaldi—and introduced many of the names which we still use today. Riccioli's method was to name the craters after famous personalities, usually—although not always—astronomers; Hevelius' geographical names were largely replaced, and only a few survive (such as the Alps and the Apennines). Riccioli gave the dark areas romantic titles, such as the Mare Imbrium (Sea of Rains) and the Mare Tranquillitatis (Sea of Tranquillity).

Obviously, the system had its drawbacks. Riccioli had no faith in the Copernican system and was convinced that the Earth is the center of the universe; therefore Copernicus was 'flung into the Ocean of Storms', although admittedly his crater is one of the most magnificent on the Moon and is the center of a system of bright rays. Predictably, Riccioli named two very large, dark-floored plains after Grimaldi and himself. Later scientists came off second-best; Newton, for example, was allotted a crater in the far south which is both large and deep, but so foreshortened that from Earth it is none too easy to identify at all.

The next important lunar map was that of TOBIAS MAYER, published posthumously in 1775. It was much smaller than that of Riccioli, a mere 8 in across, but it was reasonably accurate, and Mayer was the first to introduce a system of coordinates, the equivalent of latitude and longitude on the Moon. Unlike Hevelius, Riccioli and most of his predecessors he drew his map with south at the top, which is the way in which most telescopic observers see it—provided, of course, that they live in the northern hemisphere of the Earth.

Mayer was followed by JOHANN HIERONYMUS SCHRÖTER, who was never a professional astronomer—he was chief magistrate of the little town of Lilienthal, near Bremen in Germany—but may be said to be the first of the really great lunar observers. He made a large number of drawings and was responsible for many discoveries; for example, he was the first to show the lunar rills or clefts clearly, and his measurements of the heights of lunar mountains were better than Galileo's. Unfortunately, all his unpublished observations were destroyed in 1814, when the French invaded Germany, sacked Lilienthal and plundered Schröter's brass-tubed telescopes, which they believed to be gold.

The mantle of Schröter fell upon three of his countrymen: WILHELM LOHRMANN, WILHELM BEER and JOHANN VON MÄDLER. Wilhelm Lohrmann, a Dresden land surveyor, set out to compile a really large, accurate lunar map. The first sections were published in 1824, and were amazingly good. Unfortunately his eyesight failed him, and he had to give up.

Next came the superb work by Beer and Mädler. Using the modest $3\frac{3}{4}$ in Fraunhofer REFRACTOR at Beer's private observatory, near Berlin, they studied the Moon intensively for over 10 years, finally producing a map which was the basis for all later studies right up to the start of the space age. They followed it up with a book, *Der Mond*, which contains a full description of the entire visible surface and extended Riccioli's nomenclature. It appeared in 1838, and made a tremendous impact—and, surprisingly, actually held selenography up to some extent. Their map was regarded as definitive; the Moon is virtually changeless, so why observe it further?

Luckily there was one astronomer, Julius Schmidt, who did not agree. He was German by birth, but became Director of the Athens Observatory, and spent much of his life in Greece. He not only revised and completed Lohrmann's map, but also produced one of his own. It

was 74 in across, and stands up well when compared with modern charts.

During his observational work, Schmidt made the startling announcement that a small formation, Linné in the Mare Serenitatis (Sea of Serenity) had changed in form since the time of Beer and Mädler; they had described it as a small, deep crater, but Schmidt drew it as a white patch. The 'Linné affair' caused a great deal of discussion. In fact it seems quite definite that no change occurred there, but attention was drawn back to the Moon, and other charts were drawn up. The first important British chart was by Edmund Nevill, who wrote under the name of Neison. His book *The Moon*, published in 1876, contained a map based on Mädler's, with a description of every named formation. Neison was only 25 years old when his book appeared; curiously, he did very little more lunar work after 1882, when he went to South Africa to become director of the new observatory at Natal. Neison died in 1938, in retirement at Eastbourne in Sussex.

Systematic lunar observation was carried out around this time by the short-lived Selenigraphical Society, and, from 1890, by the Lunar Section of the British Astronomical Association. Meanwhile, photography was coming to the fore. Good photographs were obtained by pioneers such as J A Whipple and Warren de la Rue, and in the last decade of the 19th century Loewy and Puiseux, in Paris, produced an excellent series of plates covering the whole of the visible surface; subsequently, all lunar mapping was photographically based. In 1904 W H PICKERING, one of the few professional astronomers of the time to take a real interest in the Moon, issued a lunar atlas in which each region of the Moon was shown under five different conditions of illumination.

Amateur work flourished during the first half of the 20th century, with good maps by T G Elger and Walter Goodacre (successive Directors of the Lunar Section of the British Astronomical Association) and then by H P Wilkins, whose map was 300 in in diameter. In 1935 an 'official' map was published by the International Astronomical Union, drawn by W H Wesley and M A Blagg, but it was not a real success, and was defective near the Moon's limb, where the 'libration regions' are highly foreshortened. The obvious next step was to produce a complete photographic chart, similar to Pickering's but on a larger scale. This was attempted by G P Kuiper and his colleagues in the United States; it appeared in 1959. It was based on the best photographs available, but even so it did not meet all the requirements, and over-enlargement led to blurring of many features, particularly those near the lunar limb.

Then, after 1957, space research methods began to take over, and this caused a minor upheaval in procedure. Previously lunar maps had been printed with south at the top and west to the left (so that the well-formed Mare Crisium was near the western limb). The rocket men wanted to put north at the top. Finally, there was a debate in the International Astronomical Union, and the 'north-toppers' won the day; at the same time east and west were reversed, so that Mare Crisium is now near the eastern limb[1].

The first images of the Moon's far side, which is always turned away from the Earth, were obtained by the Russian spacecraft Lunik (or Luna) 3 in October 1959. Blurred and lacking in detail though they were, judged by modern standards, they represented a tremendous technical triumph. Craters, mountains and ray systems were detected, although one feature believed to be a lofty range, and even given an appropriate name (the Soviet Mountains) turned out to be nothing more than a ray, so that the name was tactfully deleted from later charts.

Once the Americans had announced plans for a manned landing before 1970, energetic efforts at mapping the surface were made. The Ranger probes crash landed, sending back pictures immediately before impact; the Surveyors made controlled landings, and these results, together with those of the Russian soft-landers, finally disproved the theory that the lunar surface was covered with a deep layer of dust. Then, between August 1966 and early 1968, the five United States Orbiters were put into closed paths around the Moon and sent back detailed photographs of both the Earth-turned and the averted hemispheres. By the end of the Orbiter program it was fair to say that the entire Moon had been surveyed in considerable detail.

Since then there have been several photographic probes, notably Clementine (launched January 1994) and Prospector (January 1998). These covered the polar regions of the Moon, which had not been mapped as accurately as the rest of the surface, and also sent back vast amounts of miscellaneous data. Of course, there have also been the observations made by the Apollo astronauts—and only the crews of Apollo 8 and 10–17 have actually had direct views of those regions which are always turned away from the Earth.

The one negative factor is that for various reasons—some of them financial—not all the Orbiter and Apollo photographs have yet been fully analysed. Much work remains to be done. There is, of course, no secrecy; all the images are made freely available to serious researchers—it is purely a matter of time and money.

The story of lunar mapping goes back a long way. It may be said to have started with the naked-eye chart by Gilbert, almost 300 years ago; then came the pioneer telescopic work, and the more detailed maps of the 18th and 19th centuries, many of them due to the work of amateurs; there followed the photographic atlases and, finally, the definitive maps drawn up from the spacecraft images.

It is interesting to look back at a comment made in 1840 by FRANÇOIS ARAGO, the leading French astronomer of the time. Arago was, very understandably, enthusiastic about photography, and said 'In this way we will be able to

[1] Piquantly, the Mare Orientale—the Eastern Sea—is now on the western limb. I have a connection here, because I was the first to show it—in 1939—and also proposed its name—PM.

accomplish one of the most difficult tasks in astronomy—mapping the Moon—in a few minutes'. Arago's timescale was wrong; we had to wait until the last part of our own century, but by now charting the Moon is to all intents and purposes complete.

Moore, Jonas (1627–79)

Born in Whitelee in Pendle Forest, Lancashire, became mathematics tutor to the Duke of York, brother of the future King Charles II, but lost this job through court intrigue; lived in London as a teacher of mathematics, and as a successful surveyor. He published text-books, and became Surveyor-General of the Ordnance, when he was knighted. His own career was thus more worthy than brilliant. Where he enters the history of astronomy as a first magnitude star is in his strong support of mathematics and astronomy. It was his support that got FLAMSTEED not only astronomical equipment and a degree from Cambridge University, but also an invitation to report as an expert witness to a commission, and to the King himself, on recently proposed methods to determine longitude. Moore then led the delegation that persuaded the King to set up the Royal Observatory at Greenwich in 1674 and to give Flamsteed the job as its first director. Moore provided Flamsteed with two clocks and a 7-foot sextant, which he used until 1688.

Moore, Patrick Alfred Caldwell (1923–)

Colorful British amateur astronomer, prolific writer, ubiquitous broadcaster and enthusiastic musician. Since 1957 he has presented monthly the BBC television program *The Sky at Night*, the longest-running such program with the exception of the news. He has published approximately one book per year of his life. His astronomical work has been in observations of the Moon and planets; his greatest impact has been inspiring a generation of British children to astronomy.

Moreton Waves

'Moreton waves', named for the observer who popularized them, are a solar phenomenon also known in scientific literature as 'Moreton–Ramsey waves', 'flare waves', 'flare-associated waves', 'MHD blast waves', 'chromospheric shock fronts' and various other combinations of terms which connote violently propagating impulsive disturbances. It is unclear whether all of the observations to which these terms have been applied pertain to a single physical phenomenon: there has perhaps been some overlap between the observations and the assumed physical properties of the observed occurrence.

Moreton waves (figure 1) are ideally observed in the wings of H alpha and appear as semicircular fronts propagating at speeds ranging from several hundred to over a thousand km s^{-1}. They form an arc, or 'brow shape', which can span up to 180°. Extrapolating the speed and locations of the arc indicates that the phenomenon's origin intersects well with the impulsive phase of the associated H alpha flare (if the flare exhibits an impulsive phase) (see SOLAR FLARES: IMPULSIVE PHASE). However, the arc may not form or may not be observable until it is tens of megameters from the flaring region, and subsequently can propagate to distances exceeding 100 Mm. The high speeds and distances of propagation, plus the associated radio and energetic particle observations, provided strong evidence of a coronal, rather than a chromospheric, origin. The H alpha manifestation of the wave is assumed to be the 'ground track' or 'skirt' of a three-dimensional disturbance.

The red- and blueshifts of the front propagating on the solar disk into the wings of H alpha appear to indicate evidence of chromospheric depression (and subsequent relaxation) as the wave propagates. The thin arc-shaped structure of the wave, the assumed force which would be required to cause depression in chromospheric features and their association with type II radio bursts (see SOLAR FLARES: RADIO BURSTS), led observers to conclude that these were shock waves or 'blast waves' initiated by the flare.

The 'ideal' observations of Moreton waves, however, may not represent all of the actual events observed. Although the 'depression' interpretation fitted some observations well, some other 'wave' observations did not exhibit strong Doppler shifts in H alpha, and some of these 'waves' were best observed in emission at the H alpha line center. Furthermore, some observations consisted of additional emission superposed on pre-existing structures, instead of the temporary enhancement of a feature due to a compressional disturbance propagating through it. It was concluded that these additional observations were best explained as ejecta moving above the CHROMOSPHERE. The ejecta, which could be SOLAR PROMINENCES or other moving material, could display speeds and structure comparable with those of the prototypical Moreton waves. Had this not been the case, perhaps these observations would have been considered as a phenomenon separate from Moreton waves. However, the wave observations consisting of ejecta and those consisting of depression fronts could also be two aspects of the same phenomenon, and some observations indicate this. The shock wave front could be observed in emission while its impact on the chromosphere could be seen in the depression of chromospheric features.

Several other observations have also been tentatively classed as Moreton waves. Before direct observations of wave disturbances were obtained in 1960, observers determined that there was evidence that a flare could initiate another flare or the abrupt activation or oscillation of a filament. Radio observations and the eventual observation of Moreton wave transients in the CORONA suggested a means of communication between the causal event and the affected region. Therefore, sudden filament activity, additional flaring and transient chromospheric brightenings have been identified as wave-associated effects. The inferred speeds of a wave transient (frequently lacking the actual observation of a wave), propagating between a flaring region and an initiated observable phenomenon, could exceed 4000 km s^{-1}. In the absence of supporting wave or radio burst observations, some of these measurements could fall under suspicion of being coincidental and not associative.

Recent observations by the Extreme Ultraviolet Imaging Telescope (EIT) on the SOHO spacecraft have provided unambiguous evidence (figure 2) for large-scale coronal impulses initiated during the early stage of a flare and coronal mass ejection. These waves are typically of lower amplitude than the Moreton wave shown in figure 1, can extend 360° surrounding the initiating region and usually propagate passively through the corona, leaving no observable signs of alteration. It is unclear whether these impulses observed by EIT correspond to the low-amplitude (and hence unobservable in H alpha) limit of Moreton wave phenomena or whether these waves have a different nature entirely. Other evidence of impulsive wave phenomena was recorded in white light coronagraph data as early as Skylab, and observations from the Mauna Loa Solar Observatory have indicated fast-moving disturbances moving in excess of several hundred km s^{-1} in the 10 830 Å He I data.

A clearer understanding of the various phenomena which have been classified as Moreton waves relies on more thorough observations and an increased understanding of their initiation mechanism. Solar flares and coronal mass ejections are magnetic reconfigurations utilized by the solar corona to liberate excess magnetic energy (see SOLAR FLARES: RELATION TO CORONAL MASS EJECTIONS). In expelling flux and mass via a coronal mass ejection, however, the corona frequently undergoes an additional reconfiguration in the form of a solar flare. For this reason, it is extremely difficult to extricate the actual driver or cause of Moreton waves.

A coronal mass ejection will deliver an impulse to the surrounding corona as the ejection propagates and expands. Some of the SOHO observations have given

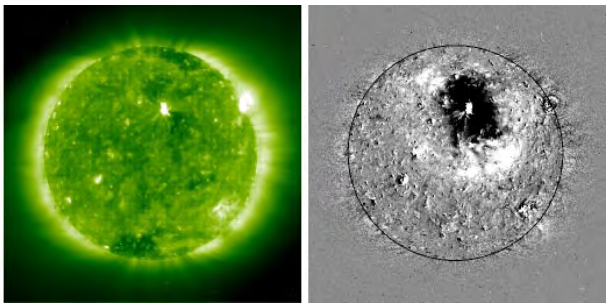
(a) (b) (c)

Figure 1. (*a*) H alpha chromospheric image of a Moreton wave at 02:47 UT on 24 September 1997, (*b*) *SOHO*/EIT 195 Å (dominated by an Fe XII emission line) coronal image of the wave at 02:49 UT and (*c*) H alpha image of the wave at 02:50 UT. The speed of the wave varied spatially and temporally, ranging from 250 to over 600 km s^{-1}. The flaring active region is visible in all three images. H alpha images courtesy of Barry Reynolds, Perth, Australia.



(a) (b)

Figure 2. (*a*) *SOHO*/EIT 195 Å image of the Sun on 12 May 1997 at 05:24 UT. (*b*) *SOHO*/EIT image at 05:07 UT with the pre-event image at 04:34 UT digitally subtracted from it. White (black) regions denote increase (decrease) in emission. The dark regions near the active region visible in both images are darkened regions associated with a coronal mass ejection. The bright circular ring of emission outside the darkened regions in the right-hand image corresponds to an increase in emission propagating at 250 km s^{-1}.

B J Thompson

evidence that some of the wave transients are driven by this effect. However, as mentioned previously, the timing and origin of H alpha Moreton wave observations coincide well with H alpha observations of flares. Because our current understanding of solar flares has advanced beyond the interpretation of 'massive bomb-like explosions', the wave initiation mechanism is unclear. Possible candidates are radiation pressure, rapid thermal expansion and accelerated particle drivers.

Morgan, William Wilson (1906–94)

American astronomer, staff member of the Yerkes Observatory, with Philip Keenan introduced stellar luminosity classes and the *Morgan–Keenan (MK)* classification scheme of stars based on the appearance of their spectra. With his students Donald E Osterbrock and Stewart Sharpless, he discovered the two nearest spiral arms in the Galaxy by mapping the distribution of bright O- and B-type stars whose distances were derived from their spectral classification. Morgan presented the paper in Cleveland in 1951 to tumultuous applause, unusual in a scientific conference.

Morin, Jean-Baptiste (1583–1656)

Doctor, alchemist and astrologer, born in Villefranche, Beaujolais, France, became professor of mathematics at the Collège Royal, published a defense of ARISTOTLE, attacked GALILEO, being convinced that the Earth was fixed in space. Morin proposed an impractical method to solve the longitude problem, based on measuring absolute time by the position of the Moon. He put the method in for a prize, and disputed for years the adjudication committee's negative verdict. Attacked DESCARTES, and his philosophy. A disputatious reactionary, he unsurprisingly was alienated from the scientific community.

Morning Star

A name given to Venus when it is visible in the east in the pre-dawn sky. Ancient astronomers believed that morning and evening apparitions of Venus were of two different planets; the morning planet was given the name Phosphor, or Phosphorus. As the morning star, Venus is moving from inferior conduction (when it lies between the Earth and the Sun) to superior conjunction (behind the Sun), and is visible for longest when it reaches the position known as greatest elongation west, when its angular separation from the Sun is greatest. The name 'morning star' is sometimes given to morning apparitions of Mercury.

Mount Graham International Observatory

The Mount Graham International Observatory at an elevation of 3200 m, is located near Safford, Arizona. The observatory specializes in advanced technology telescopic facilities that can benefit from the low water vapor and sharp images of the site, and its easy access. The observatory is operated by the University of Arizona. The 10 m diameter Heinrich Hertz Sub-millimeter Telescope (SMT) is a joint project of Arizona and the MAX-PLANCK-INSTITUT FÜR RADIOASTRONOMIE, Germany. The adjustment of the carbon fiber telescope surface has surpassed its goal of 15 microns rms. The Vatican Observatory/Arizona Lennon telescope has a 1.8 m $f/1$ primary figured to 17 nm rms. The third and largest telescope is the 2×8.4 ($f/1.14$) LARGE BINOCULAR TELESCOPE (LBT). It is a partnership between Arizona, Ohio, Italy (Arcetri), Germany and the Research Corporation. The LBT is now under construction and is expected to begin operation in 2002.

Mount John University Observatory, New Zealand

The observatory specializes in the observation of variable stars and binary stars by photometry and spectroscopy, especially using a high-dispersion échelle spectrograph. It is located in the center of New Zealand's South Island, at latitude 44 °S. Mount John is owned and operated by the Department of Physics and Astronomy of the University of Canterbury. It was founded in 1965 and currently there are a 1 m and two 61 cm reflecting telescopes. There are four resident staff at the observatory and three academic astronomers at the university site in Christchurch. A major collaboration with Nagoya and Auckland universities, the MOA project, is to study gravitational microlensing by CCD photometry.

Mount Stromlo and Siding Springs Observatories

Mount Stromlo and Siding Spring Observatories (MSSSO) are the astronomical observatories of the Australian National University. The facilities at Mount Stromlo Observatory were originally established as the Commonwealth Solar Observatory which commenced operation in the Australian Capital Territory in 1924. Expansion after the Second World War saw Mount Stromlo Observatory move into stellar astrophysics, and in 1957 it joined the ANU's Research School of Physical Sciences. Development of Canberra led to the establishment of a dark sky observatory at Siding Spring (SSO) west of Coonabarabran in New South Wales in 1964. Ten years later SSO became the host of the ANGLO-AUSTRALIAN OBSERVATORY with its 4 m and Schmidt telescopes.

The Observatories' major facility is the ANU 2.3 m telescope, opened in 1984. The telescope is a Cassegrain and Nasmyth alt-azimuth under full software control, capable of optical and infrared imaging and spectroscopy. A 1 m telescope is used for imaging, and there are smaller facilities too. At Mount Stromlo Observatory the ANU has a 1.9 m telescope with an excellent Coudé spectrograph and the 1.3 m Great Melbourne Telescope, which is fully automated and used for survey projects, such as the MACHO project. The MACHO project in 1993 recorded the first detection of gravitational microlensing, and over the following six years sought the density of massive compact halo objects by observing the Large Magellanic Cloud and the Galactic nuclear bulge. The project was a collaboration with two US universities/laboratories.

The academic staff of the ANU's Research School of Astronomy and Astrophysics is based at Mount Stromlo Observatory. The School supports a graduate program, offering a PhD in Astronomy and Astrophysics. Mount Stromlo is also the site of a satellite laser ranging facility, operated for the Australian government, and the Stromlo Exploratory, an astronomy visitor center and interactive science center. The ANU's engineering facilities for astronomical instrumentation are also concentrated at Mount Stromlo. The engineering group has built all of the current instrumentation for MSSSO and does external work for, e.g., the Anglo-Australian Observatory and the International Gemini Project.

Siding Spring Observatory also hosts the University of New South Wales patrol telescope. The Uppsala telescope is currently carrying out a Near Earth Object survey for the University of Arizona and NASA. At SSO the ANU operates a lodge for visiting astronomers and workshops for telescope maintenance and site upkeep.

Web update (30 April 2003)
In January 2003, the Mount Stromlo Observatory was largely destroyed by bushfires which ravaged Canberra. The fires destroyed four telescopes, the equipment workshop, eight houses which had been occupied by staff and an administration building. Preliminary estimates have valued the losses at more than $20 million. From a history of astronomy perspective this is a major catastrophe, as the following historically-significant telescopes were lost: the 74-in (Grubb-Parsons) Reflector, the 50-in Great Melbourne Telescope, the 30-in Reynolds Reflector, the 9-in Oddie Refractor, the Solar Telescope and the 26-in Yale-Columbia Refractor. In addition to its telescopes, the Observatory's library was destroyed, along with the Melbourne Observatory archives.

Mount Wilson Observatory

Mount Wilson Observatory, located in the San Gabriel Mountains near Pasadena, California, was founded in 1904 by George Ellery Hale with financial support from Andrew Carnegie. In the 1920s and 1930s, working at the 2.5 m Hooker telescope, Edwin Hubble made two of the most important discoveries in the history of astronomy: first, that 'nebulae' are actually island universes—galaxies—each with billions of stars; second, that these galaxies are moving away from us in all directions, resulting in an expanding universe. This second discovery became the basis for the 'Big Bang' theory of the origin of the universe.

In 1992, under a formal agreement between the Mount Wilson Institute and the Carnegie Institution of Washington, Mount Wilson Institute assumed complete responsibility for the funding and operation of the observatory.

The mission of the Mount Wilson Institute (MWI) is to maintain, manage and operate Mount Wilson Observatory for research, education and other projects in the field of astronomy. Among the institutions conducting research at the observatory in 1999 are the Harvard-Smithsonian Center for Astrophysics, UCLA, UC Berkeley, USC, Jet Propulsion Laboratory, Georgia State University and the University of Illinois. These guest research programs are funded and managed by the respective institutions, which pay a fee to MWI to defray the cost of site maintenance.

Mount Wilson Observatory facilities include the 2.5 m Hooker telescope; the 1.5 m telescope; the Georgia State University CHARA interferometer array, consisting of six 1 m telescopes arranged in a 350 m diameter configuration; the UC Berkeley Infrared Spatial Interferometer; the 45 m and 18 m solar tower telescopes; the Snow horizontal solar telescope; and the 60 cm and 35 cm remotely controlled telescopes, used by the Telescopes in Education (TIE) program for education and student research. A residence facility is maintained for the use of visiting astronomers.

The recent completion of an adaptive optics system on the 2.5 m Hooker Telescope has enabled this instrument to produce the sharpest images in the visible-light portion of the spectrum ever obtained by any telescope in the history of ground-based astronomy, achieving a resolution of 0.06 arcseconds. This is comparable to what would be obtained if the telescope were placed in space.

Mount Wilson's calm atmosphere result in the best 'seeing', i.e. natural sharpness and quality of its telescope images, in North America. This superb seeing is one of the reasons for the world-class performance of the 2.5 m adaptive optics system. It also led to selection of Mount Wilson as the site for Georgia State University's interferometer—the most powerful visible-light interferometer in the world, capable of a resolution of 0.0002 arcseconds.

Moving Groups

A moving group is a set of stars which have similar velocities and have a common origin, or, as EDDINGTON stated,

> Since some thousands of proper motions are available, it must be possible, if we take almost any star, to select a number of others the motions of which agree with its motion approximately. ... Clearly the agreement of the motions is no proof of association, unless there is some further condition which indicates that the coincidence is in some way remarkable.

The stars in a moving group are coeval, have the same chemical composition as the parental cloud and share the same space motion to within the internal velocity dispersion of the group. The space configuration of these stars is not restricted to any form. Some examples of moving groups are: GALACTIC OPEN CLUSTERS, OB and T Tauri associations and GLOBULAR CLUSTERS. The common space motion of moving-group members allows a clean identification of these stars. As a result moving groups have always been important in studies regarding STAR FORMATION, STELLAR EVOLUTION, and the UNIVERSAL DISTANCE SCALE.

Selection methods

Traditionally, stars in moving groups were selected using measurements of PROPER MOTIONS: the angular displacements of stars on the sky per unit of time. Because moving-group stars have similar space velocities they also have similar proper motions. Figure 1 illustrates the power of this approach. The top left panel shows the distribution of proper motions in the field of the globular cluster NGC 6397. There are two separate concentrations of stars, one being the cluster members (for practical purposes centered in the frame), the other being the field star population. Figure 1 shows three color–magnitude diagrams (CMDs): (left panel) CMD of all stars in the field, (middle panel) CMD of the moving-group stars and (right panel) CMD of the field stars. The simple selection criterion used in figure 1 already results in a clean CMD which can be studied to test theoretical models for stellar structure and evolution and to use them to derive the age and chemical composition of the moving group. Some more sophisticated methods to select moving groups will be discussed below.

Vector point diagram method

A diagram such as the top left panel of figure 1, in which the two proper-motion components of stars in a field are plotted versus each other, is usually referred to as a vector point diagram. A moving group in the field will reveal itself as an overdensity in this diagram. The vector point diagram selection method tries to fit the distribution of proper motions of the field star population and that of the cluster stars assuming that both can be represented by a smooth function, generally taken to be a two-dimensional Gaussian. For each star the fitted Gaussian of the field and the moving group can be evaluated at its measured proper motion; the ratio of 'moving-group Gaussian to field-plus-moving-group Gaussian' then determines the membership probability of a star (see figure 2).

The vector point diagram method works best if the spread in proper motions of the moving-group stars is small, so that they stand out clearly against the broader field star distribution. This spread in proper motions in the vector point diagram depends on (i) the internal velocity dispersion of the moving-group stars, (ii) the observational errors on the proper motions and (iii) the perspective effect, which causes the proper motions of stars with the same space velocity but different positions in the field to be different (since they are viewed from different directions). As a result, this method is optimally suited for moving groups which cover only a small fraction of the sky, typically less than $\sim$10 square degrees (depending on proper motion errors and internal velocity dispersion). Many such studies have been carried out in the past century, by comparing the stellar positions on photographic plates taken at different epochs. For moving groups which have larger angular sizes the perspective effect will wash out the concentration in the vector point diagram, and other selection methods are needed.

Convergent point method

The convergent point method exploits the perspective effect discussed above. An important characteristic of the perspective effect, although it creates a different proper motion for each star, is that the proper motions of moving-group stars will all be directed towards one point on the sky. This point is called the convergent point (see figure 2). This convergence of the proper motions is analogous to the fact that the two tracks of a rail-line appear to converge in the distance. Stars can easily be selected by determining whether their proper motions point towards the convergent point or not (see figure 2; also note the two stars that are non-members). Although selecting the moving-group stars is relatively easy, finding the convergent point is more difficult. Various versions of the convergent point method use different algorithms for finding the convergent point. They all require some numerical minimization process to search for groups of stars whose proper motions converge towards one point on the sky.

Three-dimensional velocity methods

The previous two methods select moving-group stars based on proper motions and positions. However, the preferred way to select moving-group stars is to search in velocity space directly. To calculate a three-dimensional velocity of a star, its position, proper motion, distance (or PARALLAX) and RADIAL VELOCITY are needed. The distance of a star is required to convert the proper

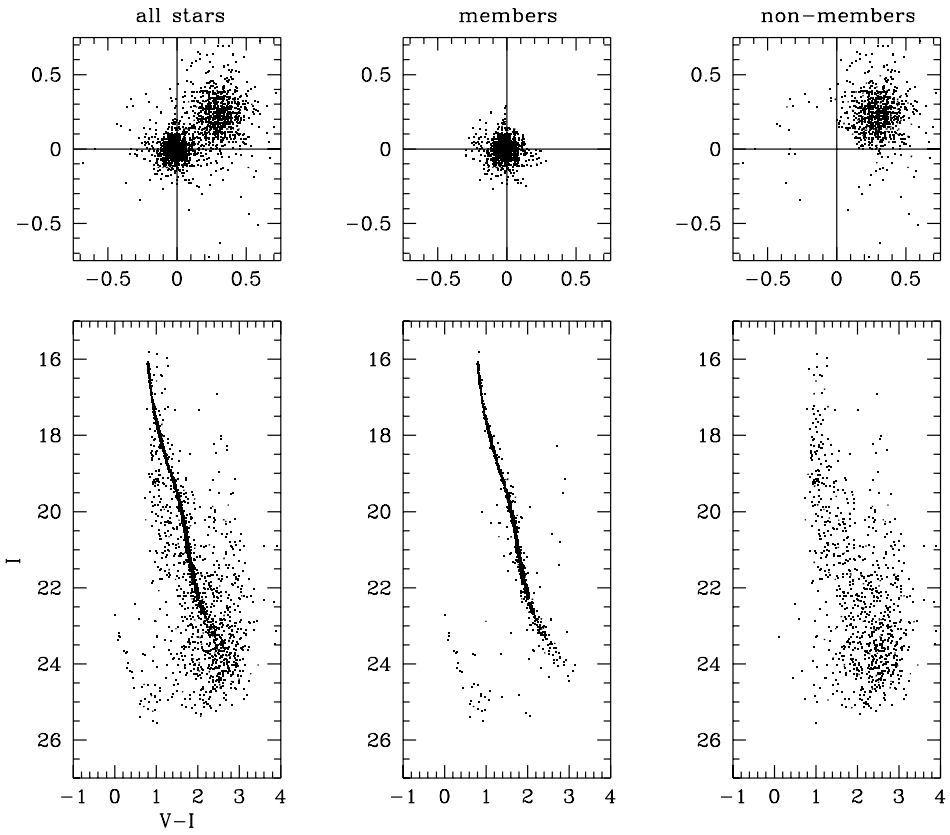

Figure 1. Vector point diagrams (top) and color–magnitude diagrams (bottom) for the globular cluster NGC 6397. All measurements were taken with the HUBBLE SPACE TELESCOPE over a period of 32 months. The left panels show all stars in the field of view of the cluster. The middle panels show the cluster stars; they have been selected based on their proper motions. The right panels show the remaining field stars after selecting the cluster. Note that after the selection of the cluster stars the white dwarf sequence (bottom left of middle panel) becomes apparent as a separate feature in the globular cluster color–magnitude diagram. The proper-motion zero point is chosen as the mean motion of the cluster stars. The proper-motion scale is the displacement in WFC (Wide Field Camera of the Hubble Space Telescope) pixels (1 pixel is 37.5 mas yr^{-1}). Adapted from King *et al* (1998 *Astrophys. J.* **492** L37–L40).

motion into the tangential velocity. The combination of the two components of the tangential velocity and the radial velocity then provides the three-dimensional (space) velocity of a star.

Many schemes have been developed to select moving-group stars using their three-dimensional velocities. The common denominator of all these methods is that they search for stars whose velocities are, within the measurement errors and internal velocity dispersion, equal to each other. The differences between the various three-dimensional velocity methods stem mostly from the differences in available data (e.g. catalog and accuracy of the data) used in the member selection. Most of these methods rely on computationally intensive numerical algorithms.

Moving groups and their astrophysical importance

Several types of moving groups will be discussed below: open clusters, OB associations, globular clusters and halo streamers.

Open clusters

Open clusters are gravitationally bound groups of stars, found in the Galactic disk. The small tidal radius (∼10 pc), combined with the small internal velocity dispersion (a few tenths of km s^{-1}), allows an easy selection of the members based on radial velocities or proper motions, e.g. with the vector point diagram method. The number of stars in an open cluster varies between a few dozen to several thousands.

The nearest open cluster, the Hyades, is located at ∼45 pc from the Sun; several other clusters, including the Pleiades, have distances on the order of 100 pc. The proximity of these clusters allows the acquisition of high-quality data. Besides easy membership selection, this results in well-defined main sequences in the HERTZSPRUNG–RUSSELL DIAGRAM, free of contamination by field stars. These main sequences and other measurements are used to refine and extend the theory of the internal constitution of the stars. The effects of stellar evolution can also be studied because the ages of observed open clusters vary between a few million years to a few billion years.

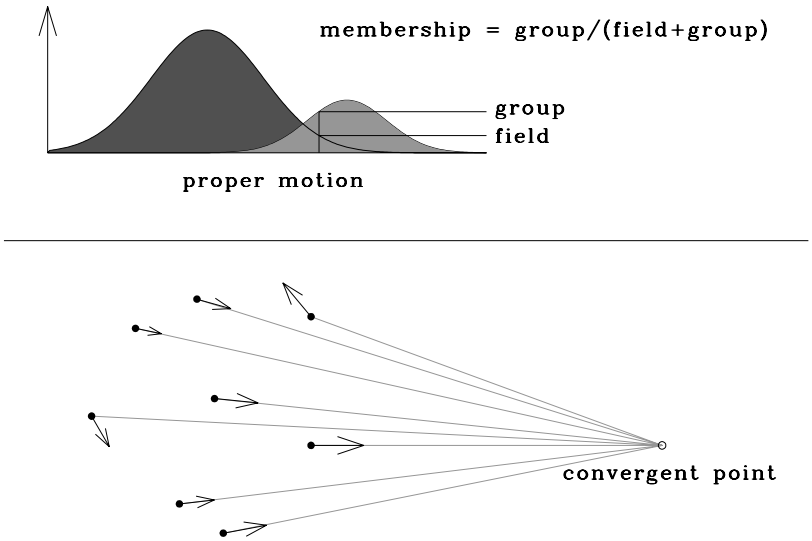

Figure 2. Schematic representation of the vector point diagram method (top): the Gaussians (here represented as one-dimensional) fitted to the proper motion distribution of the field (dark gray) and the cluster stars (light gray) are evaluated at a specific proper motion, i.e. the measured proper motion of a star. The ratio of the value of the moving-group Gaussian and the field-plus-moving-group Gaussian determines the membership probability for each star. Schematic representation of the convergent point method (bottom): stars whose proper motion is directed towards the convergent point are considered members.

Under the assumption that the unevolved parts of the main sequences of open clusters are identical, the distances of the clusters can be determined once the distance to one of them is known. The displacement between the main sequences of two clusters, corrected for interstellar extinction and for differences in metal abundance, is determined by their difference in distance (or distance modulus). For this reason open clusters, the Hyades open cluster in particular, have long been used as the main calibrator of the distance scale in the universe.

OB associations

OB associations are gravitationally unbound groups of typically a few thousand stars in the Galactic disk, including a number of early spectral type (O and B stars). The name OB association was introduced by the Russian astronomer AMBARTSUMIAN in 1947. He noted that these groups were unbound, based on their average density, and concluded that they therefore must be young; any unbound structure would have been disrupted under influence of the Galactic tidal field on a time scale of ∼50 million years. This conclusion was later supported by the theoretical insight, based on stellar evolution–structure theory, that early type (or massive) stars must be young. Further evidence for the youth of these groups was furnished by the discovery of star-forming INTERSTELLAR MOLECULAR CLOUDS nearby OB associations.

The main interest in the study of OB associations is to understand star formation in general and high-mass star formation in particular. It is thought that the majority of stars in the Galactic disk formed in OB associations. Therefore, studying these groups and their properties, such as the initial mass function or binary population, is of great importance in the understanding of stars and their evolution in general. Furthermore, the study of OB associations reveals properties of the Milky Way disk: the bright O and B stars trace the density distibution of the GALACTIC THIN DISK and in particular outline the spiral structure (OB associations generally form in or near spiral arms).

Similar groups containing only low-mass young stars have also been discovered. These are usually referred to as T associations, because of the presence of T TAURI STARS. A well-known example is the Taurus–Auriga association.

Identifying OB and T association members is more difficult than selecting open cluster members. Because associations are unbound they expand and can form large (30–100 pc) structures of which the closest ones (Sco OB2 at ∼130 pc) cover almost 1000 square degrees on the sky. Association members can thus only be identified using a convergent point method or a three-dimensional velocity method. Using photographic techniques for measuring proper motions of sufficient accuracy over such large areas proved to be nearly impossible. However, the globally accurate proper motions and parallaxes provided recently by the HIPPARCOS satellite allowed a reliable member selection for over a dozen nearby associations.

Globular clusters

Globular clusters are dense conglomerations of 10^5–10^6 stars. They have a typical tidal radius of 50–100 pc. The Milky Way contains nearly 150 of these clusters, distributed throughout the Galactic halo (see HALO, GALACTIC).

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Globular clusters played a crucial role in our view of the UNIVERSE. Based on the distribution of the visible globular clusters SHAPLEY concluded, in the 1920s, that the universe was 100 kpc in size and that the Sun was located 15 kpc from the center of the system of globular clusters. This enlarged the universe of KAPTEYN, the accepted model of the universe at the time, by a factor of 10 and put the Sun in a non-central position.

Globular clusters still play a key role in the understanding of our Galaxy, although not concerning its size, but rather its formation. They are the oldest objects (∼12 billion years) in the Galaxy and were presumably the first objects to form. Studying them gives information on the processes governing the formation of galaxies. They also provide valuable information on stellar evolution and structure theories and are ideal laboratories to test theories of STELLAR DYNAMICS in high-density environments.

Although the stellar density in globular clusters is very high, so that the cluster stands out against the background stars, member selection based on proper motions is still necessary to remove field stars from the sample (as illustrated in figure 1).

Halo streamers

The term 'halo streamers' is used for the tidal debris of small galaxies, e.g. galaxies the size of the SMALL and LARGE MAGELLANIC CLOUDS, which have fallen into the halo of the Galaxy. When this happens stars are stripped off the satellite galaxy owing to the tidal forces exerted by the Milky Way. These stripped stars then follow their own orbit in the galactic halo. This tidal debris generally forms long arcs, sometimes more than 360° on the sky (cf the MAGELLANIC STREAM and the SAGITTARIUS DWARF GALAXY).

Halo streamers are not moving groups in the sense of the definition given at the beginning of this article (they do not have the same space velocity), but stars belonging to these streams can be selected based on velocity information. The energy and angular momentum (integrals of motion) of these stars are nearly the same as for the infalling satellite galaxy. Thus instead of looking for stars with similar three-dimensional velocities, stars with similar integrals of motion can be identified as belonging to the same group. This approach can, in principle, also be applied to 'normal' moving groups.

The main reason for studying halo streamers and infalling satellite galaxies is to study the process of GALAXY FORMATION. How structure formation in the universe took place is still an open question. Did the small structures form first and did they subsequently form bigger structures (hierarchical structure formation) or were the big structures the first to form and did the smaller structures form later? By studying the Galactic halo and looking for halo streamers the questions about the formation and evolution of the halo of our Galaxy (and the Galaxy itself) may be answered (see also UNIVERSE: SIMULATIONS OF STRUCTURE AND GALAXY FORMATION.

Conclusions

The most important characteristic of a moving group is that the common space motion of the stars in such a group allows one to identify a set of stars which have similar ages and a similar formation history. Future astrometric satellites such as FAME and in particular GAIA will provide globally accurate proper motions (and radial velocities) with vastly improved accuracies, which will allow identification of moving groups and streamers not only in the solar neighbourhood but throughout the Galactic disk and halo, and will also allow measurement of the internal motions within these groups and structures. The physical characteristics of these moving groups then serve as tests for theories of star formation, stellar structure, stellar evolution, stellar dynamics and galaxy formation.

Mullard Radio Astronomy Observatory

The Mullard Radio Astronomy Observatory (MRAO) is operated by the Astrophysics Group of the Department of Physics at the Cavendish Laboratory. The observatory is located 8 km south-west of Cambridge at Lord's Bridge and was established in 1957 through the generosity of Mullard Limited with support from the Science Research Council. Current work is supported by the PARTICLE PHYSICS AND ASTRONOMY RESEARCH COUNCIL. The observatory is famed for the pioneering sky surveys of Sir Martin Ryle, who invented the technique of aperture synthesis, and for the discovery of pulsars by Antony Hewish and his student Jocelyn Bell in 1967. These contributions were recognized by the award of the 1974 Nobel prize for physics to Ryle and Hewish.

Instruments currently in operation include the Ryle Telescope, an array of eight parabolic dishes on a 5 km baseline, originally built in 1971 for high-resolution imaging of radio galaxies and quasars. It has been upgraded for mapping faint structures in the cosmic microwave background caused by the Sunyaev–Zel'dovich effect in nearby galaxy clusters and proto-clusters at high redshift. Mapping the microwave background to detect primordial density fluctuations of cosmological significance has been achieved with a prototype Cosmic Anisotropy Telescope (CAT) and this has led to the design of a more advanced instrument, the Very Small Array (VSA) soon to be commisioned on Tenerife; this is a joint project with JODRELL BANK and INSTITUTO DE ASTROFISICA DE CANARIAS. Milliarc second resolution at optical wavelengths for imaging stellar disks has been achieved with the Cambridge Optical Aperture Synthesis Telescope (COAST). Pioneered by John Baldwin, the COAST array of five mirrors on baselines up to 100 m will hopefully be succeeded by a Large Optical Array (LOA) now being designed for a site with clearer skies. At the other end of the spectrum, sky surveys at the low frequency of 151 MHz have been made with the Cambridge Low Frequency Synthesis Telescope (CLFST). This array of 60 tracking Yagi antennas provides 776 baselines up to 4.5 km simultaneously.

In addition to operations at MRAO the Astrophysics Group is developing instrumentation for the JAMES CLERK MAXWELL TELESCOPE (JCMT) on Mauna Kea, Hawaii. MRAO was closely involved with the design and construction of the JCMT, built jointly by the UK, Canada and the Netherlands, and is currently developing a submillimeter wavelength 'camera', a focal plane array of detectors for imaging large areas of sky.

The Astrophysics Group has a total staff (scientific, technical and administrative) of 68, plus 38 research students, and is engaged in a wide variety of observational, technical and theoretical projects.

Mullard Space Science Laboratory

The Mullard Space Science Laboratory (MSSL) is located in the Surrey Hills about 65 km to the southwest of London. It forms the major element of the Department of Space and Climate Physics, University College London.

The department undertakes research into climate physics, high-energy astrophysics, solar physics, space plasma physics and photon and particle detection systems. As the UK's largest university space physics institute, it includes professionally staffed electronic, mechanical and software engineering groups and has designed and built instruments for more than 30 orbiting spacecraft and 200 sounding rockets. Missions in which MSSL has participated include Giotto, Cluster, Cassini and XMM.

Multiple Mirror Telescope Observatory

At the time of its dedication in 1979, the 4.5 m Multiple Mirror Telescope (MMT) was the third largest optical telescope in the world. It featured so many ambitious design innovations that its completion heralded the beginning of the current generation of telescope design. The MMT was decommissioned in March 1998, and was replaced in March 1999 with a 6.5 m single-primary telescope.

The 4.5 m MMT was the first large optical telescope to incorporate multiple, lightweight primary mirrors in a common mount, a rotating building instead of a dome, active secondary mirror control during all observations, a high-performance altitude–azimuth mount and detailed finite element analysis of the telescope's structure during the design process. The telescope was a very successful research tool, fueling nearly 1000 scientific publications.

Studies carried out in Arizona in the mid-1980s showed that a 6.5 m primary mirror with a focal ratio of *f*/1.4 or less could be installed in the MMT building. When it was shown that such a telescope could have a substantial field of view, the interest of Smithsonian astronomers was aroused. A letter of intent to carry out such a project sealed the fate of the 4.5 m telescope in 1988. The successful casting (1992) and polishing (1997) of the first 6.5 m, *f* /1.25 primary in the STEWARD OBSERVATORY Mirror Laboratory triggered the decommissioning of the old telescope in 1998.

The new telescope was dedicated in May 2000 and scientific observations began the following month. The successful conversion of the MMT is ongoing. The first of three secondary mirrors has been installed. The new telescope has already improved the observatory's capabilities significantly. Notably, the telescope now has more than double the light-gathering power of its predecessor and two reflections have been removed from the optical path. Two new secondaries will be commissioned in 2001. The first, a 1.7 m mirror, will increase the angular field of view by a factor of 15 (to 1º) and the areal field by a factor of 225. The second, a 0.7 m deformable mirror, will provide a two-reflection, thermally clean adaptive focus.

Located at the 2600 m summit of Mount Hopkins, approximately 65 km south of Tucson, Arizona, the MMT Observatory is a facility of the University of Arizona and the Smithsonian Institution. It is staffed by approximately 20 full-time personnel and is funded jointly by its two parent institutions. Observing time is used by scientists at the University of Arizona, Arizona State University, Northern Arizona University and the Smithsonian Astrophysical Observatory. A significant amount of time is also made available to members of the international astronomical community through a public access programme.

Multiple Star

Any star system that comprises three or more components that are physically linked, i.e. that have a common gravitational field. It has been estimated that about 30% of all binary systems are actually triple; systems with more component stars are much rarer. A very few systems are known that have as many as six known components; Castor and the Trapezium at the heart of the Orion Nebula are the best-known examples.

Many triple star systems comprise a close binary pair and a much more distant (and often less massive) companion. The α Centauri system is of this type.

Multiple Stellar Systems: Types and Stability

A multiple stellar system is a gravitationally bound group of two or more stars. This rather broad definition includes binary, triple, quadruple and larger stellar systems, all the way up to star clusters and galaxies. It is useful to subdivide this diverse aggregation into three categories: binary stars, hierarchical systems, and non-hierarchical systems. Binary stars are explained at great length elsewhere in this encyclopedia, and so will not be discussed here (see BINARY STARS: OVERVIEW). Hierarchical stellar systems can be broken down into physically separate subgroups of stars that orbit each other in approximately Keplerian fashion. These systems can be completely described by a combination of individual stellar parameters, such as STELLAR MASSES, and relationships between pairs and other subgroups of stars, such as mass ratios, semimajor axes and eccentricities. This is in contrast with non-hierarchical systems, such as STAR CLUSTERS, which are best described by statistical quantities, such as central density, core radius, velocity dispersion, mass function, binary frequency and total mass.

Observed systems

Multiple stellar systems are ubiquitous. For example, among the stars within 17 light-years of the Sun in Alan Batten's 1999 catalog of the nearest stars, there are 38 single stars (including the Sun), 12 binaries and 4 systems of three or more stars. The frequency of triple and larger systems is

$$f_{\geq \mathrm{triple}} = \frac{N_{\geq \mathrm{triple}}}{N_{\mathrm{single}} + N_{\mathrm{binary}} + N_{\geq \mathrm{triple}}} \qquad (1)$$

and exceeds 7% for the 54 systems within 17 light-years. This is consistent with estimates of 5–15% in the literature for larger samples. Extrapolating this to the $\sim 10^{11}$ stars in the entire Galaxy yields a total of $\sim 10^{10}$ systems of three or more stars.

Famous multiple stellar systems include Castor (α Gem), which has six components, α and Proxima Cen, which is at least a triple system, and PSR B1620-26, a pulsar in a triple system in the globular cluster M4. All three display a hierarchical structure.

Essentially all of the systems of three to seven stars in the catalog of 612 multiples compiled by Tokovinin are hierarchical, and much of the research on multiple systems has focused on the hierarchical variety. Apart from some special situations, non-hierarchical stellar systems are dynamically unstable. Such systems will reassemble into stable hierarchical configurations on timescales that are relatively short compared with the stellar evolutionary timescale, and stars will often be ejected in the process (see STELLAR EVOLUTION).

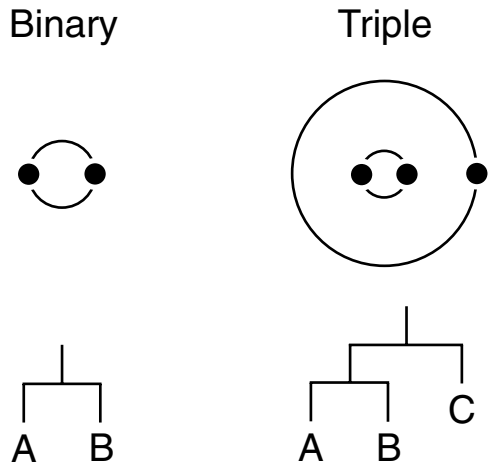

Figure 1. Schematic and 'mobile' diagrams for binary and hierarchical triple systems. A hierarchical triple system consists of two Keplerian orbits.

Some examples of hierarchies

It is useful to have a picture in mind of the structure of hierarchical stellar systems. Figure 1 shows a binary system and a hierarchical triple system. The latter can be broken down into two Keplerian orbits. The close pair of stars is called the inner pair and their orbit is called the inner orbit. The orbit of the third star about the inner pair is called the outer orbit. Figure 2 shows two hierarchical quadruple systems, and both can be broken down into three Keplerian orbits. Hierarchical systems of higher N can be broken down into $N - 1$ Keplerian orbits. Unlike the idealized systems shown in the figures, real systems are made up of eccentric and non-coplanar orbits, and stars of unequal mass, and interactions between the stars cause departures from Keplerian orbits.

Instabilities

Multiple stellar systems are subject to several kinds of instabilities. For example, non-hierarchical systems are dynamically unstable; they will rearrange themselves into stable hierarchical configurations and will often eject stars in the process. Most stability studies have focused on this, but there are additional instabilities. Close encounters in non-hierarchical stellar systems can result in stellar tidal interactions, physical collisions and mergers. The merger process may be assisted by the emission of gravitational radiation, especially when compact objects are involved. Also, stellar evolution of the individual components can result in significant mass loss from those components and mass transfer to other components. This can affect the stability of the system. Finally, external influences, such as intrusive encounters by stars, can also be the cause of dynamical instability in multiple stellar systems.

Stability of isolated systems of point masses

The literature on the stability of isolated systems of three point masses is quite extensive. A great deal of effort has

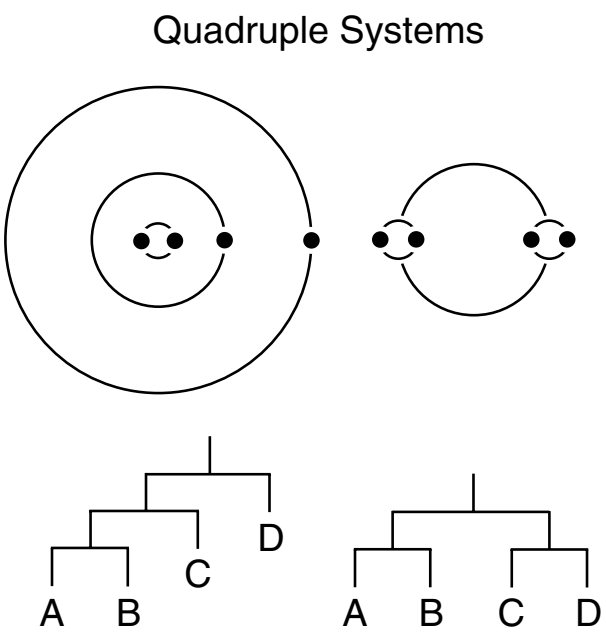

Figure 2. Schematic and 'mobile' diagrams for hierarchical quadruple systems. A hierarchical quadruple system consists of three Keplerian orbits.

gone into studying THREE-BODY PROBLEMS via a technique that was introduced in the 1870s by George Hill, and is described nicely by Szebehely and Zare. The method is based on c^2H in the two-body approximation, where c is the angular momentum of the system and H is the total orbital energy. If $c^2H < (c^2H)_{\rm crit}$, then the inner pair is permanently isolated from the outer body. This guarantees stability, since otherwise interactions between the third body and the inner pair can result in exchanges and ejections. The critical value, $(c^2H)_{\rm crit}$, is calculated for a configuration that is borderline stable, such as when all three bodies remain on a line as they orbit each other. The stability criterion in the case of coplanar circular prograde orbits and equal-mass stars reduces to $a_{\rm outer}/a_{\rm inner} \gtrsim 3$. Application of the c^2H criterion to the real triple systems in the sky indicates that the observed systems are all quite stable.

At least as much effort has gone into investigations of the stability of three-body systems through numerical integrations, which is perhaps the most effective way to study the problem. In N-body simulations, the initial conditions decide the outcome, and therefore the task is reduced to identifying those initial conditions which lead to stable systems and those which do not.

The numerical integrations reveal that many close stellar encounters occur in non-hierarchical systems, and this ultimately results in the ejection of one of the three bodies, usually the body with the smallest mass. Ejection often takes place following a close 'triple' encounter, which is when the eventual escaper approaches the center of mass of the three-body system as the other two bodies move away from it. The result is that the deceleration felt by the escaping body as it moves away from the center of mass is less than the acceleration the body felt as it approached the center of mass, leaving the body with sufficient velocity to escape from the other two. Additional results are that systems with high angular momentum are more stable than those with low angular momentum, retrograde inner and outer orbits are more stable than prograde orbits and systems with circular outer orbits are more stable than those with eccentric outer orbits.

There are many empirical formulae in the literature for the stability of triple systems, and those of Eggleton and Kiseleva are given here as an example. These are based on a large number of numerical experiments of triple systems with a variety of orbital eccentricities and inclinations, and component masses. They correspond to n-stability for $n \gtrsim 2$, which is the persistence of the hierarchical configuration for 10^n times the period of the outer orbit. Systems with an initial period ratio, X_0, exceeding $X_0^{\rm min}$ are stable, where

$$(X_0^{\rm min})^{2/3} = \left(\frac{q_{\rm out}}{1+q_{\rm out}}\right)^{1/3} \frac{1+e_{\rm in}}{1-e_{\rm out}} Y_0^{\rm min} \qquad (2)$$

and

$$(Y_0^{\rm min}) \approx 1 + \frac{3.7}{q_{\rm out}^{1/3}} + \frac{2.2}{1+q_{\rm out}^{1/3}} + \frac{1.4}{q_{\rm in}^{1/3}} \frac{q_{\rm out}^{1/3}-1}{q_{\rm out}^{1/3}+1} \qquad (3)$$

where $q_{\rm in} = m_1/m_2 \geq 1$ and $q_{\rm out} = (m_1+m_2)/m_3$ are the inner and outer mass ratios.

It has been mathematically proven that a three-body system cannot remain bound for all time if it was previously unbound. That is, a temporary triple system created by a collision between a binary and a single star cannot last forever. Ultimately one component will be ejected, probably the least massive one, although it could be any of the three. A binary–binary collision can, on the other hand, create a stable three-body system via the ejection of one star that carries away with it enough binding energy to allow the other three to remain bound indefinitely in a hierarchical configuration.

In comparison with three-body systems, far less has been written on the stability of systems consisting of four or more stars. Non-hierarchical four-body systems can decay into (1) a binary plus two single stars, (2) two binaries and (3) a stable triple plus a single star. There are currently no empirical formulae for the stability of four-body or larger systems. There are, however, many statistical results from numerical integrations regarding the properties of the break-up products. High-velocity escapers from the decay of small-N stellar systems can account for some of the OB runaway stars observed in our Galaxy (see STELLAR N-BODY SYSTEM: DISSIPATION). Kiseleva and collaborators found that 1% of all escapers from such systems have speeds greater than 30 km s^{-1}. Sterzik and Durisen successfully fit the speed distribution of the escapers from $N = 3$, 4 and 5 stellar systems to analytic distributions derived for zero-angular-momentum initial conditions. They also found that the binding energies, E_B, of the remnant binaries follow an $|E_B|^{-7/2}$ distribution.

Finite stellar sizes

Close encounters in non-hierarchical stellar systems can result in stellar tidal interactions, physical collisions and mergers. For example, if two main-sequence stars pass within a distance of twice the sum of their radii, then tidal effects will cause the pair to merge into a larger main-sequence star, which may be observable as a BLUE STRAGGLER. This mechanism can quickly decrease the number of stars in a non-hierarchical stellar system by one or more. Blue stragglers can be produced by the binary–single and binary–binary interactions that occur in the cores of star clusters. Finite stellar sizes also limit the maximum possible speeds of runaway stars ejected from small-N stellar systems, since it is the interactions with the closest encounters that avoid mergers which result in the highest ejection speeds.

Tidal effects in the inner pair of a hierarchical triple system can affect its stability. Circularization and synchronization are difficult to achieve in the inner pair, as tidal friction tends to circularize the inner orbit, while the presence of the third star does the opposite. Slower than synchronized rotations in the inner pair of three-body systems increase stability by shrinking the inner orbit, while faster than synchronized rotation decreases stability by expanding the orbit.

Angular momentum in three-body systems can be transported from the inner orbit to the outer orbit, and this may be a way of producing short-period binaries. There is observational evidence for an excess of distant companions to contact binaries compared with other types of binaries, which provides some support for this mechanism. If the contact binary eventually merges into a blue straggler, then the hierarchical triple system is reduced to a binary.

Stellar evolution

Mass loss from stars and mass transfer between stars in a multiple stellar system due to stellar evolution can significantly affect the stability of the system (i.e. the criterion given by equations (2) and (3) can change if the masses change). For example, slow mass loss from the outer component can improve the stability by gradually increasing the distance of the outer component from the inner pair of the system. Of course, too much mass loss, especially the essentially instantaneous mass loss that results from a supernova explosion, will unbind the system, so this represents a form of instability. Mass transfer between the inner components will also have an effect, albeit small, on the system stability, according to equations (2) and (3).

Systems in star clusters

The connection between multiple stellar systems and star clusters is intimate, as a star cluster is essentially a very large non-hierarchical multiple stellar system, and the endpoint of the dynamical evolution of a cluster is probably several small-N multiple stellar systems. Multiple stellar systems are created within star clusters via gravitational encounters between binaries and other stars. Subsequent exchange interactions tend to replace the component stars of multiple stellar systems with more massive ones and increase the system binding energy. Strong interactions can even kick the systems out of the cluster. The hierarchical triple system containing the pulsar PSR B1620-26 in the globular cluster M4 was probably formed by a binary–binary interaction. Continual encounters with stars in M4 will alter this system, and limit its stability.

Black hole triple systems

Multiple stellar systems consisting of SUPERMASSIVE BLACK HOLES are possible. If most galaxies contain central black holes, then galaxy mergers will inevitably produce binary black holes, since dynamical friction will guarantee that the holes will sink to the center of the merged galaxy and find each other. A subsequent merger with another galaxy has the potential to produce a triple (or larger) black hole system. Whether the third black hole can get close to the inner pair of black holes before the latter merge owing to dynamical friction and the emission of gravitational radiation depends on v_c, the root-mean-square velocity of stars at the center of the merged galaxy. Makino's calculations indicate that the binary black hole probably will not have merged before the third hole reaches the center if $v_c < 200$ km s^{-1} and that the binary probably will have merged by the time the third hole arrives if $v_c > 600$ km s^{-1}. The observed v_c in real galaxies span this range, so probably both outcomes happen. If the third black hole arrives at the center of the merged galaxy to find a binary black hole already there, then the resulting binary–single interaction may eject one of the black holes from the galaxy.

Musca

(the Fly; abbrev. Mus, gen. Muscae; area 138 sq. deg.) A southern constellation which lies between Carina and Circinus, and culminates at midnight in late March. It was first shown on Petrus Plancius' celestial globe of *c*. 1598 as Apis Indica (the Indian Bee), though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7. It was named Musca Australis (the Southern Fly) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2 (at which time there was also a now defunct constellation Musca Borealis, the Northern Fly). The shortened form was adopted by the IAU in 1922.

A small but not inconspicuous constellation, the brightest stars in Musca are α Muscae, magnitude 2.7, and β Muscae, a close binary with bluish-white (B2) components, magnitudes 3.5 and 4.0, separation 1.2″. There are three other stars brighter than fourth magnitude. Other interesting objects include NGC 5189, a tenth-magnitude planetary nebula of irregular structure, and two seventh-magnitude globular clusters, NGC 4372 and 4833, the former of which is partially obscured by dark nebulosity.

Muses-C (Mu-launched Space Engineering Satellite)

Japanese–US sample return mission to asteroid Nereus (1989ML). Scheduled for launch in early 2002. Intended as a technology demonstration mission. A US-built nanorover will image the surface and collect three samples for return to Earth. Other technologies to be tested include use of solar powered electrical propulsion system and autonomous navigation and guidance. The mission will last four years.

Naked-eye Astronomy

It is often assumed that to take a real interest in astronomy means acquiring a large and expensive telescope. This is emphatically not the case. Binoculars are relatively cheap, and are of great value astronomically (see BINOCULAR ASTRONOMY). But even with the naked eye there is much to see, and much to be learned. After all, telescopes were not invented until less than 400 years ago, and all the knowledge acquired in previous years depended upon the naked eye alone.

Probably the very first step after acquiring a preliminary knowledge of the main facts is to learn how to identify the constellations (figure 1). The stars become so much more interesting when you know which is which, and there is no real difficulty here, because the stars always remain in the same relative positions (their individual or proper motions are too slight to be noticed except over periods of many lifetimes). Moreover, it is seldom or never possible to see more than 2500 naked-eye stars at any one time, and the main constellations stand out clearly. A few nights' observation is enough to grain a working knowledge of the brightest patterns—that is to say, the stars of the first, second and third magnitudes. (The magnitude scale works in the manner of a golfer's handicap, with the brightest stars having the lowest magnitudes. The faintest stars normally visible without an optical aid are of magnitude 6.)

The best procedure is to select a few constellations which are immediately obvious, and use these are 'guides' to the rest. In the northern hemisphere, the two best guides are URSA MAJOR (the Great Bear) and ORION. Ursa Major is so far north in the sky that as seen from latitudes similar to those of Britain it never sets, and remains well above the horizon even when at its lowest; Orion, which is crossed by the celestial equator, is out of view during the middle of the year, when it is above the horizon only during daylight. From countries well south of the Earth's equator, such as Australia and New Zealand, Ursa Major is more or less inaccessible, though Orion can be seen from every inhabited country. However, there are other conspicuous 'guides' in the far south, and most people living in the southern hemisphere can readily identify the Southern Cross.

Consider first Ursa Major, with the seven fairly bright stars which make up the pattern known popularly as the Plough or, in America, as the Big Zipper. Two of these stars show the way to POLARIS, the Pole Star in Ursa Minor (the Little Bear), which lies within one degree of the north celestial pole, and which therefore seems to remain almost motionless in the sky, with the entire celestial sphere turning round it once in 24 hours. The 'handle' of the Plough shows the way to Arcturus, the brilliant orange star in the constellation of Boötes, the Hersdman, and so on. Orion is an even better guide when it is visible, because its stars are much brighter than those of Ursa Major; thus the three stars of the 'Belt' point southward to Sirius, the most brilliant star in the sky, and northward to Aldebaran, the red star in the constellation of Taurus (the Bull).

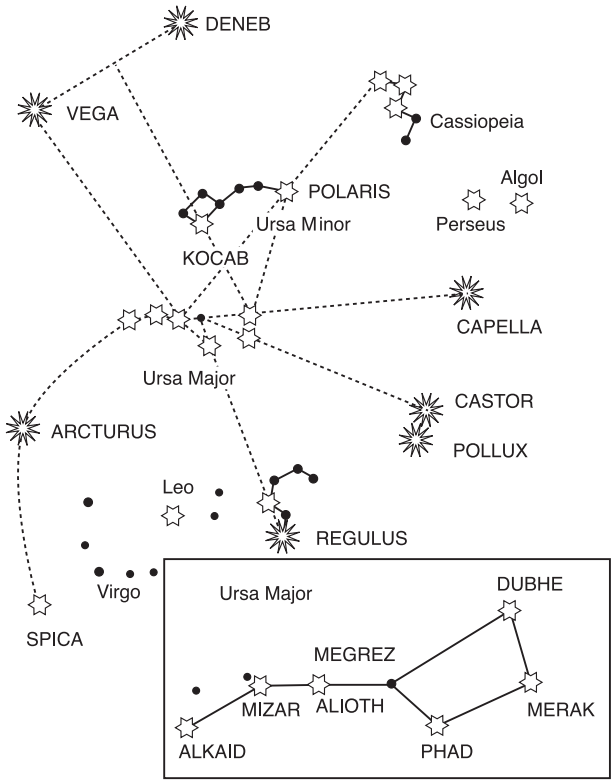

Figure 1.

Only the planets seem to wander around the sky. They keep to the Zodiac, and most are easy to recognize. Venus and Jupiter are always much brighter than any star; Mars is characterized by its strong red colour, and Mercury is always so near the Sun in th sky that it will probably not be seen unless deliberately sought. Only Saturn looks deceptively like a fairly bright star. The positions of the planets for any time can be looked up in astronomical ALMANACS or periodicals; and as soon as they have been identified they will easily be found again.

The MOON is much the closest natural body in the sky, and it has virtually no atmosphere, so that its surface features are always sharp and clear-cut. With the naked eye it is easy to see the outlines of the main dark areas, still miscalled seas (Latin, *maria*) even though there has never been any water in them (figure 2). Really keen-sighted persons can also make out indications of some of the mountain ranges, notably the Lunar Apennines, which form part of the boundary of the huge Mare Imbrium (Sea of Showers).

The Moon has no light of its own, and depends upon reflecting the rays of the Sun. At some full moons—they is to say, when the Sun, Earth and Moon are lined up—the Moon passes into the cone of shadow cast by the Earth; its direct supply of sunlight is cut off, and the Moon

Figure 2. Naked-eye view of the full moon: 1, Mare Frigoris (Sea of Cold); 2, Mare Imbrium (Sea of Showers)' 3, Mare Serenitatis (Sea of Serenity); 4, Mare Crisium (Sea of Crises); 5, Mare Tranquillitatis (Sea of Tranquillity); 6, Oceanus Procellarum (Ocean of Storms); 7, Mare Fœcunditatis (Sea of Fertility); 8, Mare Nectaris (Sea of Nectar); 9, Mare Humorum (Sea of Humours); 10, Mare Nubium (Sea of Clouds).

turns a dim, often coppery colour until it passes out of the shadow again. Lunar ECLIPSES do not happen at every full moon, because the Moon's orbit is appreciably tilted, and most full moons avoid the cone of shadow; eclipses may be either total or partial. Not all eclipses are equally 'dark'; everything depends upon conditions in the Earth's upper atmosphere, through which all sunlight reaching the eclipsed Moon has to pass. On some occasions the eclipsed Moon becomes so faint that it is difficult to see at all.

Another interesting phenomenon can be seen when the Moon is a slender crescent. The 'dark' side can usually be seen shining faintly. This is due to light reflected on to the Moon from the Earth, and is therefore known as the EARTHSHINE.

Naked-eye observations of the Sun can be dangerous; it is unwise to stare directly, even when the Sun is low over the horizon and looks deceptively mild and harmless. Now and then sunspots become large enough to be seen with the naked eye, but a dark filter should always be used. (Never use binoculars or a telescope for direct observation of the Sun, even with a filter; see SUN: SAFE OBSERVATION.) The Sun has a fairly regular cycle of activity; maxima occur about every 11 years. The next maximum is due around 2000–2001, so that naked-eye spots may be expected now and then.

Near maximum activity, electrified particles from the Sun cascade down into the Earth's upper atmosphere, producing the lovely glows known as AURORAS or polar lights—*auroras borealis* in the northern hemisphere, *aurora australis* in the southern. Because they are electrically charged, the particles tend to spiral down in the regions of the magnetic poles. Thus a dark night in, say, North Norway will very probably be lit by an aurora, but from Southern England displays are much less common, and from regions near the Earth's equator they are very rare indeed (though it is on record that an aurora was once seen from Singapore!).

Auroras may take many forms. Some are mere glows; others may produce vivid colours, with rays, curtains and 'coronas', shifting and changing in brightness constantly. A mahjor auroral display is a magnificent sight, and is of course ideally suited to photography. Amateur observations of auroras are of real value, and are collected and correlated by local and national astronomical societies.

When the Sun is setting, a brilliant green flash may occasionally be seen as the last segment of the solar disk passes below the horizon. This 'green flash' is a purely atmospheric phenomenon, and is very uncommon; a very clear horizon is essential, preferably over the sea. Much more common are solar and lunar haloes, luminous rings round the Sun or the full Moon. These are due to very high ice-crystal cloud at well over 20 000 feet above ground level. They can be quite spectacular.

A solar eclipse occurs when he new moon passes directly between the Sun and the Earth, blotting out the brilliant solar dsisk for a brief period. Eclipses of the Sun may be either total, partial or annular. During a total eclipse the entire brilliant disk of the Sun is hidden, and the solar atmosphere flashes into view; for a brief period—never as long as eight minutes, usually much less; the naked-eye observer can see the solar CHROMOSPHERE, the red glowing masses of hydrogen once called red flames and now known as prominences, and the glorious pearly CORONA, which extends outward from the eclipsed Sun. A total eclipse is probably the most magnificent sight in all Nature (figure 3), but the Moon's shadow is only just long enough to touch the Earth, so that as seen from any particular locality total eclipses are rare; from England, the total eclipse of 11 August 1999 was the last until 2090. During totality it is quite safe to look directly at the Sun, without any dark filter, but even a small segment of the brilliant disk remaining visible means that the dangers return. It is only too easy to damage one's eyesight. Partial eclipses are much less interesting, since the Sun's surroundings cannot be seen. If exactly alignment occurs when the Moon is in the far part of its orbit, it cannot cover the Sun completely, and a ring of sunlight is left showing round the dark mass of the Moon; this is an annular eclipse (Latin *annulus*, a ring).

Observations of METEORS are best made with the naked eye, and here the amateur observer can carry out work of real importance (see also AMATEUR–PROFESSIONAL COLLABORATION IN ASTRONOMY). Meteors are cometary débris. As a comet moves along in its orbit, it leave a dusty 'trail' behind it; when the Earth passes through such a tail it collects many particles, and the result is a shower of shooting stars. Many meteor showers occur each year; the most reliable shower is that of the Perseids, seen from late July through to mid August. The average meteor is smaller than a grain of sand, so that what we see is not the particle itself, but the effects which it produces in the atmosphere as it burns away.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Figure 3.

Because the meteors in a shower are moving through space in parallel paths, they seem to issue from one particular region of the sky; thus the August meteors come from the direction of the constellation Perseus, hence their name. Other showers are much less predictable; the Leonids, of 17 November, are usually sparse, but may at times produce true 'meteor storms', as in 1966, when it was said that meteors rained down from the sky like snow flakes' for a few hours. There may also be sporadic meteors, not connected with any showers, which may appear from any direction at any moment.

The naked-eye meteor observer can make useful observations simply by counting the numbers of meteors seen over definite periods. To plot their paths, the best method is to hold a rule up again the star background, noting the points where the meteor is first and last seen, and then drawing the track on a chart; the radiant position will soon become evident. For this work, a sound knowledge of the constellations is of course needed.

Naked-eye COMETS are not common, though they do appear sometimes: comets Hyakutake (1996) and Hale-Bopp (1997) have been two recent examples. The periodical comets, which return regularly, are in general too faint to be seen without optical aid. Even *Halley's Comet*, which returns every 76 years and can become very bright indeed, was inconspicuous at its last return in 1986; unfortunately it will be no better at its next return, that of 2061.

Finally, what about naked-eye observations of the stars? They are of different colours; some are white, some bluish and some orange or red. Thus in Orion the two leaders, Betelgeuse and Rigel, are quite different. The warm orange of Betelgeuse contrasts sharply with the glittering whiteness of Rigel. Stars twinkle only because their light is disturbed as it comes to us by way of the Earth's atmosphere; a star such as Sirius will twinkle strongly, and will seem to flash various colours of the rainbow, even though Sirius is in fact a pure white star. A star near the zenith or overhead point will twinkle much less than a star which is lower down in the sky, because its light is coming to us by way of a thinner shell of atmosphere.

Most stars shine steadily for year after year, century after century, but there are some which do not; these are the VARIABLE STARS. One such star is Betelgeuse in Orion, which is well advanced in its evolution and has become unstable; it swells and shrinks, changing its output as it does so. At times it may be almost as bright as Rigel, while at others it is more comparable with Aldebaran. Another variable is Mira in Cetus (the Whale), which can rise to the second magnitude—as bright as the Pole Star—but which remains below naked-eye visibility for much of the year; it reaches maximum about every 331 days (the period is not constant). Algol, in Perseus, fades by more than a magnitude every 2.3 days, remaining faint for a mere 20 minutes before recovering, not because it is intrinsically variable but because it is regularly eclipsed by a darker companion passed in front of it. Naked-eye observers can follow the changes in these variable stars, by comparing them with nearby stars which are constant in brightness.

Occasionally a star will flare up where no naked-eye star has been seen before. This is termed a NOVA. Nova means 'new', but a nova is not in fact a new star at all; what happens is that a formerly dim star suffers a tremendous outburst, and flares up to many times its normal brilliancy before fading back to obscurity. Novae cannot be predicted, and several have been discovered by naked-eye observers. One nova, seen in 1918 in the constellation of Aquila, briefly outshone every star in the sky apart from Sirius, but has now become a very faint telescopic object.

It is clear, then, that there is much to be seen in the skies, even without any optical equipment. the naked-eye observer will always find plenty to occupy their attention.

Nançay Radio Observatory

The Nançay Radio Observatory has the largest radio telescopes in France. Founded in 1952, it is located 200 km south of Paris and is operated by the Paris Observatory, in association with the CNRS, and co-financed by the 'Région Centre'. A technical staff of 50 operates the site. Its main instruments are: the decimetric telescope, with the equivalent surface of a 94 m diameter dish used for 21 cm H I and 18 cm OH spectral line observation of comets, evolved stars and galaxies as well as pulsar observations; the radioheliograph, a 43 element interferometer dedicated to solar corona observations at metric wavelength; the decametric array of 144 elements operating at 3–30 m wavelength for studies of Jupiter and the Sun.

Napier [Napeir, Nepair, Nepeir, Neper, Napare, Naper, Naipper], John [Jhone] (1550–1617)

Born in Merchiston Castle, Edinburgh, Scotland, educated in protestant theology at St Andrews University, and on the continent of Europe (Paris, Italy and the Netherlands). Invented logarithms, formulae used in solving spherical triangles (*Napier's analogies*) and *Napier's bones*, an 'analog computer' used for multiplying dividing and taking square and cube roots. Logarithms were a breakthrough for the astronomical calculation of planetary and cometary orbits to the large number of decimal places that high precision required, and Napier himself wrote of his motivation to invent them: 'Seeing there is nothing (right well-beloved Students of the Mathematics) that is so troublesome to mathematical practice, nor that doth more molest and hinder calculators, than the multiplications, divisions, square and cubical extractions of great numbers, which besides the tedious expense of time are for the most part subject to many slippery errors, I began therefore to consider in my mind by what certain and ready art I might remove those hindrances'. It was through the use of logarithms that KEPLER was able to reduce BRAHE's observations, determine his laws and pave the way for Newton's theory of gravitation. LAPLACE wrote that logarithms, 'by shortening labor, doubled the life of the astronomer'.

NASA

The guiding principles for US exploration of air and space have remained remarkably consistent for more than 80 years. In 1915, Congress created an organization that would 'supervise and direct the scientific study of the problems of flight, with a view to their practical solutions'. That organization, the National Advisory Committee for Aeronautics (NACA), evolved into NASA four decades later.

In 1958, NASA was established and the journey begun in 1915 has been continued by aviators, astronauts and robotic spacecraft from the dunes of Kitty Hawk to the edge of the atmosphere and to the surface of the Moon and Mars. American spacecraft have explored more than 60 worlds in our solar system, while methodically peering back in space and time to reveal many of the secrets of the universe.

NASA employs 18 500 civil servants and generates thousands of high-tech jobs in the private sector. The Agency operates nine Field Centers, the contractor-operated Jet Propulsion Laboratory, and the Wallops Flight Facility. The Fiscal Year 2000 NASA budget is $13.6 billion.

NASA provides a variety of on-line services via the Internet. The URL's listed below provide key information about each of the topics. In addition, photographs, scientific and technical information, news releases and organizational data are accessible through a number of World Wide Web sites. Other key starting points for exploring NASA on the 'net' are listed below.

- NASA's main web site is:
  http://www.nasa.gov

NASA Infrared Telescope Facility

The NASA Infrared Telescope Facility (IRTF) is the principal observatory in the world dedicated to solar system astronomy; 50% of the observing time is specifically reserved for such observations. It is a 3 m telescope located at 4145 m on the summit of Mauna Kea, on the island of Hawaii. It has been operated for NASA by the University of Hawaii's Institute for Astronomy since it opened in 1979. It is optimized for infrared observations and has imaging and spectroscopic instrumentation covering the region; active optics also provide very high angular resolution.

For further information see
http://irtf.ifa.hawaii.edu.

Nasir al-Din al-Tusi (1201–74)

Astrologer, astronomer and mathematician, born in Tus, Khorasan (now Iran), astrologer to the Isma'ili governor Nasir ad-Din 'Abd ar-Rahim. Captured and imprisoned in Alamut, in a fortress which was the headquarters of the terrorist Assassins, he betrayed the defenses to the invading Mongols. He was rewarded by Ilkhanid dynast Hulagu with an observatory, built with Chinese assistance at Meragha in 1262, and fitted out with instruments some of which were designed by al-Tusi himself. He used them in a 12-year program to observe planetary movements, and published the *Ilkhanic Tables* of planetary and star positions. Al-Tusi wrote about astronomical instruments, translated and commentated on classical works and researched into trigonometry.

Nasmyth Telescope

An altazimuth reflecting telescope with relatively stable platforms for mounting heavy, large, delicate or developmental equipment which cannot be, or has not been, engineered to cope with attitude changes during the tracking of a star. The optical configuration is the Cassegrain type, with a primary and secondary mirror, and an additional third flat mirror mounted at the intersection of the altitude and azimuth axes. The third, plane mirror, known as the 'Nasmyth flat', reflects the light beam from the secondary mirror through a right angle, along the altitude axis, and through an altitude bearing to a focus at the side of the telescope. Analysis equipment is supported at the Nasmyth focus on a platform mounted on the pillar that supports the altitude bearing. The Nasmyth platform rotates on the azimuth bearing, typically relatively slowly at a speed of one revolution per day (more during the transit of a target star across the meridian), but remains horizontal. The Nasmyth flat can be turned about the optical axis to switch the light beam of the telescope from one bearing to the other, so a Nasmyth telescope usually has two Nasmyth platforms. The William Herschel Telescope on La Palma is a Nasmyth design. The Gemini telescope project considered and rejected the Nasmyth design in order to avoid the thermal effects of the third mirror and its support mechanism in the light beam.

James Nasmyth was an English mechanical engineer and gentleman astronomer who invented this telescope configuration in his less agile later years as a means to provide a convenient viewing arrangement, in which he sat on one of the platforms and viewed the sky comfortably through an eyepiece at the altitude bearing.

Nasmyth, James (1808–90)

Engineer, born in Edinburgh, invented the steam hammer and many other devices in mechanical engineering especially for canal working. A childhood interest in astronomy meant that he maintained an interest in astronomical instruments in his professional engineering career, making two conventional small telescopes for himself, and visiting STRUVE during a visit to St Petersburg, for example. He made speculum mirrors and telescopes for WILLIAM LASSELL, WARREN DE LA RUE, and himself. The largest telescope which he made in 1845 had a 20 in mirror, and had a novel mechanical design, which 'brought the stars down to him'. It was an altazimuthally mounted Cassegrain-type, but a third mirror in the optical path reflected the light out of the telescope tube along the altitude axis. This arrangement is called a *Nasmyth telescope mounting*, and is used on all large modern telescopes. Nasmyth sat comfortably and stably with his eye at the center of the altitude bearing, operating handles to move himself and the telescope in azimuth, and to move the telescope in altitude, making his observations of the Moon and the Sun. On the Sun he observed, during occasional moments of superb seeing, what he termed a 'willow leaf' pattern; this appears to have been the discovery of solar granulation.

National Astronomical Observatory, Japan

The National Astronomical Observatory of Japan (NAOJ) was founded in 1988, integrating the Tokyo Astronomical Observatory of the University of Tokyo, the International Latitude Observatory of Mizusawa, and the solar radio group of the Research Institute of Atmospherics, Nagoya University. It is an inter-university research institute for astronomy under the jurisdiction of the Ministry of Education, Science, Sports and Culture. The headquarters is located in Mitaka near Tokyo. It has six division groups, and the scientific coverage is quite wide, ranging from geodesy to radio astronomy, even including the research and development of gravitational-wave detectors. Some groups are participating in joint space science missions such as the solar x-ray telescope (Yohkoh), radio telescope (Halka).

A total of about 300 permanent staff are working in NAOJ. There are nine ground-based research facilities: Mizusawa Astrogeodynamics Observatory; Norikura Solar Observatory; Okayama Astrophysical Observatory; Dodaira Astronomical Observatory; Nobeyama Solar Radio Observatory; Nobeyama Cosmic Radio Observatory; Astronomical Data Analysis Center; Advanced Technology Center; Public Relations Center; World Solar Data Center; and Subaru Telescope Hawaii Facility, which is the overseas facility having an 8 m optical/infrared telescope 'Subaru' on Mauna Kea, Hawaii.

Since April 1992 NAOJ has been participating in the Department of Astronomical Science, School of Mathematical and Physical Science, the Graduate University for Advanced Studies, and fulfilling the responsibilities of postgraduate education.

National Centre for Radio Astrophysics

India's National Centre for Radio Astrophysics (NCRA), located on the Pune University Campus, is part of the TATA INSTITUTE OF FUNDAMENTAL RESEARCH. At Khodad, 80 km from Pune, NCRA has set up the Giant Metrewave Radio Telescope (GMRT), the world's largest telescope operating at meter wavelengths. GMRT consists of 30 fully steerable dishes of 45 m diameter, spread over a 25 km area. Another meter-wavelength facility operated by NCRA is the Ooty Radio Telescope (ORT), a unique 530 $\times$ 30 m steerable parabolic cylinder located along a hill slope in southern India. NCRA has about 20 astronomers, 30 engineers and other technical and support staff. NCRA's research activities are mainly in the areas of: cosmology and extragalactic sources like radio galaxies, quasars etc; galactic sources including pulsars, supernovae remnants, etc; Sun and solar wind; and the interstellar medium.

National Radio Astronomy Observatory (NRAO), Tucson

One of the radioastronomy facilities funded by the US National Science Foundation, and operated under cooperative agreement by Associated Universities, Incorporated. Located in Tucson on the campus of the University of Arizona.

The NRAO operates and maintains a 12 m telescope on Kitt Peak, 80 km southwest of Tucson, for astronomical observations at millimeter wavelengths. It is the only millimeter-wavelength telescope in the US operated full-time as a national facility.

Originally known as the 36 Foot Telescope, the instrument was responsible for the birth of millimeter-wavelength molecular astronomy. Dozens of molecular species in the interstellar medium were first detected at Tucson.

In 1984, the telescope's reflecting surface and surface support structure were replaced and the 36 Foot was renamed the 12 Meter. Current research covers studies of molecular clouds and galactic star formation, evolved stars, astrochemistry and external galaxies.

Engineers at NRAO Tucson are also involved in development and support for the ATACAMA LARGE MILLIMETER ARRAY (ALMA).

National Research Council

The National Research Council of Canada (NRC) has the Parliamentary mandate 'to operate and administer any astronomical observatories established by the Government of Canada'. NRC exercises this mandate through its HERZBERG INSTITUTE OF ASTROPHYSICS, which provides astronomical facilities, and related infrastructure and services to university scientists and their students. NRC also provides a time service through its Institute of National Measurement Standards.

National Solar Observatory

The National Solar Observatory (NSO) operates several solar telescopes on Sacramento Peak in Sunspot, New Mexico, on Kitt Peak near Tucson, Arizona, and in a global network with six sites around the world. These telescopes provide unique capabilities and have an unsurpassed wealth of focal plane instrumentation available, including the first solar adaptive optics system. The NSO mission is to provide state-of-the-art telescope facilities to the solar community and to conduct pioneering research in solar physics. Highlights include the discovery of solar filigree (small magnetic flux tubes), elucidation of the global nature of the solar five-minute oscillations, and mapping of the interior structure of the Sun. The world's first and best-instrumented vacuum tower telescope, the 76 cm Richard B Dunn Solar Telescope, the Evans Coronal Facility (40 cm coronagraph), and Hilltop flare patrol are located at Sacramento Peak. The McMath–Pierce, located on Kitt Peak, is the world's largest (1.5 m) solar telescope and it is the premier facility for infrared studies of the Sun. The Kitt Peak Vacuum Tower Telescope makes daily magnetic maps of the entire visible solar disk. The six GLOBAL OSCILLATION NETWORK GROUP telescopes continuously measure solar oscillations. Research at the NSO concentrates on the nature of solar convection and magnetism, the origins of solar activity and variability, the structure and heating of the solar corona, and the interior structure of the Sun. The NSO was founded in 1983 by merging the solar programs at Sacramento Peak Observatory (1949) with those at Kitt Peak (1950). Most of the funding for the NSO comes from the National Science Foundation, with contributions from the USAF and NASA.

National Space Development Agency, Japan

The National Space Development Agency (NASDA) was established by the Japanese government in 1969 to act as the nucleus for the development of space exploration and to promote the peaceful use of space and its practical applications.

The agency's headquarters are in Tokyo, but it also operates launch facilities at Tanegashima Space Center in Kagoshima and tracking stations at Katsuura, Masuda (Kagoshima) and Okinawa. Its main test laboratories and operations buildings are located at Tsukuba Space Center.

NASDA is responsible for the development of communications, meteorological and Earth observation satellites, such as the Engineering Test Satellite series. A number of NASDA experiments and astronauts have flown on the Space Shuttle. Future plans include the addition of the Japanese Experiment Module to the International Space Station. It also oversees the development of launch vehicles, such as the H-II rocket and the Hope-X experimental spaceplane.

NASDA carries out studies into future development and utilization of the Moon and planets, including research into development of materials for use on the Moon and into planetary orbiters and robotic surface explorers. The first practical example of this will be the Selene lunar orbiter–lander mission, a joint project with the INSTITUTE OF SPACE AND ASTRONAUTICAL SCIENCE.

Navigation

Navigation is the knowledge required to sail a ship between two known points by the shortest appropriate way, and in the least possible time. *Coastal navigation* is practised within sight of the coast, and orientation is provided by local data such as the coastline, knowledge of conspicuous landmarks, and the water depth. *Oceanic navigation*, by contrast, is possible only by observation of celestial bodies. Here, a distinction should be made between the passive use of astronomical knowledge based purely on what was visible in the sky, and the active use of scientific instruments and astronomical EPHEMERIDES.

Navigation by observation of the Sun and stars

The level of astronomical knowledge of the Babylonians, Phoenicians, Greeks and Arabs is well documented, but although it is probable that such knowledge was used to improve the navigation of seafarers, little is known about the actual transfer of information between the two disciplines in Antiquity and the early Middle Ages. Seafarers of these peoples were mainly coastal navigators, but they covered large distances and sometimes ventured beyond the sight of land, especially in the enclosed and therefore relatively safe Mediterranean. The first seaman whom we are told steered by stars is Odysseus. At one stage of his imaginary voyage, he had to keep the stars of the Great Bear on his left hand, night after night: the method of steering by horizon stars. A star was observed shortly after rising (or before setting) and used as a compass direction. After a while, the next rising (or setting) star that had similar amplitude was used to steer by in the same way, and thus the ship was held on the same course. A simple way of finding latitude at night which was used in the Mediterranean, was by observation of zenith stars. Seafarers memorized which star was overhead in a particular port. By observing the star's position during their voyage they could see if they were to the north or the south of their destination, and adjust their course accordingly.

During daytime the position of the Sun was observed and used for orientation. Culmination indicated south (or north), while in low latitudes sunrise and sunset pointed to two other major compass directions, east and west. In northern latitudes the Pole Star, although some degrees off the celestial North Pole, also indicated north when observed in combination with the Great Bear. Even south of the equator experienced seafarers could, at least for a while, continue to use the Great Bear to locate north. The Pole Star was also used to determine latitude by means of a primitive finger system. Around AD 650, Arabs, who were experienced in finding their way in the desert by observing stars, used a compass rose of which the points were named after the rising and setting of fixed stars.

The Vikings, when crossing large stretches of ocean, used the Pole Star for orientation at night, and the Sun during daytime. They probably also used these celestial bodies for setting out their courses.

Because of the great distances from the continents and between the islands, the inhabitants of the Pacific had to sail large stretches of water beyond the sight of land. Early documentary evidence about their history is extremely sparse, but information that European voyagers collected from the eighteenth century onwards suggests that Pacific islanders used the Sun for their orientation and steering. Like Mediterranean seamen they steered by horizon stars and used zenith stars for reaching the latitude of their destination.

The dawn of astronomical navigation

When, in the fifteenth century, the Portuguese embarked on voyages along the west coast of Africa their courses were generally north–south. They found their latitude by observing the Pole Star at night, and during daytime the Sun's altitude at noon. Beyond the equator, which was reached by 1474, it was no longer possible to observe the Pole Star. Although the Southern Cross had been seen by Portuguese seamen as early as 1454, it was found that there was no southern Pole Star. This led them to attempt to improve the method of finding latitude from the Sun at noon. Accordingly, the astronomer Abraham Zacuto of Salamanca and his pupil José Vizinho compiled the first day-to-day declination tables of the sun, the *Regimento do Astrolabio e do Quadrante*. When Columbus sailed towards America in 1492, he was supplied with such tables in manuscript. It has been suggested that the first printed edition appeared in 1495, but the only known printed copy dates from about 1509.

The ongoing maritime expansion of both Portugal and Spain called for cooperation between astronomers and navigators. Scientific instruments that had traditionally been astronomers' tools were adapted for navigational purposes. The mariner's ASTROLABE was developed out of the astronomical astrolabe, probably around 1445, and was employed to measure angular altitudes. The astronomer's cross-staff (used to measure the angular separation between celestial bodies) underwent the same transformation, perhaps by the German-born astronomer Martin Behaim, and was used as a navigating instrument after about 1515. Astronomers were involved in teaching and examining navigators, and they were also responsible for providing navigational instruments and correcting charts. Stimulated by commercial successes, Portugal and Spain created institutions that were centers of astronomy, cartography and navigation. The *Casa de Guinea e India* was established in Lisbon, the *Casa de Contratación* in Seville.

After the Atlantic Ocean was crossed in 1492, and the Indian Ocean in 1497, east–west courses were sailed more frequently, and there was an increasing need to measure longitude with accuracy. The difference in longitude between two places is of course equivalent to the difference in local time. In 1494 Columbus tried to find his longitude in the New World from observing a lunar eclipse, and comparing the local time of its occurrence with the time predicted for its occurrence in Spain. The effort failed because of the inaccuracy of the prediction, a consequence

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of imperfect knowledge of the Moon's motion. Martin de Magellan's astrologer Andrés de San Martín in 1519 unsuccessfully tried to find the longitude in South America by conjunction of the Moon and Jupiter; failure was similarly the result of errors in the predicted astronomical ephemeris.

The Nuremberg astronomer Johann WERNER, in 1514, was probably the first to suggest that longitude could be determined by measuring lunar distances, the angle between the Moon and a fixed star. The Moon moves relatively rapidly across the sky, and at a given time the angle between the Moon and a given star is virtually the same for every observer who can see them both. The angle between the Moon and a number of stars can be calculated ahead for certain dates and times, for a standard meridian. An observer measuring such an angle would compare the result, and his local time, with the predicted angle and time. When the angles were the same, the difference between the two times would provide the difference in longitude between the observer and the standard meridian. Werner's method is feasible, but until the second half of the eighteenth century it was technically impossible to develop the required instruments and lunar tables.

Astronomy in navigation

In 1598, as the attempts to solve the question of longitude had so far failed, the Spanish king offered a considerable prize for anyone who devised a practical solution. This example was soon followed by the Dutch States-General, the governments of France and Venice, and in 1714 by the British Parliament. Many claims resulted, one of them from GALILEO GALILEI, who proposed that the eclipses and occultations of Jupiter's satellites could provide a solution, as they are visible at the same instant for every observer. For his proposal Galileo received a gold chain from the Dutch States-General in 1636; nevertheless, it was hardly possible to observe Jupiter's satellites from the deck of a moving vessel. Lunar eclipse observations to determine longitude were carried out successfully by Edmond HALLEY at sea near the Cape of Good Hope in 1719, and on land by Captain James COOK in Canada in 1766; but lunar eclipses are rare events.

The method of lunar distances called for an accurate and manageable observing instrument, an accurate mathematical theory of the lunar motion, and accurate tables of the positions of the fixed stars. Important steps towards the third of these goals were taken with the founding of the OBSERVATOIRE DE PARIS in 1667 and the ROYAL OBSERVATORY, GREENWICH in 1675. Both were commissioned to rectify the existing tables of stars to help solve the problem of longitude at sea. The Paris Observatory was the first institution to publish tables of astronomical data for navigation, such as the daily celestial positions of the Sun, Moon and planets, and the Right Ascension of stars. These appeared in the *Connaisance de Temps*, for the first time in 1678. From 1761 onwards the *Connaisance* also contained lunar tables, accurate lunar tables having been calculated for the first time a few years previously by the German mathematician Tobias MAYER. The British Astronomer Royal, Nevil MASKELYNE, became the driving force behind the *Nautical Almanac and Astronomical Ephemeris*, which first appeared in 1765, for the years 1767–9, and also contained lunar tables. Around the time Mayer calculated his tables, the requirement for accurate observing instruments was also fulfilled, with the development of the sextant, and later the reflecting circle.

The lunar method was soon firmly established as a reliable way of determining longitude at sea. Cook was among the first to apply it, in New Zealand in 1769, using the first edition of the *Nautical Almanac*. For many years this method, which was strongly promoted by Maskelyne, competed with that of finding longitude by use of a chronometer. The Astronomer Royal strongly believed that the astronomical solution was the only accurate answer to the longitude question, and opposed the 'mechanical' one. Eventually, however, the chronometer won, once the required horological technology had been developed, for it was immeasurably simpler to use than the method of lunar distances. Nevertheless, lunar distances remained in use throughout the nineteenth century, and until 1907 the necessary tables were published annually in the *Nautical Almanac*. The method was used at sea by those who could not afford an expensive chronometer, and also for checking the rate of chronometers before radio time signals were introduced around 1904.

Once the solution for the longitude problem had been found, astronomers became less involved with navigation. Astronomical ephemerides, however, remained indispensable to navigation, and the nautical almanacs that were annually published in various seafaring countries were of course compiled by astronomers.

Meanwhile there had been parallel improvements in methods of determining latitude. In the eighteenth century the Dutch teacher of navigation, Cornelis Douwes, developed a method of double altitudes by which latitude could be found without restriction to the traditional noon observation. This method was improved in the nineteenth century, when position line navigation gradually also came into use. This is the name for various ways by which, through astronomical observation and subsequent calculation, a ship's position could be found at almost any time of the day. Various methods were developed by which a single observation of the sun or a star would result in a position line being drawn on the chart. The intersection of several such lines, taken from different stars, provided an accurate position. Most of these methods were developed by merchant or naval seamen; but occasionally astronomers were involved, among them the Frenchman Yvon Villarceau who, in the 1860s, helped develop a method which was named 'La nouvelle navigation astronomique'. By the end of the century celestial navigation had reached the level at which it would remain until long after the Second World War. It was adapted for aviation, and seamen and aviators found their position by taking observations of the Sun, selected

stars, the planets and (occasionally) of the Moon, and the use of a nautical almanac. Matters changed when satellite navigation was introduced, in the late 1970s. A position could then be obtained instantly, almost as often as one wished, and it was far more accurate than celestial navigation. In the 1980s and 1990s global positioning systems became cheaper and easier to obtain, and the use of satellites started to replace sextants and nautical almanacs. The first sign that astronomy and navigation will soon part company altogether came from the United States Naval Institute in Annapolis. There, in 1998, it was decided to abandon altogether the teaching of celestial navigation. Future American naval officers, when crossing an ocean, will have to rely entirely on satellites and computers.

n-Body Problem

Calculations involving the gravitational interaction of an arbitrary number (n, greater than two) of masses. The motion of two bodies is easily analyzed but there are no general solutions for three or more bodies interacting. Solutions do exist for particular cases but these take vast amounts of computation. Examples are the restricted three-body problem to determine the effect of Jupiter's perturbations of the asteroids and the use of successive approximations of series solutions to sequentially add the effects of smaller and smaller perturbations for the motion of the Moon. Examples requiring the solution of the n-body problem include the motion of a space probe in the solar system and the orbits of stars within a cluster.

NEAR Shoemaker

The Near Earth Asteroid Rendezvous (NEAR Shoemaker) mission is the first mission to orbit one of the ASTEROIDS. NEAR, a spacecraft of NASA's new Discovery program was launched successfully on 17 February 1996 on a looping 3 yr trajectory to EROS, one of the NEAR-EARTH ASTEROIDS (NEAs). Starting on 14 February 2000, NEAR undertook a 1 yr investigation in orbit around Eros. On 12 February 2001, the mission was terminated with a controlled descent to the surface in order to provide extremely high-resolution images. On its way to Eros the NEAR spacecraft passed within 1225 km of asteroid 253 Mathilde on 27 June 1997. The spacecraft carried five science instruments: a multispectral imager (MSI), a near-infrared spectrometer (NIS), an x-ray and γ-ray spectrometer (XGRS), a magnetometer (MAG), and a laser range finder (NLR). A sixth investigation consisted of analyzing the radio signals of the spacecraft telemetry to measure the effects of the gravitational attraction of the two asteroid targets in order to determine their masses. On its year-long orbital study of Eros, NEAR gave unprecedented views of the asteroid surface with the highest-resolution images obtained so far for a small body.

Introduction

The NEAR Shoemaker mission is the first space mission to an NEA. It was named in honor of the late Eugene M. Shoemaker, a pioneer in the study of asteroid and comet impacts on Earth and other planets. NEAs are a dynamically young population of objects having orbits close to the Earth's. The general idea on the NEAs' origin is that these objects are efficiently removed from other regions of the solar system by collisions and subsequent gravitational interactions with the planets on a time-scale of 10^6–10^8 yr. Since the NEAs have unstable orbits, a continuous resupply of new objects is needed. In fact, some of them can come from the main belt and some can be derived from dead or dormant COMETS. It is believed that most METEORITES are collisional fragments of NEAs, but the meteorites may be a biased and incomplete sample of the materials actually found in NEAs. About 2000 near-Earth objects (NEOs) of all sizes are currently known, but the entire population contains perhaps 1000 objects with diameters larger than 1 km. These objects, thought to be similar in many ways to the ancient planetesimal swarms that accreted to form the planets, are interesting and highly accessible targets for scientific research. They carry records of the solar system's birth and the geological evolution of small bodies in the interplanetary region. Their

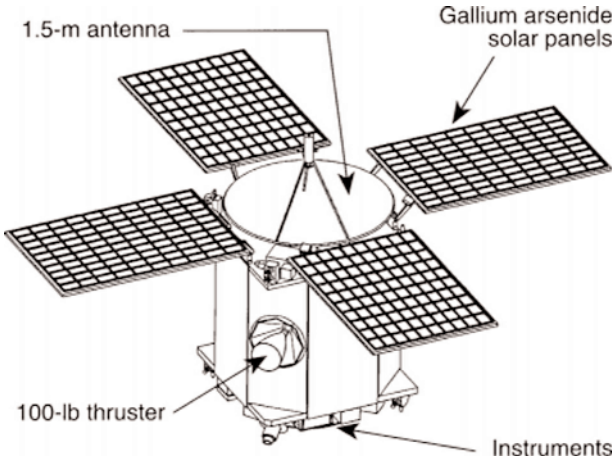

Figure 2. Spacecraft configuration. The solar panels and the fixed high-gain antenna are mounted on the forward deck. The MAG is on the high-gain antenna feed. The other instruments are mounted around the spacecraft adapter. From left to right, they are MSI, NIS, NLR and XGRS. Credit: NASA.

relations with comets, main belt asteroids and meteorites will clarify the links among these small bodies. Because collisions of NEOs with Earth pose a finite hazard to life, the exploration of these objects is particularly urgent. They may also serve as resources for use by future human exploration missions.

Mission design

NEAR was launched on a Delta II-7925 rocket into a 2 yr Earth-gravity assist trajectory (figure 1). The spacecraft passed, during its 23 month orbital loop around the Sun, close to the asteroid 253 Mathilde. NEAR carried out a close flyby (at 460 km) with the Earth on 22 January 1998 to obtain a gravity assist to change the orbital inclination. NEAR was originally planned to rendezvous with Eros in January 1999, but it did not complete its rendezvous burn on schedule, and the ground controllers lost all contact with the spacecraft for 27 h. NEAR was recovered and performed a first flyby of Eros on 23 December 1998. NEAR executed another flyby of Eros on 14 February 2000, and began its year-long orbital mission the same day.

Spacecraft and instruments

The NEAR spacecraft (figure 2) is a solar-powered, three-axis-stabilized spacecraft with a 1.7 m^2 base. The mass is 468 kg (805 kg including propellant). NEAR uses X-band telemetry to the NASA Deep Space Network. The spacecraft structure is composed of aluminum honeycomb decks connected to eight aluminum honeycomb side panels. On the outside of the forward deck there are a fixed X-band high gain antenna of 1.5 m diameter, four fixed solar panels and the solar x-ray monitor system. The NIS has a scan mirror that allows it to look more than 90° away from the common boresight. The spacecraft carries a complement of six science instruments: MSI, NIS, XGRS, MAG and NLR, in addition to a radio science investigation. The MAG is mounted on top of the high-gain antenna feed where it is exposed to the minimum level of spacecraft-generated magnetic fields. The remaining instruments (MSI, NIS, NLR, XGRS) are all mounted on the outside of the aft deck. They are on fixed mounts and are co-aligned to view a common boresight direction.

MSI

MSI is a 537 pixel × 244 pixel charge-coupled device camera with five-element refractive telescope, radiation hard refractive optics. The telescope is $f/3.4$ with a 168 mm focal length. The imager provides a field of view of 2.25° × 2.9° with a pixel resolution of 95 nrad × 161 nrad. The spectral range covers from 400 to 1100 nm. A filter wheel has seven spectral filters (450, 550, 760, 900, 950, 1000, 1050 nm). The main goal of the MSI was to determine the mineralogical and morphological characteristics of the surface at high spatial resolution.

NIS

NIS is a scanning spectrometer which covers the near-infrared wavelength region 800–2600 nm with 64 spectral channels. The NIS slit has two fields of view: 0.38° × 0.76° and 0.76° × 0.76°. A gold scan mirror that rotates over an angle of 140° controls the direction of viewing. Spectral images can be built up by a combination of spacecraft motion and the scan mirror. NIS has a gold calibration target that can be placed to provide a quantitative, in-flight spectral calibration. The InGaAs (indium–gallium arsenide) focal plane array does not require cooling to liquid nitrogen temperature to achieve a high signal-to-noise ratio. NIS was very important for studying the surface composition and, in particular, in determining the distribution and abundance of the asteroid surface minerals, such as olivine and pyroxene.

XGRS

XGRS consists of two sensors: an x-ray fluorescence spectrometer and a γ-ray spectrometer. Redundant solar monitors are used to determine the incident solar x-ray spectrum. The x-ray fluorescence experiment uses three gas-filled proportional counters to cover x-rays in the energy range from 1 to 10 keV. The x-ray spectrometer detects the x-ray line emissions excited by solar x-rays from major elements of the surface. The γ-ray spectrometer uses a body-mounted NaI scintillator and a BGO (bismuth germanate) anticoincidence shield that define a 45° field of view. It detects characteristic γ-rays in the 0.3–10 MeV range emitted from specific elements in the surface. The XGRS is the primary experiment for determining surface/near-surface element composition of the asteroid 433 Eros. In fact x-rays are emitted from the surface (less than a millimeter deep) while γ-rays tend to probe deeper material, up to about 10 cm in depth.

MAG
MAG is a fluxgate magnetometer that uses ring core sensors made of highly magnetically permeable material. The sensor is mounted approximately 1 m from the main spacecraft bus, on the high-gain antenna feed support. MAG conducted the first close-up search for coherent body-wide magnetism at an asteroid. This search was motivated by the ambiguous evidence of magnetic signatures detected during the Galileo flybys of Gaspra and Ida.

NLR
NLR is an incoherent, direct-detection laser altimeter. NLR uses a chromium–neodymium–yttrium–aluminum garnet (Cr–Nd–YAG) solid-state laser and a compact reflecting telescope. The transmitter generates a brief laser impulse, and the instrument measures the time required for the light to reach the asteroid and return. It measured the distance from the spacecraft to the asteroid surface.

Radio science
There are no dedicated radio science (RS) instruments. The radio transponder allows the spacecraft's position and velocity to be determined in inertial space. This X-band transponder operates at 8438 MHz and is capable of determining the spacecraft's radial velocity to better than 0.1 mm s^{-1} when the data are properly calibrated. The coherent X-band transponder on NEAR was used to conduct an RS investigation by measuring the Doppler shift due to the spacecraft radial velocity component relative to the Earth. Accurate measurements of the Doppler shift allowed us to determine the gravity field and therefore the mass of the asteroid. Despite the NEAR mission being part of the Discovery program, which is synonymous with its being fast and cheap, the instruments were the results of many technical innovations. The x-ray instrument, the γ-ray detector system, the NLR and the InGaAs focal plane array for NIS all flew in space for the first time.

Scientific objectives

The primary objectives of the NEAR Shoemaker mission were the rendezvous with an NEA, and to achieve orbit around it to conduct the first scientific exploration of an object of this population. NEAR flew past Eros on 14 February 2000 at a closest approach distance of 300 km, continued the mission through several altitude orbits and spent 6 months in a 35 km orbit. The spacecraft passed successfully within 1200 km of the main belt 253 Mathilde on 27 June 1997. The measurement objectives of the mission were to determine (1) the bulk properties (size, shape, mass, density, gravity field and spin orientation), (2) the surface properties (elemental and mineralogical composition, geology, morphology, and texture), (3) the internal properties (search for heterogeneity and magnetic field) and (4) to search for possible satellites. All this information was important to characterize the physical and chemical properties of the target asteroids to study their mineralogical composition, to better understand the relationship between comets, asteroids and meteorites, and to improve the understanding of the boundary conditions of the processes that governed the formation and early evolution of the planets.

Figure 3. This mosaic image of Mathilde is constructed from four images acquired when NEAR was at a distance of 2400 km. Details as small as 380 m can be observed. The surface exhibits many large craters, including the deeply shadowed one at the center. Credit: NASA.

Mathilde flyby

On its way to Eros the NEAR spacecraft passed within 1225 km of the asteroid 253 Mathilde on 27 June 1997 at a velocity of 9.9 km s^{-1}. During the encounter with this C-type carbon-rich asteroid, NEAR was at 1.99 AU from the Sun, and because the solar panels were built to provide adequate power for the Eros rendezvous at closer solar distances, only the MSI was turned on. NEAR does not have a movable instrument platform and the whole spacecraft had to be turned to point the camera. NEAR took spectacular images and determined Mathilde's mass to an accuracy of about 5%. The spacecraft approached Mathilde looking close to the direction of the Sun (at an approaching phase of about 140°). The imaging sequence started 5 min before closest approach, obtaining a resolution of about 500 m. The highest resolution (160 m) was obtained at a distance of 1225 km (closest approach), when the phase angle was close to 90°. Then the imaging sequence continued for another 20 min, obtaining images at a phase angle of about 40°. During this time multicolor images with the seven color filters were obtained. Mathilde was on about 330 of the 534 MSI frames obtained. Because of the very slow rotational period of Mathilde (17.4 days), only roughly half of its surface was seen (figure 3) during the 25 min of the imaging coverage. The determined size dimensions supposing a triaxial ellipsoid shape are 66 km × 48 km × 46 km with a volume of $78\,000\ ^{-11\,000}_{+12\,000}$ km^3. On the 50% of the surface imaged by the spacecraft there are five craters with diameters between 19 and 33 km. A total of 91

craters have been identified and 70 have a diameter larger than 0.6 km. Analysis of the Mathilde craters shows that those craters larger than 5 km exceed the empirical equilibrium densities seen elsewhere in the solar system and that the largest craters are near the geometric saturation limit (see CRATERS). The similarity of the densities of small craters on Mathilde and IDA suggests similar ages for the surfaces; in the case of Ida, the age has been estimated at 1–2 billion yr. The crater ages depend on the estimation of the collisional strengths of asteroids, but in the case of Mathilde the preservation of giant craters and the low density of the interiors do not allow us to estimate the asteroid's collision age in a reliable way. The crater morphology and actual evidence of downslope movement on crater walls indicate that the surface of Mathilde is covered with regolith, indicating some retention of ejecta produced during crater events. An ALBEDO between 0.035 and 0.050 has been determined. The NEAR colors (between 400 and 1100 nm) show similar results to those previously obtained by ground-based telescopic observations, matching the CM meteorite Murchison, and showing no variations of albedo. On the basis of the volume determined by images ($78\,000\ ^{-11\,000}_{+12000}$ km^3) and the mass determined by the RS instrument ($(1.024\pm 0.058)\times10^{17}$ kg), a mean density of 1.1–1.5 g cm^{-3} has been determined. The density is less than half of that measured for CM meteorites, indicating a porous or underdense structure for the interior of Mathilde. Several hypotheses have been produced to explain this low density, such as water ice in the interior, a rubble pile structure, etc. It is also possible that C-type objects consist of unprocessed primitive material and the low density, in some sense, may be a primordial signature. About 200 images were taken during the closest approach to cover the sky around Mathilde at a distance between 300 and 600 km (10–20 radii) to search for possible satellites. The existence of a satellite could explain the low spin. No objects have been found down to a limit of 40 m across. The NEAR's photometric observations at Mathilde confirm that the ground-based methods used to determine the albedos and global photometric properties of distant asteroids are reliable.

Main results on Eros

Images from the MSI as well as near-infrared, x-ray, laser and radar measurements have been returned from NEAR during its orbital mission around Eros. MSI images were obtained at much higher resolution (~5 m/pixel) than available for any other asteroids and at even higher resolutions (couple of cm/pixel) during landing descent. In addition, γ-ray data were obtained at the landing site.

The asteroid 433 Eros, discovered in 1898, was classified as a typical S-type (silicate-rich) asteroid with a rotational period of 5.27 h but few details on its composition were available from ground-based observations. Eros has shown an irregular, curved shape with dimensions of 34.4 km × 11.2 km × 11.2 km, slightly smaller than previously estimated from the ground (figure 4). The images show chains of craters, numerous blocks, grooves and long ridges, e.g. the Rahe dorsum that extends for several kilometers across the surface. Almost all the features on Eros were named after famous historical and fictional lovers from a sampling of different cultures. The name of the largest feature, Himeros, comes from Greek mythology. Himeros, an attendant of the god Eros, personifies the longing of love.

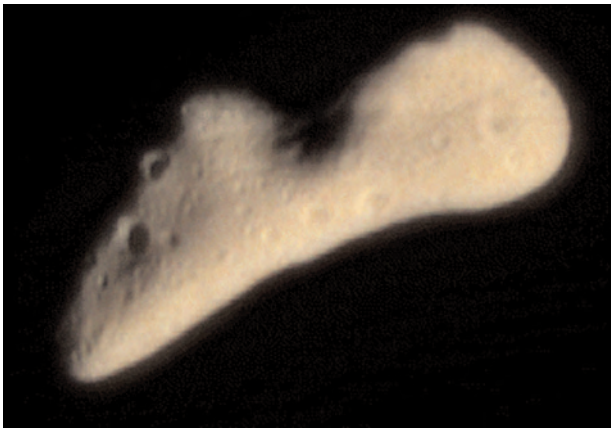

Figure 4. This image of 433 Eros was acquired on 12 February 2000 by NEAR's MSI. The largest depression, Himeros (about 9 km across), is visible in the center top of Eros. Credit: NASA.

These features, and other data, suggest that Eros is a consolidated body rather than an agglomerate of loosely bound, much smaller components. Huge tectonic features are found, which cannot occur in the absence of material strength. Steep slopes are found, where unconsolidated material would be expected to slide off. Many craters have shapes that indicate the influence of material strength in their formation, such as the square craters shown in figure 5. The rubble pile structure—e.g. an agglomerate of smaller component bodies bound mostly by gravity—has been inferred for many asteroids, but it does not apply to Eros. Its irregular, peanut shape houses a homogeneous internal structure. Although Eros is consolidated, the ubiquitous fabric of ridges and grooves suggests an extensively fractured interior.

Composition

The infrared spectrometer showed variations in the mineral composition such as pyroxene, olivine and iron-bearing minerals. The first x-ray results revealed the presence of magnesium, iron, silicon and also aluminum and calcium. Both x-ray data and near-infrared spectra are most consistent with a primitive, largely undifferentiated composition for Eros. Eros, as an undifferentiated body, is made of material that has been scarcely altered since the beginning of the solar system, and probably since before the formation of the Earth. The relative proportions of rock-forming elements in Eros are similar to those found in the Sun itself. Eros was never subjected to

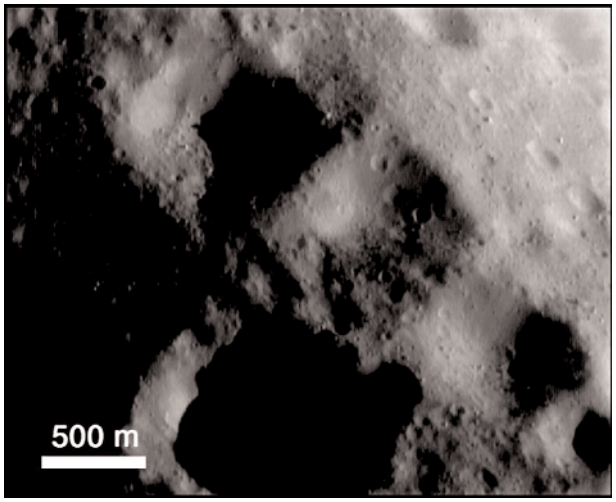

Figure 5. Squared craters on Eros: an example of a structurally controlled feature consistent with Eros as a consolidated body. This image was taken on 26 April 2000, when NEAR Shoemaker was 50 km above the surface. Credit: NASA.

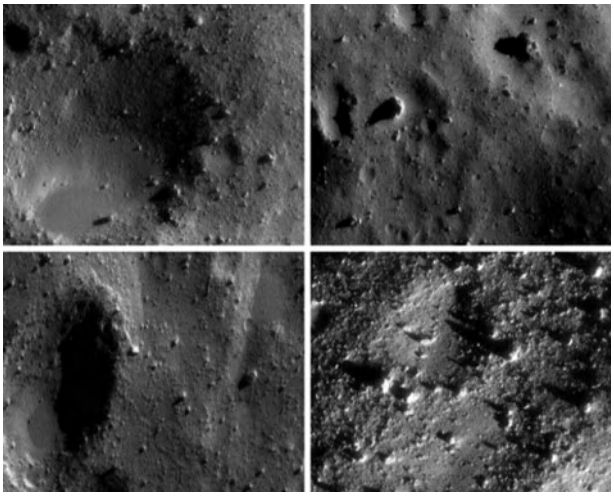

Figure 6. Details of Eros' surface. From upper left to lower right, the images show Eros' featured surface at increasing resolution. Blocks are ubiquitous on Eros. The image at upper left was taken on 27 January of a point 13.5 km away and shows a ponded deposit inside the crater; the one at the upper right was taken on 26 January from 11.1 km away. Signs of blocks partly buried by regolith are apparent. Each upper scene is about 550 m across. The image at bottom left was taken on 26 January from 4.9 km away, and the bottom right image was taken on 28 January from a similar distance. Each lower scene is about 230 m across. Credit: NASA.

the melting and the separation into compositionally distinct layers that Earth, Mercury, Venus and Mars have all experienced (see DIFFERENTIATION). X-ray measurements probing the uppermost 100 μm of surface material showed that abundances of Ca, Al, Mg, Fe and Si are consistent with compositions of either ordinary chondrites or certain primitive achondrites. However, there is a marked depletion of S compared with expectations for these meteorite types. This could be due either to removal of a small fraction of partial melt (which would imply that Eros is primitive achondritic) or to devolatilization of a thin surface layer by impacts.

Using ground-based Doppler and range measurements—and by tracking surface landmarks—scientists have determined that the asteroid's mass is $(6.687 \pm 0.003) \times 10^{15}$ kg and density is 2.67 ± 0.03 g cm^{-3}, which is about the average density of Earth's crust but is less than the average bulk density of ordinary chondritic meteorites, indicating that bulk Eros is significantly porous and/or highly fractured, but not to the same extent as Mathilde. The density is relatively uniform throughout the asteroid. There is a small center-of-mass offset with respect to the center of the asteroid's image that may indicate an underdense regolith layer of up to 100 m depth.

Craters and rocks

As with other asteroids, craters, almost certainly of impact origin, characterize the surface morphology of Eros. The three largest depressions are Himeros (about 9 km across), Shoemaker (7.6 km) and Psyche (5.3 km). The presence of a large number of craters indicates a rather old object. Many large craters have bright albedo features on their interior walls. The morphological and spectral properties of these features, associated with steep slopes, are consistent with a darkened, space-weathered material that slides down crater walls exposing brighter, less weathered underlying material. The space weathering process alters the asteroid regolith which, exposed to the interplanetary environment (micrometeorite impact, solar wind, cosmic rays,…), progressively changes color with time. The asteroid surface appears darker and its reflectance spectrum is redder (with much weaker absorption bands) than the spectrum of its constituent rocks. It has been known that such processes are responsible for altering the lunar regolith and data analyses from Galileo's Ida encounter have provided convincing evidence that the space-weathering process is operating on Ida. However, thorough investigations of spectral properties of these processed materials suggest that space weathering affects the regoliths on Eros and the Moon differently, perhaps because of differences in gravity or location in the solar system.

Flyover images have revealed a profusion of blocks up to 150 m across (see figure 6). These rocks are believed to have been produced as ejecta blocks from large craters. Most of these rocks were inside the Shoemaker crater, positioned near one end of the potato-shaped asteroid. The positions and orientations of the blocks indicate that most of them originated from the relatively young Shoemaker crater. Blocks have shapes ranging from angular to rounded and clodlike. Aprons of debris at the base of some of the larger blocks indicate that varying

degrees of erosion exist at the surface of the asteroid, whose origin is not clear.

Ponded deposits

Another one of the big surprises scientists found from NEAR's highest-resolution mapping is that Eros' surface appears to have a global cover of regolith, i.e. surface dust and debris. It is estimated to be tens of meters in depth. The surface appears to be blanketed with a fine material, some of which has created flat deposits, particularly in depressions, such as craters. These fine deposits appear to have been sorted from the upper portion of the asteroid's regolith. These so-called 'ponded' deposits are intriguing because of their extremely smooth and flat surfaces. Their slightly bluish color may be attributed to the optical properties of submicrometer particles. The probe landed in one of these ponds, revealing its contents to be like dry cement (see figure 6). Ponds have not been seen on any other solar system objects and their origin is not clear. Some researchers hypothesized that the ponds formed after seismic shaking or by electrostatic levitation. For the latter effect, particles can build up photoelectric charges with long exposure to the Sun, and this charge might separate out finer particles.

Eros has a stable rotation and an escape velocity that ranges from 3.1 to 17.2 m s^{-1}, which would allow a baseball thrown from its surface to leave forever. The acceleration of gravity on the surface of Eros varies from 2.3 to 5.5 mm s^{-2}, thousands of times smaller than on Earth. A person who weighs 70 kg on Earth would weigh from 16 to 39 g on Eros.

No satellites down to a limiting size of 50 m have been observed. Another negative result was the lack of magnetization of Eros. Even the close look-up at the landing site showed no evidence for an intrinsic magnetic field, which is a surprising result. Indeed, most meteorites, including chondrites, are much more magnetized than Eros.

Conclusion

NEAR provided the first ever close-up look at an asteroid and has increased drastically our knowledge of primitive bodies in the solar system. The spectacular images and surprising results that the spacecraft returned have started to answer the many questions we had about Eros and asteroids but they also revealed new mysteries that scientists will explore for years to come. A lot of work remains to be done with the wealth of data returned by NEAR.

Nearby Groups of Galaxies

Groups of galaxies are gravitationally bound aggregates of tens of galaxies, like the LOCAL GROUP (LG), the home of our MILKY WAY GALAXY. What we call a 'nearby' group has to be sufficiently close such that the group can be studied, in terms of structure and contents, with similar (but of course always inferior) detail as the LG. This is roughly met by groups lying in the Local Supercluster—a flattened metagalactic structure of galaxies approximately 120 million light-years (40 Mpc) across and centered on the VIRGO CLUSTER. The LG is in the outskirts of this system. There may be more than 100 groups in the local supercluster, but this is impossible to pin down exactly, as the identification, or definition, of a group gets increasingly difficult with increasing distance: faint group members are harder to detect at greater distances and there is increasing confusion due to projection effects (several groups can be projected on top of each other along the line of sight).

Some of the more conspicuous nearby groups were undoubtedly known already to the early workers in extragalactic astronomy, like E Hubble and H Shapley. But it really was Gerard de Vaucouleurs, in the 1960s, who made the first successful attempt to disentangle the essential supergalactic systems (groups, clouds and clusters) from the sparse data on the distribution of nearby galaxies available at the time. His work is still a major reference in the field, and his nomenclature was largely adopted.

Here we confine ourselves to the six groups of galaxies that are found within a distance of 10 Mpc (or 30 million light-years), excluding the LG. These most nearby groups are of course also the best-studied ones. They are described here one by one. Some of the groups, like the M81 Group and the Cen A Group, are fairly rich (several times the LG) and dense, with clear signs of galaxy interaction. The M101 Group, on the other hand, is very poor: it is as a single giant galaxy with a swarm of dwarf satellites. Others still (CVn I and Sculptor) are even denied the title of a group, they are regions of slightly enhanced galaxy density without appreciable internal motion, called 'clouds'. Finally, there is a large group (IC 342/Maffei) behind the dust absorption band of the Milky Way. Most of its fainter members may still be hidden from our view. But more surprising than the structural variety of the groups is perhaps their external interconnectedness. It seems that the groups are embedded in a coherent supergalactic structure. For example, the LG cannot strictly be separated from the Sculptor Cloud; and there may be other 'cloudy' bridges between the groups.

The neighborhood of the Local Group

The distribution of galaxies in the universe is highly non-uniform. On a scale of about 100 Mpc one finds a sponge-like network of 'filaments' and 'sheets' of galaxies, with rich CLUSTERS OF GALAXIES typically lying at the vertices of these structures. The sheets and filaments are dynamically cold (non-virialized) systems whose internal structure is probably fractal, with (still non-virialized) subsystems on any scale being called 'clouds'. Embedded in the cold clouds of predominantly late-type galaxies (SPIRAL and IRREGULAR GALAXIES) are—as 'hot spots'—dynamically more virialized groups and loose clusters of galaxies. These, depending on density, may contain an appreciable fraction of early-type galaxies (ELLIPTICAL GALAXIES, S0s).

Our home sheet is the Local Supercluster, whose primary hot spot is the loose Virgo cluster. Our home cloud is the 'Coma-Sculptor Cloud', and our home group is of course the Local Group (LG). The Coma-Sculptor Cloud is a cigar-shaped feature of length 15 Mpc, stretching from Sculptor in the anti-Virgo direction all the way to the Coma I Cluster, which is roughly in the direction of Virgo at $D \approx 15$ Mpc. Several known nearby groups belong, like the LG, to the greater environment of the Coma-Sculptor Cloud. Others seem to be connected with neighboring clouds. There are apparently no isolated groups.

Due to this embedding of the groups and also their internal substructure, a clear-cut definition of even a nearby group (in fact, even the LG!) is very difficult to attain. A primary factor is the absolute magnitude down to which galaxies are recorded. At very faint levels every giant galaxy will have a swarm of bound dwarf companions and could therefore be regarded as a group of its own (like the Milky Way Galaxy with its MAGELLANIC CLOUDS and DWARF SPHEROIDAL satellites). So the definition of a group is, to a large extent, a matter of convention.

Groups within 10 Mpc distance

Our most complete knowledge of the LG neighborhood is confined to objects less distant than 10 Mpc from the Milky Way Galaxy. Around 300 (mostly dwarf) galaxies are at present known to lie in this volume. Their sky distribution is shown in figure 1. The strong concentration of the galaxies towards the supergalactic plane, the symmetry plane of the local supercluster, is striking. Roughly 70% of the galaxies appear to be members of a small number of groups; but the remaining 'field galaxies' are unlikely to be isolated but will be members of the embedding cloud(s). Six groups, excluding the LG, are conventionally adopted. Two of these, Sculptor and CVn I, have from the beginning (i.e. from de Vaucouleurs' pioneering study) been known to be rather clouds. As well-distinct nearby supergalactic structures they are treated here along with the other, real groups.

Figure 2 shows the spatial distribution of the galaxies projected onto the supergalactic plane. The cloud nature of Scl and CVn I—by their large extension—is obvious; both appear as mere substructures of the Coma-Sculptor Cloud. A clear separation between the LG and the Sculptor Cloud is almost impossible and perhaps also not physically meaningful.

In the following the six major nearby groups and clouds are briefly described in some detail. The order is by supergalactic longitude.

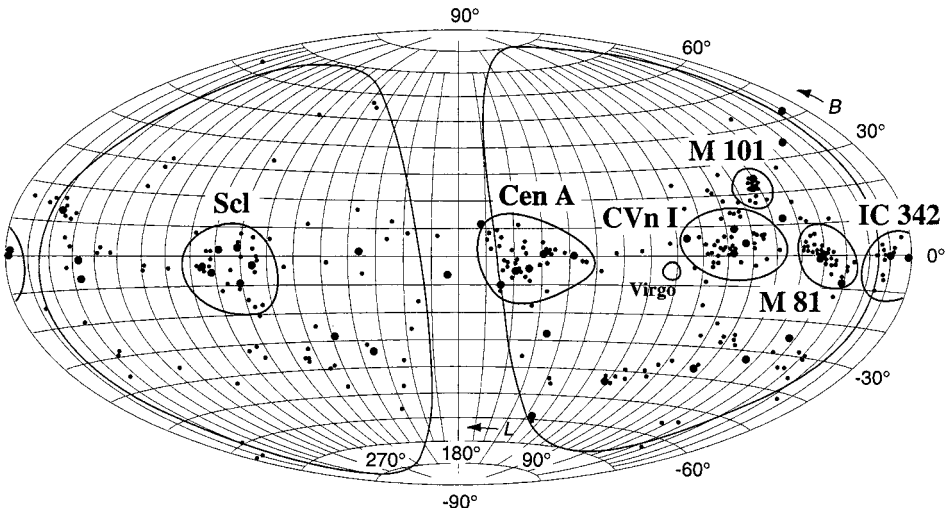

Figure 1. Sky distribution, in supergalactic coordinates, of all galaxies known within a distance of 10 Mpc. Approximate boundaries of the main groups in this volume, as well as the position of the Virgo Cluster, are indicated. The galactic zone of avoidance ($|b| < 15^\circ$) is delineated with a heavy line. Large dots, giant galaxies ($M_B > -18$); small dots, dwarf galaxies ($M_B < -18$).

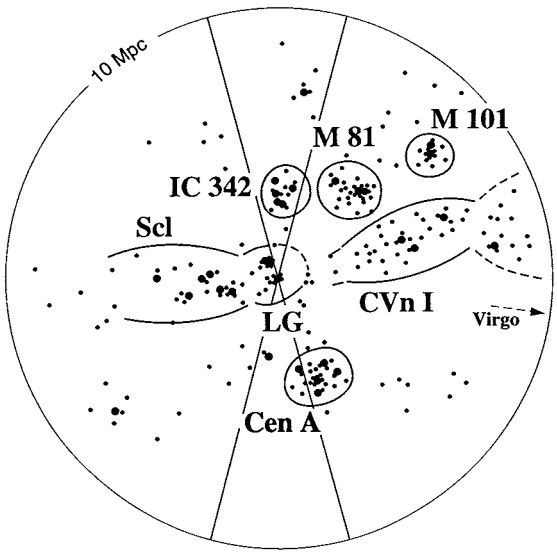

Figure 2. Spatial distribution, projected onto the supergalactic plane, of all galaxies lying closer than 10 Mpc. The Milky Way Galaxy is at the center, with the zone of avoidance as indicated by the double sector ($|b| < 15^\circ$). The orientation is also given by the direction to the Virgo Cluster. Approximate boundaries of the main groups and clouds, including the Local Group, are indicated. Large and small dots as in figure 1. This plot should not be taken as a true map, but rather as a schematic, as most distances used here are rough estimates only.

IC 342/Maffei Group

This galaxy group is named after the Italian astronomer Paolo Maffei who by chance, in the late 1960s, discovered two of its brightest members on a near-infrared-sensitive Schmidt plate. As it later turned out, Maffei discovered the tip of an iceberg whose extension and depth remain largely unexplored even today. What we now call the IC 342/Maffei Group is a fairly massive galaxy group at a distance of ≈3.5 Mpc which, unfortunately, happens to lie entirely in the zone of avoidance of our Galaxy (see figure 1). This means that all of its member galaxies are very heavily obscured by dust absorption, with a dimming of up to 10 (!) magnitudes in the visual. Thus the galaxies are essentially invisible in the optical, but as dust extinction is less severe at longer wavelengths, they may be detected in the near-infrared and radio wave bands. One of the main constituents of the group, Dwingeloo 1, was discovered as late as 1994. Without galactic absorption, Dw 1 would indeed be one of the 10 largest spiral galaxies in the sky.

The four brightest members of the group are IC 342 (of Hubble type Scd), Maffei I (elliptical), Maffei II (SBb), and Dw 1 (SBb). In luminosity they are comparable to our Galaxy and M31. Nine further, fainter galaxies, mostly of the dwarf irregular type, add up to a total of 13 group members identified so far. Clearly, there must be many more dwarf members of the group still awaiting discovery. The mean distance of the group has been controversial until recently, which is not surprising given the enormous amount of dust absorption. Early estimates placed the group at ≈2 Mpc distance, i.e. just barely beyond the classical confines of the LG. If true, this would have had strong consequences for the dynamics of the LG. The mean distance favored at present, 3 to 3.5 Mpc, is more comforting in this respect. However, the zone of avoidance of our Galaxy may harbor more surprises!

M81 Group

The M81 Group is the 'classical' nearby group in the Northern hemisphere, lying at high latitudes in Ursa Major

Dirac House, Temple Back, Bristol, BS1 6BE, UK

(the Big Dipper). It is about two or three times as rich as the LG: around 40 members and possible members have been found so far down to a $M_B \approx -11$ (note that the faintest LG members have about -7). The mean distance of the group is ≈4 Mpc. There are five giant members in the core region: M81, the well known Sb spiral galaxy; M82, equally well known for its peculiar, amorphous appearance which is caused by its STARBURST activity; NGC 3077, again an amorphous; and the late spirals NGC 2976 (Sd) and IC 2574 (Sm). These galaxies (with the exception of IC 2574) have been observed to be embedded in a huge, dynamically complex cloud of neutral hydrogen. This—and probably the starburst activity of M82 as well—must be taken as a sign of ongoing interaction. The core region of the group is indeed rather dense, which, by way of the MORPHOLOGY–DENSITY RELATION GALAXY, is also suggested by the presence of a fair number of bright DWARF ELLIPTICALS. Notwithstanding, the majority of group members are faint dwarf irregulars which tend to lie more in the outskirts of the group. Very faint dwarf spheroidals of the type known in our vicinity have not yet been (but may soon be) detected around M81.

Studies of the M81 Group are traditionally hampered by a strong mixing of Galactic and extragalactic features. Here the problem is not dust obscuration but the presence of Galactic 'cirrus' (REFLECTION NEBULAE) and HIGH-VELOCITY CLOUDS in the region. Deep optical exposures reveil a disturbing criss-cross of cirrus on top of the galaxies. There are low-surface brightness objects whose nature (Galactic versus extragalactic, i.e. cirrus versus dwarf M81 Group members) is still unclear.

M101 Group

The M101 Group is probably the poorest group of all (including our LG). The group is completely dominated by M101 itself, a beautiful giant Sc spiral at a distance of ≈7 Mpc (which can be regarded as group distance). The second-ranked group member is already three magnitudes fainter than M101. Only about 12 members and possible members of the group are known to date, half of which lie very close to M101 and can therefore be considered as M101 satellites. With one exception they are all of the late spiral (Sd, Sm) and irregular (Im) type. One peculiar feature of the group is its LUMINOSITY FUNCTION OF GALAXIES: the population of very faint and diffuse dwarf galaxies (elliptical or irregular), which is so frequent elsewhere, is apparently simply missing here (the faintest member known is as bright as $M_B \approx -14$). Deep Schmidt searches and a recent blind radio survey have not resulted in a single new member of the group. However, it has to be acknowledged that the M101 group is the most distant one considered here. Future surveys of increased sensitivity will likely uncover the sought for exponential rise of the luminosity function.

Canes Venatici (CVn) I Cloud

What is called the Canes Venatici (CVn) I Cloud covers a huge area of sky. There is no obvious concentration of bright galaxies, which would be characteristic of a group, yet the roughly 30 or 40 spirals and irregulars in the area clearly belong together because they have similar velocities and (by implication) distances. G De Vaucouleurs rightly called the feature a cloud. The brightest (possible) cloud members are M64 in the South and M94 in the North, both Sab spirals of roughly Milky Way Galaxy luminosity. But these giants are well separated from each other and almost isolated. The most conspicuous (gravitationally bound?) clumping of galaxies in the cloud, near NGC 4214, involves about ten late-type spirals (Sd, Sm) and irregulars (Im) whose brightest members are not much brighter than the LARGE MAGELLANIC CLOUD. The lack of early-type galaxies is a clear sign of low galaxy density and is typical for clouds.

From the velocities of CVn I members one has inferred a prolonged structure of the cloud, roughly aligned with our line of sight. Direct distance measurements based on the brightest resolved blue stars in CVn I irregulars give 2.3 to 8 Mpc as distance range, i.e. depth of CVn I.

The whole CVn region is very complex. There are several clouds and groups/clusters projected on top of each other. Slightly to the North (in the mean) there is the CVn II cloud which is more distant but may simply be the extension of CVn I backwards to greater distances, merging with the UMa cloud in the North and the Coma I cluster in the South.

Centaurus A Group

The Centaurus A (Cen A) Group is the Southern analog of the M81 Group. It is equally rich and dense, with 40 members known at present, it is equally distant, with $D \approx 4$ Mpc, and there are also a number of giant galaxies, some of which show signs of strong interaction. The 'padrone' of the group is of course the famous peculiar galaxy and strong radio source Cen A (NGC 5128): it is the nearest giant elliptical, the nearest merger, and the nearest ACTIVE GALAXY (AGN) at the same time.

The other giant group members ($M_B > -18$) are M83, a magnificent Sc spiral galaxy, NGC 4945 (also Sc), and NGC 5068 (SBc). Other bright members of the group include NGC 5102 (S0) and NGC 5253 (Im). About 20 faint dwarf irregular and 10 dwarf elliptical members are known in addition. The group shows clear substructure, essentially a double structure (like the LG)—defined by the main clump around Cen A in the South, and a smaller subclump around M83 in the North. Both giant galaxies possess extended swarms of dwarf galaxy satellites. The dwarf ellipticals tend to be clustered around Cen A, as expected from the morphology–density relation of galaxies. The two hot spots of the group, the Cen A and M83 subclumps, are embedded in an oddly triangle-shaped cloud of dwarf irregulars.

Sculptor (Scl) Cloud

The Sculptor, or 'South Polar' Cloud (as it is sometimes called for its unique position in the southern sky), is the most nearby supergalactic structure beyond the LG. It is a prolate feature of length 3 Mpc and thickness 1 Mpc,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

which we see pole-on because we are situated near one of its ends. Owing to the low mean galaxy density, there are no real giant, Milky Way-type galaxies, but one finds a handful of bright late-type spirals (Sc, Sd) plus about 15 fainter dwarf irregulars and 5 dwarf spheroidals.

The 28 Scl members known at present seem to fall into three or four (gravitationally bound?) subclumps, centered on NGC 300 (Sc) and NGC 55 (Sc) at the near side ($D \leq 2$ Mpc); NGC 247 (Sc) and NGC 253 (Sc, the most nearby starburst galaxy) at $D \approx 2.7$ Mpc; NGC 45 (Scd) and NGC 59 (dwarf S0) at $D \geq 4$ Mpc; and possibly NGC 7793 (Sd) at $D \approx 3$ Mpc. But not all Scl members are companions to these bright main members; the dwarf irregulars are dispersed in the whole cloud.

It has always been noted that the distribution of LG members is rather asymmetric, with an extended population of Southern dwarf members out to $D \approx 1.5$ Mpc, in the direction of Sculptor (like WLM, Tucana, Pegasus, IC 5152, *et al*). It now appears that these galaxies form a perfect bridge to the Scl Cloud, which means that the LG can be regarded as the major subclump (hot spot) in an extended 'Sculptor-LG Cloud' of dimension 6×2 Mpc (see figure 2), which itself is part of the very large 'Coma-Sculptor Cloud'. The consequences of this new picture for the dynamics of the Local Group have yet to be explored.

Near-Earth Asteroids (NEAs)

Asteroids whose orbits bring them into the inner solar system, by definition those with perihelion distances of less than 1.3 AU. They are also known as *Earth-approaching asteroids*; the term *near-Earth object* (NEO) is sometimes used in recognition that some of these objects are cometary in origin. There are three classes of NEA: Amor asteroids, Apollo asteroids and Aten asteroids. As of April 2000 the numbers known in each class were 450, 464 and 75, respectively. *Amor asteroids* are defined as those with a perihelion distance between 1.017 AU (the Earth's aphelion distance) and 1.3 AU, and are named after the 1 km diameter asteroid (1221) Amor. The largest are (1036) Ganymed, at 40 km, and (433) Eros, at 35×13 km; Eros was the first to be found and is the most studied, having been orbited by the NEAR Shoemaker probe. *Apollo asteroids* are defined as those with a perihelion distance less than 1.017 AU and semi-major axis greater than 1 AU. They are named after the 1.5 km diameter asteroid (1862) Apollo; the largest is the 8 km diameter (1866) Sisyphus. These two groups are sometimes classified together as *Apollo–Amor objects*. *Aten asteroids* are defined as those whose semi-major axis is less than 1 AU, and are named after the 1 km diameter asteroid 2062 Aten. The terms *Mars-crossing*, *Earth-crossing* and *Venus-crossing* are used for asteroids which intersect the orbit of a particular planet.

Three-quarters of NEAs are thought to be asteroids perturbed inwards from the main asteroid belt. The mechanism is believed to be based on chaotic dynamics near the Kirkwood gap corresponding to a 3:1 resonance with Jupiter. The others are thought to be extinct comet nuclei. The lifetime of NEAs is probably not much more than 10 million years, their likely fate collision with one of the terrestrial planets or gravitational ejection from the inner solar system via a close encounter. That objects continue to collide with terrestrial planets is evidenced by, for example, the geologically very recent Meteor Crater on Earth. In 1980 the Spacewatch Program was instituted to track down what have become known as *potentially hazardous asteroids* (PHAs): the closest-approaching NEAs that are considered to be large enough that an impact of one of them with Earth would endanger human civilization. Attempts to quantify the likelihood of future Earth impacts of PHAs suggest that a civilization-threatening event might occur once in several hundred thousand years—in other words, the odds of such an occurrence in a given century are several thousand to one. Estimates of the population of NEAs suggest that there may be 2000 bodies of 1 km or more, and 100 000 larger than 100 m. Objects of 100 m or less would cause local damage, as in the Tunguska event of 1908, while objects of around 10 m would burn up during their passage through the atmosphere. The closest recorded approach was 104 700 km by the 9 m diameter 1994 XM_1; for a 100 m plus object, the record is held by 1996 JA_1 (220 m) at 448 800 km.

Two asteroids hit the news in 2002 because of their predicted close approach to the Earth. On 9 July 2002, MIT astronomers discovered 2002 NT7, a 2 km-wide space rock in a curious orbit. Unlike most asteroids, which circle the Sun in the plane of the planets, 2002 NT7 follows a path that is tilted at 42°. It spends most of its time far above or below the rest of the solar system. Every 2.29 years, the asteroid plunges through the inner solar system not far from Earth's orbit. Researchers calculated there was a chance that 2002 NT7 might hit our planet on 1 February 2019. This made headline news, worrying some members of the public. What was not reported was that the odds of impact are 1 in 250 000.

On 14 July, astronomers discovered 2002 NY40. This asteroid measures about 0.800 km across, and follows an orbit that ranges from the asteroid belt to the inner solar system. Its closest approach was on 18 August 2002, passing only 1.3 times farther away than the Moon, and being visible through binoculars.

Nebula

A diffuse aggregation of interstellar matter, mostly gas but often also containing dust grains. The name (Latin for 'cloud') is applied to a variety of objects, visible either because they are bright and seen against the dark background sky or because they are dark and seen in silhouette against a brighter background object. The term is also used to describe objects that have a similar appearance when observed in wavebands outside the visible region, in the infrared for example. Until the later 1800s, a 'nebula' was any fuzzy patch that telescopes were incapable of separating into component stars. Spectroscopy demonstrated that some were indeed gaseous, and not unresolvable star clusters; others, that were found to lie well outside the Milky Way, and subsequently found to be other galaxies, were originally referred to as 'extragalactic nebulae'.

Bright nebulae may be either emission nebulae or reflection nebulae. Emission nebulae are self-luminous. Most shine because the gas from which they are composed is ionized by ultraviolet radiation from a nearby star; examples are H II regions and planetary nebulae. Other mechanisms include synchrotron radiation, responsible for the emission of light from supernova remnants such as the Crab Nebula. Reflection nebulae are cool clouds of dust and gas; the dust scatters the light of nearby stars. An example is the nebulosity surrounding the stars of the Pleiades and other star clusters, and many reflection nebulae are the remnants of the interstellar matter from which a cluster of stars was born. Dark nebulae are also known as absorption nebulae: they absorb light from nearby sources. The light is re-emitted as infrared radiation or scattered, making the nebulae appear dark. A famous example is the Horsehead Nebula.

Other uses of the term include protoplanetary nebula (also called a protoplanetary disk), for the cloud of matter around a newly formed star from which planets form (and also applied to an early stage in the development of a planetary nebula), and solar nebula, for the cloud of interstellar matter from which the Sun and the solar system formed.

Needham, Joseph (1900–95)

Historian of science, he was educated at Gonville and Caius College, Cambridge, where he eventually became Master. A friendship with three young Chinese researchers in Cambridge inspired him to learn Chinese, and during the Second World War he was posted to Chongqing, where he became acquainted with Chinese achievements in science and technology, and was astonished. This inspired him to devote the rest of his life to research his massive work on *Science and Civilization in China*, including its astronomical history. Amongst the high points were the first recorded observation of sunspots, invention of quantitative cartography and the Mercator projection, pre-discovery of the solar wind through observation of comet tails, invention of equatorially-mounted astronomical instruments (see KUO SHOU-CHING), and observation of novae, supernovae, comets, auroras, meteors and other phenomena.

Neptune

Orbiting the Sun in 164.79 years, at a mean distance of 30.06 AU (4.50×10^9 km), Neptune is the outermost of the four GIANT PLANETS. Its orbit is nearly circular (eccentricity 0.009) and inclined to the Earth's orbit plane by only 1.77°. Neptune's outer atmosphere, like those of the other giant planets, is composed predominantly of molecular hydrogen and helium with traces of methane (CH_4). Yet Neptune, together with URANUS, forms a distinct subclass of ice-rich Jovian planets. Most of the planet's mass is in the form of 'ices', primarily water, with possibly a 'rock' component. Despite its remoteness, Neptune's atmosphere is one of the most dynamically active in the outer solar system. Small bright clouds evolve with a timescale shorter than a day while large dark spots, slowly moving and oscillating in shape, persist for months. In the upper atmosphere, photolysis of methane initiates a suite of photochemical reactions producing heavier hydrocarbons and condensation hazes. Neptune possesses a large and complex magnetic field, much like that on Uranus, with a magnetic dipole offset from the planet's center and tilted by 47° to the spin axis.

Basic data

Table 1 presents basic physical data about Neptune, with some comparison with the Earth (⊕). Uranus and Neptune are similar in mass (14.53 and 17.14 Earth masses respectively), radius (25560 and 24760 km respectively), and mean density (1.27 and 1.64 g cm^{-3} respectively). They are smaller, less massive, and denser than the 'inner' pair of giant planets, Jupiter and Saturn.

The interior of the planet rotates in 16.11 h, slightly more rapidly than Uranus. This rotation is responsible for the slight flattening (or oblateness) of the planet of 1.7%, the polar radius at 1 bar being 420 km smaller than the equatorial radius.

The equatorial plane of Neptune is tilted by 29.6° to the orbit, causing significant seasonal variations of insolation. Neptune emits 2.6 times more energy than it absorbs from the Sun. Reflecting 29% of the incident sunlight, its equilibrium temperature, without any additional heat source, would be 46.7 K. The effective temperature, related to the total energy emitted by the planet, is significantly larger (59.3 K). The excess emission is due to the presence of a substantial source of internal heat, as is the case in Jupiter and Saturn but not in Uranus. This internal heat flow is thought to derive from cooling of Neptune's hot interior.

Table 1. *Neptune's physical parameters*

Mass	1.024×10^{26} kg	(17.14 ⊕)
Equatorial radius at 1 bar	24 760 km	(3.88 ⊕)
Equatorial gravity at 1 bar	10.9 m s^{-2}	(1.11 ⊕)
Oblateness	0.017	
Rotation period	16.11 h	(0.673 ⊕)
Obliquity of rotation axis	29.6°	
Effective temperature	59.3 K	
Bolometric Bond albedo	0.29	

Discovery and exploration

Neptune was first observed and identified as a planet in September 1846. The quest for Neptune actually began in 1781 when WILLIAM HERSCHEL accidentally discovered Uranus. Soon after it was recognized as a planet, it became clear that Uranus' orbit was 'irregular' and perturbed by some unidentified influence. Around 1834 came the first suggestions that a trans-Uranian planet might be causing the deviation from Uranus' predicted orbit. Independently, two astronomers, JOHN COUCH ADAMS from Cambridge University Observatory and Urbain Jean JOSEPH LE VERRIER from Paris Observatory, tackled the problem of the irregularities in the motion of Uranus. By 1845, both ended with very consistent predictions for the position of the disturbing planet. J C Adams wrote to JAMES CHALLIS, professor of astronomy, who in turn contacted George Airy, director of the ROYAL OBSERVATORY, GREENWICH, to conduct a search for the expected planet. His request, however, did not receive immediate attention. It was only in June 1846, on receiving a memoir from Le Verrier, that Airy decided to launch into the search and asked Challis to urgently undertake the observations. With no good map of the relevant sky area, the survey went on very slowly and Challis soon lost faith. On 18 September 1846, Le Verrier decided to contact Johann Gottfried Galle from Berlin Observatory, asking him to search at the position he had predicted. On 23 September, the same day he received Le Verrier's letter, JOHANN GALLE, assisted by a young student HEINRICH D'ARREST, turned the telescope to the expected position. On checking the stars in the field with the recent Berlin Academy's Star Atlas, Galle and D'Arrest very soon noticed an object not in the catalog. The hunt was over: Neptune had been discovered within 1° of its calculated position. This brilliant discovery, based purely on calculations of orbital perturbations, marked the triumph of celestial mechanics.

With a visual magnitude of 7.8, Neptune is too faint to be seen by the naked eye. Through a telescope, it appears as a bluish disk with an angular diameter of 2.3 arcsec at mean opposition. Photographic spectroscopy at the beginning of the century allowed the detection of absorption bands of methane (CH_4). The presence of hydrogen (H_2), the main atmospheric constituent, was only demonstrated in 1952 for all the giant planets. In the 1970s, spectrophotometric observations of the visible and near-infrared spectrum of Neptune yielded a first determination of the CH_4 abundance and of the pressure level of the upper haze layer. Emission bands from ethane (C_2H_6) and acetylene (C_2H_2) were also detected. The development of infrared astronomy allowed observers to measure the thermal radiation emitted by Neptune and to infer the existence of a large internal heat source. Numerous photometric observa-

tions in the near-infrared region established that the atmosphere of Neptune shows large temporal variations on timescales from hours to years. Direct imaging of Neptune using sensitive CCD cameras revealed the presence of discrete clouds rotating in the prograde direction, i.e. in the same sense as the orbital revolution. In the early 1980s, the presence of rings around Neptune was sought through stellar OCCULTATION techniques. After a perplexing series of positive and negative detections, a partial occultation was simultaneously detected in 1984 by independent telescopes on one side of the planet only. As a result, the presence of 'ring arcs' around Neptune was proposed.

But most of what we know about Neptune and its environment comes from the VOYAGER 2 flyby in August 1989. Thousands of images were recorded and observations were conducted in the visible, infrared, ultraviolet, and at centimeter wavelengths. Voyager images revealed the presence of prominent cloud systems including an Earth-sized 'Great Dark Spot'. Wind speeds were measured over most of the planet from tracking of cloud motions. The radio science experiment and ultraviolet solar occultations yielded vertical profiles of temperature at selected locations on the planet. The temperature field was mapped in the upper troposphere and lower stratosphere. The mixing ratio of helium (He) was determined as well as the abundance profiles of the main hydrocarbons in the stratosphere. The magnetic field experiment discovered a strong and complex magnetic field and an associated magnetosphere. The rotation period of the interior was determined from the periodicity of radio bursts emitted by Neptune. Broad and narrow rings circling the planet were observed, with the outermost having optically thicker arc segments (see NEPTUNE: RINGS). Six new moons were discovered with diameters between 50 and 400 km (see NEPTUNE: MINOR SATELLITES). Voyager's observations of TRITON, Neptune's largest satellite, revealed a geologically young surface, a covering of seasonal ice over the polar regions, a thin nitrogen (N_2) atmosphere with traces of methane (CH_4), and active geyser-like plumes.

Our knowledge of Neptune's atmosphere continued to grow beyond the wealth of data harvested by the Voyager spacecraft. Hubble Space Telescope (HST) imaging of Neptune in 1994–96 revealed changes in atmospheric features (dark spots and bright clouds) over that period. In addition, the pattern of zonal bands was different from that at the time of the Voyager encounter. Observations at large radiotelescopes yielded detections of two new compounds (hydrogen cyanide HCN, and carbon monoxide CO) in the stratosphere of Neptune. In 1997, the Infrared Space Observatory (ISO) orbiting the Earth recorded the solar reflected and thermal emission spectra of Neptune. These high spectral resolution observations led to the first detections of water vapor (H_2O) and carbon dioxide (CO_2) in the upper atmosphere; methyl radicals (CH_3), direct products of methane photolysis, were also observed.

Atmosphere

Current theoretical models suggest that the atmosphere of Neptune extends down to about 3500 km below the 1 bar level, up to a pressure of ~100 kbar, and overlies a denser fluid comprising mainly water, methane and ammonia. The mass of this outer layer, between 0.5 and 1 Earth mass, is a small fraction of the total mass of Neptune, in contrast to the gas-rich JUPITER and SATURN. Only a tiny fraction of Neptune's atmosphere, the upper 100 bar, is accessible to observations by remote sensors.

Thermal structure

Figure 1 shows a mean vertical profile of temperature in Neptune's atmosphere. In the lower atmosphere—the troposphere—the temperature increases with depth and with increasing pressure. The temperature minimum, located near the 0.1 bar level, defines the tropopause. This is the base of the stratosphere, where temperature increases with altitude. Above the stratosphere, at pressure levels less than ~0.1 microbar, lies the thermosphere.

The temperature profile in the troposphere and stratosphere mostly results from a balance between heating by the internal heat source and the sunlight absorbed and cooling by infrared thermal emission at wavelengths longer than ~7 μm. Deeper than ~0.5 bar, the dominant energy transport mechanism is convection and the lapse rate follows an 'adiabat', i.e.,

$$\frac{\mathrm{d}\ln T}{\mathrm{d}\ln p} = \frac{R}{C_p}$$

where T is temperature, p is pressure, C_p is the molar specific heat of the atmosphere and R the gas constant. Above this level, the atmosphere is more transparent, radiation dominates over convection, and the lapse rate is smaller than the adiabatic one. The 'temperature inversion' above the 0.1 bar level is due to the presence of various heat sources in the stratosphere, including absorption of solar energy by methane gas and cloud/haze particules.

Tropospheric temperatures on Neptune and Uranus are very similar despite Neptune's greater remoteness. The reason for this is the presence of a large internal heat

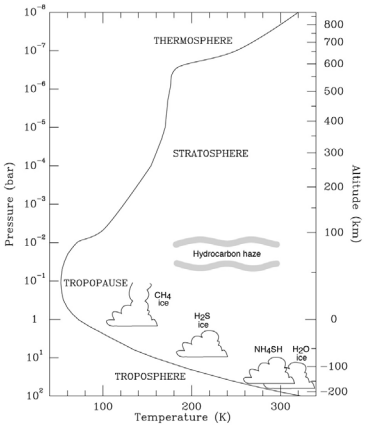

Figure 1. Vertical profile of temperature on Neptune as a function of atmospheric pressure and altitude above the 1 bar level. The location of clouds or hazes derived from thermochemical calculations and assumed abundances of constituents is indicated.

flow on Neptune that nearly compensates for the reduction in solar heating from Uranus to Neptune. The slope of the temperature profile shows a small change near 1.9 bar. This corresponds to the region where methane condenses and forms haze particles. The change in the lapse rate results from the release of latent heat that accompanies methane condensation.

A striking feature of Neptune's thermal structure is the existence of a relatively warm stratosphere. The temperature reaches ~120 K at the 1 mbar level, increasing up to 170–180 K in the range 10–0.3 μbar. This is higher than observed in Uranus' stratosphere even though Neptune receives 60% less sunlight. This feature may be partly explained by the enhanced solar heating on Neptune due to the larger methane abundance and possibly to stratospheric aerosols that are optically thicker. Radiative heating, however, seems to be insufficient to support the warm temperatures observed and an additional non-radiative heating mechanism may be required. A possibility is the dissipation of GRAVITATIONAL WAVES propagating upward into the stratosphere.

At the base of the thermosphere, the temperature rises steeply to reach ~750 K near 10^{-5}μbar. This rise is caused by the downward transport of heat through molecular conduction. The source(s) of this high-altitude heating is not yet clearly identified. Some proposed mechanisms are dissipation of gravity waves, electron precipitation from the magnetosphere, Joule heating generated by the atmospheric motion in the magnetic field, or collision of supersonic jets generated by the auroral energy deposition (see AURORA).

Composition

Neptune's atmosphere is primarily molecular hydrogen (H_2) and helium (He). Hydrogen is present in both the symmetric (ortho) and antisymmetric (para) states—relative to the spin of the two protons—with an ortho/para abundance ratio consistent with thermodynamic equilibrium. The He mole fraction lies between 16 and 22%. The lower part of this range is compatible with the estimated abundance of He in the presolar nebula from which Neptune formed 4.6 billion years ago. Deuterium (D), the heavier isotope of hydrogen (H), is enriched in Neptune's atmosphere. The D/H ratio is inferred to be 0.5–1×10^{-4}, higher than the value in the primordial solar gas. This enhancement is due to incorporation of deuterium-rich ices during the formation of the planet (see below).

Beyond these two light elements, Neptune's observable atmosphere contains methane. The CH_4 mole fraction is about 2% in the 3 bar region. This corresponds to a ~30-fold carbon enhancement over the solar carbon-to-hydrogen ratio, thought to be representative of the presolar nebula (see discussion below). Absorption of sunlight at red wavelengths by methane is at least partly responsible for the bluish appearance of the planet. Above the 1.9 bar level (T~93 K), the methane abundance is severely depleted by condensation processes. The CH_4 abundance is then limited by the saturation law in the upper troposphere and decreases with altitude as temperature decreases. At the temperature minimum of ~53 K reached near 0.1 bar, the saturated CH_4 mole fraction is ~1×10^{-4}. As methane is carried upward through this 'cold trap', one would expect the stratospheric mole fraction not to exceed 10^{-4}. This is not the case and a mixing ratio ten times larger (~10^{-3}) is measured in the lower stratosphere. This situation, contrasting with Uranus' atmosphere, is discussed later.

A small amount of carbon is also in the form of carbon monoxide (CO). The CO mixing ratio of about 1×10^{-6} is orders of magnitude larger than expected from thermochemical equilibrium at Neptune's cold observable levels. Its presence is very likely due to rapid convective transport from the deep hot interior where it is stable.

Microwave measurements indicate that, in contrast to Jupiter and Saturn, ammonia (NH_3) is severely depleted in Neptune (and Uranus) down to at least the 30 bar pressure level. This is at first glance surprising, considering the large enrichment observed in carbon and the fact that both C- and N-bearing ices were probably present in the planetesimals that accreted to form Neptune. The most likely explanation is that NH_3 is removed by chemical reaction with H_2S (hydrogen sulfide) to form NH_4SH crystals. This, however, requires that H_2S is more abundant than NH_3, and consequently that the S/N ratio is at least five times larger than in the Sun. If H_2S is, like CH_4, enriched by a factor of 30 relative to the solar abundance ratio while NH_3 has a solar abundance ratio, the NH_4SH cloud should form near the 40 bar level and the corresponding gas profiles then provide a satisfactory interpretation of Neptune's microwave spectrum. An alternate possibility is that most of the nitrogen is in the form of N_2 rather than NH_3.

Due to the low atmospheric temperatures, water (H_2O) condenses out even deeper and cannot be probed by remote-sensing observations.

Photochemistry

In the upper stratosphere, methane undergoes photolysis due to ultraviolet radiation from both the Sun and the local interstellar medium. CH_4 photodissociation produces CH, CH_2 and CH_3 radicals. Subsequent reaction schemes of various complexity yield a suite of hydrocarbons, ethane (C_2H_6) and acetylene (C_2H_2) being the most abundant. These compounds slowly diffuse down to the lower (colder) stratosphere, where they are lost by condensation. Hydrocarbon ice particles eventually fall through the tropopause and the warmer troposphere, where they sublimate and are recycled into methane in the deep hot layers. The C_2H_6 and C_2H_2 mole fractions near the 0.1 mbar level are about 2×10^{-6} and 1×10^{-7} respectively. Neptune's carbon cycle is illustrated in figure 2.

A tiny fraction of hydrogen cyanide (HCN) is present in the stratosphere of Neptune. HCN production is initiated by the reaction between CH_3 radicals and N

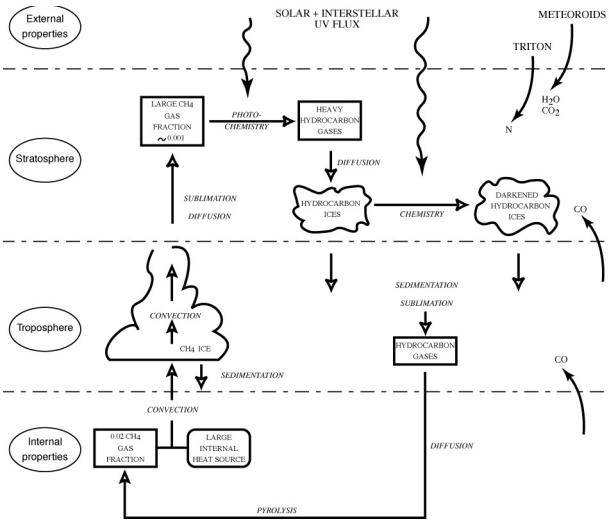

Figure 2. Chemical and physical processes governing the carbon cycle on Neptune. Methane is delivered to the stratosphere by convective plumes that form near the condensation region in the troposphere. Methane photodissociation in the upper atmosphere produces heavier hydrocarbons that diffuse downward to the lower stratosphere, where they condense out. Hydrocarbon ice particles then fall into the warmer troposphere, where they sublimate. Deeper in the atmosphere, hydrocarbon gases are pyrolized back to methane.

atoms. Two possible sources of N atoms can be envisaged: escape from Triton's atmosphere, or galactic cosmic ray impact on N_2 supplied from the deep interior via rapid vertical mixing. The HCN mole fraction is ~1×10^{-9} in the mbar region; condensation near the 2–3 mbar level drastically reduces its abundance at greater depths.

Neptune's upper atmosphere also contains small amounts of oxygen-bearing compounds having an external origin: water vapor (H_2O) and carbon dioxide (CO_2) with column densities of ~3 and 8×10^{14} molecules/cm2 respectively. Water probably originates from the continuous infall of interplanetary dust and meteoroids rich in water ice and silicates. The equivalent of a few liters of water falling every second on the planet is enough to explain the observed quantities. Carbon dioxide may have the same origin, as the infalling meteoroids probably contain CO_2 ice. Another possible source is the reaction of CO, present in Neptune's atmosphere, with OH radicals formed from the photolysis of H_2O.

Clouds and hazes

Formation of condensation clouds in the troposphere of Neptune is expected, considering the atmospheric temperature profile and the presence of various volatile gases. From thermochemical modeling, a solution cloud of liquid water with dissolved H_2S and NH_3 is predicted to form at pressure levels of one or a few hundred bars depending on the H_2O abundance. Moving upward, a water ice cloud is expected around 50 bar (T~270 K). Near 40 bar (T~250 K), reaction of NH_3 and H_2S produces a cloud of NH_4SH solid particles. The amount of H_2S in excess of NH_3, thus not incorporated in the NH_4SH cloud, is expected to condense out at ~5 bar (T~150 K). Methane, more volatile, forms the uppermost cloud layer in the troposphere with a condensation level at 1.5 bar (T~80 K). It should be noted that the precise location, thickness and vertical extent of the cloud layers in Neptune are in fact rather uncertain due to unknowns in the atmospheric composition and to the important role of cloud microphysics and dynamical motions (see CLOUDS IN PLANETARY ATMOSPHERES).

How does this cloud model correlate with actual observations of Neptune's atmosphere? Near-infrared spectroscopy and imaging indicate that the bottom of the visible atmosphere is at a pressure of about 3–4 bar and thus probaby corresponds to the top of the optically thick H_2S cloud. Above this background, the CH_4 cloud appears to be very thin on a planet average, with an optical depth as low as ~0.05 in the red. Neptune's atmosphere is not, however, homogeneous and shows a variety of light and dark features (see below). Some prominent bright cloud features are likely made of CH_4 particles near the 1 bar level. Dark ovals (figure 3) can be interpreted as holes in the H_2S cloud cover.

In the stratosphere, gases formed from CH_4 photochemistry in the microbar region are expected to condense out to form a haze as they diffuse downward. Ethane is probably the main constituent of the 'photochemical' haze (75% by mass), with the remainder provided by heavier hydrocarbons. The haze top, associated with the condensation level, is located at 10–15 mbar. On a disk-average basis, the mean stratospheric haze burden is 1–2 μg cm^{-2}. It is substantially lower in the equatorial region. This haze is composed of sub-micron particles which absorb the ultraviolet radiation from the Sun very efficiently. Linear cloud streaks observed by the Voyager spacecraft in the north have been associated with enhanced wisps of hydrocarbon ice particles.

Dynamic meteorology

Neptune has some of the fastest winds measured on any planet, despite the small amount of energy received from the Sun. The circulation pattern is characterized by large retrograde (westward) winds at the equator transitioning to prograde (eastward) winds poleward of ~50°. Wind speeds measured at the cloud tops vary from 400 m s^{-1} at the equator to 250 m s^{-1}at –70° latitude. The zonal wind structure is similar to that found on Uranus and much simpler than on Jupiter or Saturn. It corresponds to a nearly uniform value of the angular momentum for air parcels aloft over the planet. The observed zonal winds are probably forced by a system of symmetric zonal jets deeply rooted in the atmosphere (yet not in the interior). The amplitude of the winds decays with altitude because of eddy viscosity.

The temperature field in the upper troposphere shows a maximum at the equator, minima at mid-latitudes (~50°) and a rise towards the poles. The latitudinal

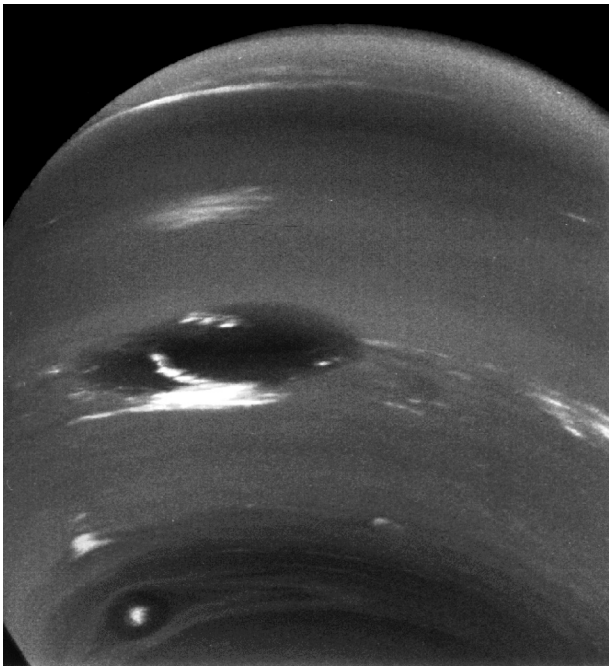

Figure 3. Image of Neptune taken by the Voyager 2 spacecraft in August 1989. The Great Dark Spot (GDS) accompanied by cirrus-like clouds is prominent. The 'Scooter', a small bright cloud feature, is visible to the lower left. Below the Scooter lies another dark spot (DS2) with a bright core (NASA/JPL).

contrast amounts to 3 K near 0.5 bar, 5 K at the tropopause (0.1 bar), and seems to persist in the stratosphere (~10 K around 0.2 mbar). The mid-latitude cool regions are thought to result from upwelling causing adiabatic expansion and cooling. Conversely, subsidence in the equatorial region and at the poles produces atmospheric heating and higher temperatures. The meridional velocities associated with this flow are small, of order 1 cm s^{-1}. The latitudinal temperature gradients and meridional circulation are in fact associated with the frictional damping of the zonal winds, as required by geostrophic balance.

Neptune's atmosphere is visually very active. The most remarkable feature revealed by the Voyager images is the Great Dark Spot (GDS), a dark oval spot in the southern hemisphere (Fig. 3). Between January and August 1989, the GDS moved steadily equatorward from –27 to –17° latitude. Like most of the Jovian vortices (see JUPITER: ATMOSPHERE), it is an anticyclone—a high-pressure center. The GDS was oscillating with an eight-day period, its latitudinal size varying between 12 000 and 18 000 km and its longitudinal size between 5200 and 7400 km. The source that was maintaining the GDS, given that some dissipation must occur, is unknown. Observations with the Hubble Space Telescope (HST) in 1994 showed that the GDS had disappeared or faded away. A second large dark spot (DS2) was present during the Voyager flyby at about –50° latitude. It was 5200 km wide in longitude (~20°) and 2600 km high in latitude (~6°). This spot had a bright central core which was showing strong convective activity. The latitude and longitude of DS2 oscillated with a 36-day period. In 1994 a new spot (GDS-94), similar in size to the GDS, was reported in the northern hemisphere at 31° latitude. It was still present at the same latitude eleven months later.

The dark spots GDS and GDS-94 are accompanied by bright cloud features which are probably composed of condensed methane. The GDS companion, located at its southern border, changed markedly over several hours (figure 4). In 1995 the bright companion of GDS-94 was located northward of the spot whereas, in 1994, a large complex of cloud features extended from slightly north of the spot almost to the equator. Near –41° latitude, a bright long-lived feature, named 'Scooter', was observed by Voyager. Relatively small (3° in latitude and 7.5° in longitude), it consists of many bright east–west streaks which change on timescales of days; its shape itself varies from rectangular to triangular. The Scooter is located beneath the methane cloud top, deeper in the atmosphere than the bright companions of the GDSs. In addition, numerous transient bright features were observed by both Voyager and the HST. In particular, the South Polar Feature (SPF), between the latitudes –68° and –74°, was a very active region at the time of the Voyager encounter, showing many short-lived linear cloud features.

A low-contrast zonal (banded) pattern is also visible on Neptune. The zonal structure present from 1994 to

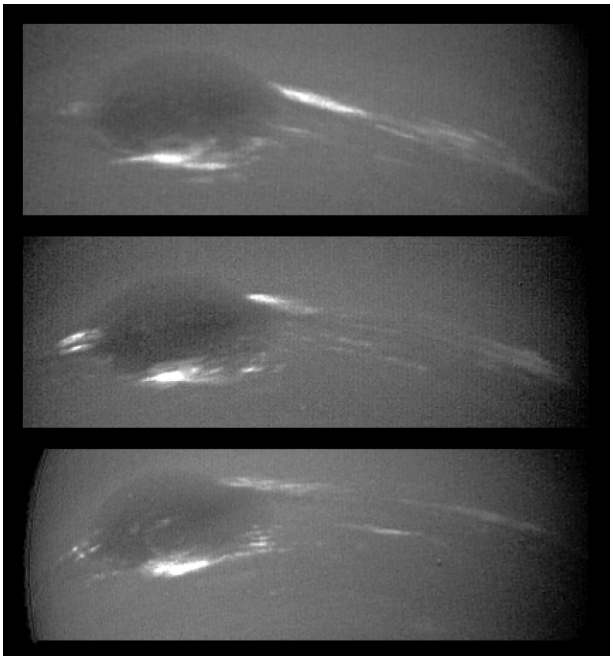

Figure 4. Cloud evolution in the region of the Great Dark Spot (GDS). Panels are separated by 18 hours. The bright cirrus-like clouds of Neptune change rapidly, forming and dissipating over periods of several to tens of hours (NASA/JPL).

1996 differed from that in 1989. The prominent dark band seen by Voyager between –40° and –68° was weaker and narrower (–55° to –70°) in 1994–1996.

Other evidence of activity is the presence of a significant abundance of methane in the stratosphere, an order of magnitude larger than allowed from diffusion through the 'cold trap' (see above). It is thought that convective penetration conveys methane in the form of ice crystals from the condensation region in the troposphere (~1.5 bar) upward to the lower stratosphere (~0.05 bar) where they can sublimate and contribute to enhancing the methane mixing ratio (figure 2). In ascending plumes (several km in diameter) uplifted above the cloud base or supersaturated in methane, buoyant moist convection could transport a significant fraction of the condensed methane at least up to the tropopause. Eddy diffusion may further raise the small CH_4 particles into the sublimation region. The delivery of methane to the stratosphere must be of the order of 1000 kg s^{-1} to balance photochemical losses.

Neptune is a surprisingly active planet considering the weakness of the solar energy available to power the wind system and meteorology. It is possible that the low level of insolation actually reduces the source of small-scale turbulence and thus of dissipation. The low frictional losses then allow strong zonal winds to build up and the large dark vortices to persist.

Interior and formation

At pressures higher than 100 kbar, beneath the hydrogen-rich envelope, lies the denser interior of Neptune. Most plausibly, it is mainly composed of the abundant 'ices' H_2O, CH_4 and possibly NH_3. Although these molecules are *not* in the solid state in Neptune's interior, they are referred to as 'ices' because they were in the form of ice in the outer solar nebula, unlike hydrogen and helium. The interior probably includes a significant fraction of 'rocks' (~25% by mass), mostly silicates and iron, and also some hydrogen and helium. The temperature increases inwards from 2000 K at 0.1 Mbar to 8000 K at the center, where the pressure is ~8 Mbar. There is no evidence for a differentiated rocky core at the center although a small one comprising at most 1 Earth mass is possible.

Unlike Jupiter and Saturn, most of the mass in Neptune (80–90%) is in the form of 'ice' and 'rock' rather than hydrogen and helium. The reason lies in the way the giant planets formed. In the outskirts of the solar nebula, dynamical times were longer and the surface density of grains was smaller than closer to the Sun. Neptune thus took longer to accrete a massive core than did the other giant planets, and did not have the time to trap gravitationally a large envelope of gaseous hydrogen and helium before the nebula was dispersed (see SOLAR SYSTEM: FORMATION). It might even have been difficult to pull out the observed amount of hydrogen and helium directly from the nebula. These gases might then have been initially trapped in large ice-rich planetesimals and incorporated into Neptune in the final stages of planetary growth, after dispersal of the nebula.

The enrichment of Neptune's outer atmosphere in deuterium (D) and heavy elements (C, S…) is a signature of the pre-eminence of ices in the planet. It may originate from icy D-rich planetesimals accreted during the last stages of planetary formation, slowed down and dissolved in the outer envelope before reaching the interior. It is also possible that the enrichment results from subsequent mixing between the ice-rich interior and the outer hydrogen–helium atmosphere.

Neptune's intrinsic heat flow amounts to 0.4 W m^{-2}, that is 1.6 times the solar flux absorbed. Transport of heat from the hot interior by convection and radiation is responsible for this energy source and for cooling of the planet since its formation. This behavior contrasts with Uranus, for which only an upper limit of 0.09 W m^{-2} was derived, indicating that the deep-seated heat is no longer transported outwards. Part of the difference in heat flows is due to the fact that Uranus is closer to the Sun so that escape of internal heat is hampered. Compositional stratification, inhibiting convective transport, might also involve a larger fraction of the interior in Uranus than in Neptune.

The magnetic field of Neptune (see below) is probably due to convective motions deep in the interior. At the temperatures and pressures relevant to Neptune's interior, a fluid of ice composition is partly ionized and dissociated and presents some electrical conductivity. Considering the velocities expected for convective motions, a dynamo can be sustained and magnetic field generated. It is possible that the dynamo-generating region is limited to a relatively thin shell (20% of the radius) where the conductivity is high enough, whilst convection is not inhibited by stable stratification.

Magnetic field and plasma

Neptune has a substantial magnetic field with a magnetic dipole tilted from the axis of rotation by 47° and offset 0.55 Neptune radii (R_N) from the planet's center (figure 5). These characteristics are rather similar to those at Uranus. The dipole representation of the field is valid typically at distances of 3 to 20 R_N. Higher-order multipole moments are very significant and affect the magnetic field at shorter distances. The field magnitude at 1 R_N varies on the planet between 0.1 and 0.8 G; it is smaller in the northern hemisphere than in the southern.

A consequence of the large tilt of the magnetic dipole moment is that the internal configuration of the magnetosphere changes rapidly as the planet rotates in the solar wind. The interaction of the solar wind with Neptune's magnetosphere produces a bow shock 35 R_N ahead of the planet. The solar wind plasma is slowed to subsonic speeds and traverses the turbulent magnetosheath as it flows around the magnetopause. The latter, located at 26 R_N sunward from the planet, marks the outer boundary for the pre-eminence of Neptune's own magnetic field. This transition region is a rotational discontinuity across

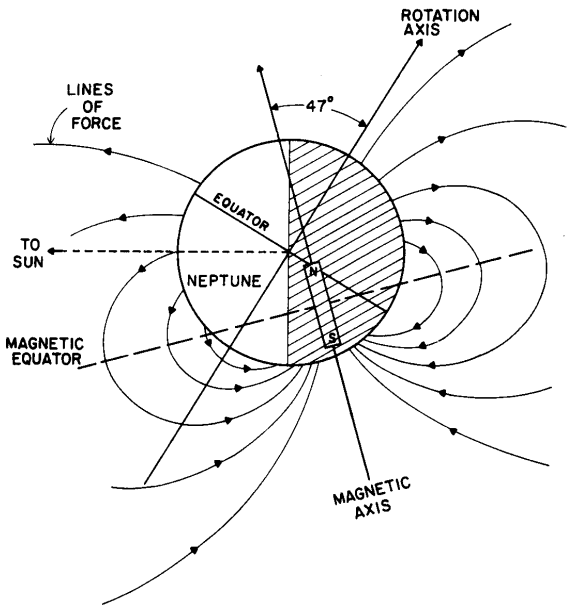

Figure 5. Configuration of Neptune's magnetic field lines. The magnetic field can be represented to first order by a dipole tilted by 47° from the axis of rotation and offset 0.55 Neptune radii. (This figure is adapted from Ness N F, Acuña M H, Burlaga L F, Connerney J E P, Lepping R P and Neubauer F M 1989 Magnetic fields at Neptune *Science* **246** 1473–8.)

which the field direction changes by ~45°, allowing some plasma to flow from the magnetosheath to the magnetosphere. The magnetotail extends to great distances in the anti-sunward direction.

Triton is the main source of magnetospheric plasma. It is created as neutral atoms escape Triton's thin atmosphere and are ionized in the magnetosphere. Neptune's atmosphere may also be a source of neutral H feeding the magnetospheric plasma. The dominant ions are N^+ and H^+. A maximum density of 2 ions/cm^3 was found by the Voyager spacecraft near closest approach to Neptune. This is the lowest plasma number density of all four giant planets. The N^+ ion temperature is about 100 eV (10^6 K) outside 5 R_N and 700 eV (8×10^6 K) near Neptune. The protons H^+ have about the same thermal speed as the N^+ ions and, being less massive, much smaller temperatures.

Plasma is removed by transport mechanisms at the same rate it is produced from the Triton source. This transport is rapid and may occur through an organized convection system and/or by diffusion resulting from stochastic changes in the electric field. Such changes are induced by changes in the atmospheric winds which occur in the planet's ionosphere. Plasma is eventually lost near the planet. Possible loss mechanisms are charge exchange within an extended neutral cloud around Neptune, ion precipitation into Neptune's atmosphere, and absorption by rings as the charged particles move planetward.

Weak auroral emissions have been detected by Voyager on the night side of Neptune: a diffuse emission spanning a wide range of latitudes and a more localized emitting region near the south magnetic pole. It has been suggested that the diffuse emission originates from photoelectrons produced on the day side by the solar flux and transported to the night side along the magnetic field lines. Another possibility is the direct precipitation of trapped particles drifting around the planet into a region of anomalously low magnetic field. This region is very extended due to the particular geometry of Neptune's magnetic field. The second emission is more consistent with usual auroral morphology and is probably associated with precipitation of trapped particles near the south magnetic pole. An aurora is also expected to occur near the north pole. The total power radiated by these auroral processes is $\approx5\times10^7$ W. The much larger magnetospheric input power required to produce the auroras may derive from Neptune's rotational energy or from the solar wind through relatively complex mechanisms.

Weak radio emissions have been detected on Neptune, strikingly similar to those seen on Uranus. They appear strongly controlled by the rotation of the magnetic field and hardly influenced by solar wind variations. Their analysis provides the most accurate measurement of Neptune's interior rotation period (16 h 06 m 30 s). The mechanisms generating these emissions are not well understood. They may originate from regions of low plasma density ('cavities'), or from continuous or impulsive injection of energetic electrons in the auroral regions.

Web update (30 April 2003)

Three previously unknown moons of Neptune have been discovered, boosting the number of known satellites of the gas giant to eleven. These moons are the first to be discovered orbiting Neptune since the Voyager II flyby in 1989, and the first discovered from a ground-based telescope since 1949. The new satellites were a challenge to detect because they are only about 30-40 km (18-24 mi) in size. Their small size and distance from the Sun prevent the satellites from shining any brighter than 25th magnitude, about 100 million times fainter than can be seen with the unaided eye. To locate these new moons, an innovative technique was used with the 4.0-meter Blanco telescope at the Cerro Tololo Inter-American Observatory, Chile, and the 3.6-meter Canada-France-Hawaii Telescope, Hawaii. Multiple exposures of the sky surrounding the planet Neptune were taken. After digitally tracking the motion of the planet as it moved across the sky, many frames were added together to boost the signal of any faint objects. Since the planet's motion was tracked, stars showed up in the final combined image as streaks of light, while the moons accompanying the planet appeared as points of light. It now appears that each giant planet's irregular satellite population is the result of an ancient collision between a former moon and a passing comet or asteroid. These collisional encounters

Neptune: Minor Satellites

All but one of Neptune's minor satellites orbit within or just outside its ring system; the exception is the distant object Nereid. Some of them are better described as 'mid-sized' rather than 'minor', but are included under this heading as little is known of them. The inner four, with approximate diameters, are Naiad (60 km), Thalassa (80 km), Despina (150 km) and Galatea (160 km). The first three lie within the Le Verrier ring, to which Despina appears to act as an inner shepherd. All four were discovered during the Voyager 2 flyby in 1989. Diameters of the other satellites are rather more certain. The next, Larissa (195 km), was discovered in 1981 by Harold Reitsema when it occulted a star; it acts as an inner shepherd to the Adams ring. Proteus, orbiting outside the ring system at 118 000 km, is Neptune's second-largest satellite, after Triton. It is a rather blocky object, measuring about 435 by 400 km, and is a dark, heavily cratered body; the largest crater, named Pharos, is some 250 km across. It is another Voyager discovery. The outermost satellite, Nereid, orbiting at an average distance of 5.5 million km, has the most eccentric orbit of any known planetary satellite, at 0.753. It was discovered in 1948 by Gerard Kuiper, and has a diameter of 340 km. It may be a captured object, or it may have been perturbed into this orbit when Triton was captured (if indeed it was).

Neptune: Rings

NEPTUNE, the outermost of the giant planets, has held out against ring observers the longest. This planet, 25 000 km in radius, orbits at about four and a half billion km from the Sun. Its apparent diameter on the celestial sphere is a little larger than two arcseconds, which makes it difficult to detect by ground-based telescopes. Unknown until 25 years ago, the rings of Neptune present key dynamical problems not currently understood. Indeed, the presence of puzzling arcs among the rings of Neptune place this ring system in a class by itself. In this article, we review the observations of Neptune's rings attempting, as much as possible, to provide a description sufficiently broad that it may serve to elucidate the possible links between rings and satellites.

Discovery

Stellar OCCULTATIONS provide a powerful tool with which to detect and study the material surrounding a planet. An occultation observation consists of the measurement of the signal of a star as it approaches and then disappears behind the planet during its apparent motion on the celestial sphere. The variations in the strength of the signal as the star nears occultation provide information on the presence or absence of material around the planet. In July 1984, observations at three telescopes in the European Southern Observatory and the Cerro Tololo Inter-American Observatory recorded the near-simultaneous occultation of a bright star by a semi-transparent object 15 km in width and at least 100 km long. The dip was observed on one side indicating that Neptune had a ring, but also that it was incomplete! This discovery led NASA to reprogram observations of Neptune's environment by the VOYAGER spacecraft, both to learn more about its ring system and also to avoid collisions with its circumplanetary material. Voyager 2 encountered Neptune in 1989 and its instruments succesfully collected data on Neptune's rings and satellites. As the initial detection suggested, Neptune's rings are in a class by themselves. The presence of ring-arcs has been particularly puzzling. Such arcs would not remain azimuthally limited for very long, unless actively confined, but would spread into a full ring. Many models have been proposed to account for the occurrence of ring arcs. Before reviewing these models, let us describe the surprising and varied morphology of Neptune's rings.

Morphology

Neptune's ring system comprises four dusty narrow rings, as well as low-optical-depth dust extended over broad regions. Because of the large fractional abundance of fine, micron-sized 'dust', the rings are best imaged at moderate to high phase angles (the angle formed by the line from the Sun to the ring and the line from the ring to the observer) such that the presence of fine material is brought out by DIFFRACTION.

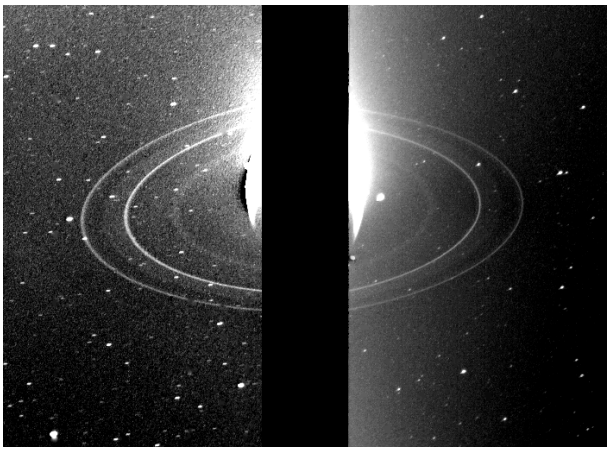

Figure 1. Rings of Neptune. Mosaic of two images of Neptune's rings taken by Voyager spacecraft in 1989. The two bright rings (the inner le Verrier and the outer Adams) are clearly visible. During this period, the bright ring arcs in the Adams ring are not visible. Other discrete structures are also visible like the innermost ring Galle and the broad ring extending from the le Verrier ring towards Adams.

The Adams ring, which houses the ring arcs, is the outermost ring at a radius of $62\,932.57 \pm 0.02$ km from Neptune. Also clearly visible in figure 1, is the narrow le Verrier ring at $53\,200 \pm 20$ km. In between the two outer bright rings lies Lassell, a broad ring, $\sim$ 4000 km, extending from the le Verrier ring and out to the narrow ring Arago. Further in, at an orbital radius of 42 000 km, lies the broad ring ($\sim$ 2000 km) Galle. Finally, a very faint and narrow feature, not visible in figure 1, appears to orbit at the same distance as the satellite Galatea, $\sim$ 980 km interior to the Adam's ring. It is at present unknown whether or not a sheet of low optical depth extends from the innermost ring to the planet.

The arcs in the Adams ring are the most striking example of longitudinal structure in Neptune's rings, and perhaps of any PLANETARY RING (see also JUPITER: RINGS, SATURN: RINGS, URANUS: RINGS). In figure 2 the three arcs named Liberté, Egalité and Fraternité can be seen. They span a region of $\sim$ 40 degrees in longitude. There are, in fact, at least two more arcs, and Egalité itself is composed of two distinct arcs. These features are believed to be clumps of material denser than the average ring particle density found in the Adams ring as a whole. The radially integrated brightness of the Adams ring is observed to vary by about a factor of three, from a maximum near and between the arcs to a minimum far from the arc region. The arcs themselves exhibit clumping and structure on scales ≤ 10 degrees, perhaps resulting from the accumulation of dust-sized particles around bigger particles which might provide the source of the dust through collisions.

Voyager's passage through the ring plane was used to place an upper limit of ≤ 30 km on the vertical extent of the le Verrier and Adams rings. The limit of the vertical extent for one of the arc regions is $\leq$ 110 km.

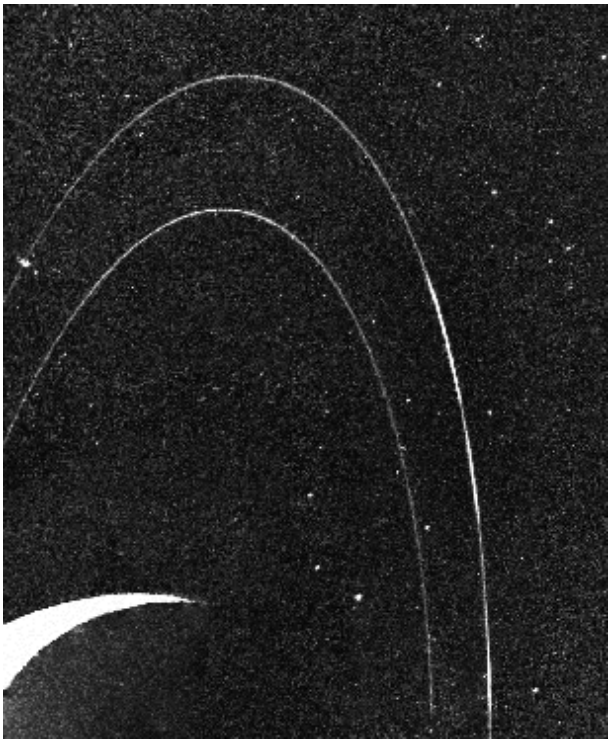

Figure 2. Neptune's arcs from Voyager. The inner ring, le Verrier, is uniform, but the outer ring, Adams, contains three main arcs: from the bottom to the top, Liberté, Egalité and Fraternité.

Further information about the vertical extent from Voyager measurements shows that dust is present throughout the Neptune system, even over Neptune's north pole.

From Voyager photometry the optical depth for the arcs (which measures the degree of extinction of light passing through them) is of the order of 0.1, consistent with occultation observations. For the narrow continuous rings the optical depths depend on the ring widths used to calculate them. The optical depth for the Adams ring is ~ 0.004, and for the le Verrier ring it is ~ 0.002. Both the Lassell and Galle rings are consistent with an optical depth of the order of ~ 0.0001. Uncertainties in the particle size distribution make it difficult to calculate dust fractions for any ring. The problem is exacerbated in the case of the Lassell and Galle rings by the large uncertainties in the low-phase-angle measurements of their scattering properties. Adopting large particle albedos and particle size distribution, the fraction of dust in the arcs, as well as the Adams and le Verrier rings, appears to be comparable with that observed for Saturn's F ring.

The physical and chemical nature of the ring particles is still unknown, mostly because the Voyager spacecraft did not carry a spectrometer, in particular one that operated in the infrared, which would have allowed detection of the absorption band of ices and silicates. However, the study of light diffused by the rings points to a composition of 'dirty ice', perhaps with silicates or some carbon bearing material.

Arc confinement

As soon as Neptune's arcs were discovered, efforts were made to try to understand how they could be azimuthally confined. It was soon realized that unless actively 'herded' the arcs would spread into a complete ring in a matter of years. This is due to the differential rate of rotation around Neptune between those particles located in the inner part of the arc, and those located in the outer part; the latter, being more distant from Neptune, have slightly lower orbital velocities. While one may think that particle self-gravity could counteract this spread, the particles are too small for their gravity to play a significant role.

One possible solution to this conundrum involves satellite confinement in the neighborhood of specific equilibrium locations named Lagrange points. A close analog to such a configuration exists elsewhere in the solar system: a family of asteroids, called the TROJAN ASTEROIDS, are kept in orbit around Jupiter's Lagrange points; however, there is the important distinction that rings are a collisional system. Since Lagrange points correspond to local energy maxima, energy dissipation should lead to the eventual decay away from these locations. As a result, for this model to work it would require the presence of yet another (undiscovered) satellite to counteract the dissipation of energy due to inelastic collisions between ring particles.

An alternative model uses two distinct resonances by one single satellite simultaneously at work to produce ring arcs. For a resonance to take place there needs to be a matching of frequencies; in this context, one possibility is for the orbital period of the ring particles and the satellite to be related by a ratio of integers (i.e. a given number of revolutions by the ring particles corresponds to an integer number of revolutions by the satellite). But for objects orbiting an oblate (slightly non-spherical) planet there are other possibilities; in such a case, the frequency with which they move in and out of the orbital plane (if inclined), and in and out of their orbital radius (if eccentric), is distinct from the frequency with which they revolve around the planet. This gives rise to a panoply of possible resonance conditions which can result in complicated dynamical phenomena. A model that uses two different kinds of resonances to explain ring arcs received some support when analysis of Voyager data found that a 42:43 eccentricity resonance with the satellite Galatea could be controlling the ring's radial excursions. At the same time, its 42:43 inclination resonance (Galatea orbits at a slight inclination inside the Adams ring) could prevent the arc from spreading azimuthally. This model places very stringent conditions on the relative radial locations of the ring and the satellite resonance. While it is clear that Galatea plays a role in shaping the Adams ring, it remains uncertain whether its resonances are directly responsible for arc confinement. In the first place, the number and location of the arcs does not appear to correspond to what one would expect on the basis of the resonance model.

Also, the first ground-based images of the arcs taken in 1999 have improved the orbital parameters for this ring system, and have shown that the mean semi-major axis of the arcs is located outside the region defined by the corotation inclination resonance with Galatea. If true, this calls into question the role of Galatea in confining the arcs.

It is possible that, taken together, the observations indicate that the presence of larger librating particles, which provide the source of (at most) partially confined dust, controls the locations of the ring arcs. Then dust escaping from the arcs would populate first the Adams ring (which might explain the variable opacity for this ring), and possibly other inner rings as well. This sourcing mechanism also appears to be a good candidate to explain the presence of dust at the same orbital radius occupied by Galatea. But this, as well as other models, will have to be tested by further observation and theory if we are to understand this challenging ring system.

Conclusion

Ever since rings were first discovered, and later identified as disks of material nowhere touching the planet, astronomers have grown accustomed to celestial objects which come in two basic shapes: spheres and disks. The prospect of coming to grips with a system distinct from these two groups, in that it breaks the azimuthal symmetry we have come to expect, is too tantalizing for astronomers to resist. Whether these structures have more to tell us with regard to the formation of satellites, the longevity of ring systems in general, or the nature and composition of solar system objects, it is clear that the sheer challenge of Neptune's ring system will keep astronomers coming back for more for a long time to come.

Neutral Point

A point in space at which an object (strictly, a point mass—a theoretical particle with mass but no volume) would experience no net gravitational force. The simplest circumstance in which such a point could exist would be between two motionless masses, and it would lie on a line joining their centers of mass, closer to the larger mass. In the universe all masses are in motion relative to one another; in these circumstances neutral points do exist, but calculating their positions for the combined gravitational fields of a number of bodies is less straightforward. For the simplest case of two massive bodies in circular orbits around their center of mass, there are five neutral points, known as the Lagrangian points. These points remain fixed with respect to the two bodies.

See: Lagrangian points.

Neutrino Astronomy

The Sun generates energy deep in its core by nuclear fusion processes. A SUPERNOVA (of type II) explodes and blows off the entire star by gravitational energy liberated when the central core collapses. These interesting phenomena of energy generation can never be observed with visible light or any other electromagnetic waves. The places where these phenomena take place are buried deep in dense material and the created heat is quickly thermalized before it comes out of the stellar surface. Relevant information is lost during thermal equilibration.

Nevertheless, one may want to observationally probe the deep interior of the Sun or the gravitational collapse in the supernova core. One then has to find electrically neutral particles that have guaranteed straight travel paths in space. They obviously have to be produced in the regions and should not participate in thermal equilibration in order to bring the desired information. NEUTRINOS are exactly the particles that possess these features. Neutrinos are produced in nuclear processes, but interact with matter so weakly that as soon as they are created they leave the region with very nearly the speed of light as their mass is very small.

The universe about 1 s after the big bang had a temperature as high as the core of a supernova, and light particles such as electrons and positrons were in thermal equilibrium. Cosmic expansion in the meantime cooled down the universe and lowered the energy density. Electrons and positrons then annihilated, disappeared and created photons and neutrinos. These relic neutrinos should exist in the present universe and have important information on the early universe.

COSMIC RAYS are accelerated somewhere in our Galaxy or, if they are very energetic, perhaps in distant active galaxies, too. The extremely energetic cosmic rays (above 10^{20} eV) might even be produced by the decay of exotic objects created in the early universe and floating around even at the present, whose existence is conjectured in grand unified theories of elementary particles. Cosmic rays bend in galactic or intergalactic magnetic fields and cannot be traced back to their birthplaces. Even to this day, we do not know for sure where cosmic rays are actually born. Cosmic rays may interact with the medium surrounding the acceleration region and produce mesons, which decay in a short time and produce neutrinos. Neutrinos then escape freely to open space and may reach Earth with fruitful information.

Neutrino astronomy is used to study the central engines of the Sun and supernova, to identify the origin of cosmic rays and to study the very early universe. Astronomical neutrinos can also be used as beams useful for investigating neutrino properties, such as mass and mixing. Indeed, only after having completed the study of neutrino properties can one begin real neutrino astronomy.

Neutrinos from the Sun were first observed by R Davis Jr in the Homestake gold mine in the late 1960s. The experiment is still going on 30 yr after the initial operation. Since then four other experiments have joined this field and two more are coming into operation in the near future. All five experiments did observe solar neutrinos, thus confirming that the Sun is actually generating energy by nuclear fusion processes (see SOLAR INTERIOR: NEUTRINOS). The reason why this field is still so active even now is that there are serious discrepancies between observations and expectations. What the experiments observed is only 30–60% of what the standard solar model predicts. It would be shocking if the Sun were not working as theory tells us, because all life on Earth depends on stable solar heat generation. The so-called solar neutrino problem has not been completely solved. The most popular idea is not that the solar engine works with an efficiency of only 30–60% but that the 'deficit' of solar neutrinos is caused by neutrino oscillations, namely electron neutrinos that are produced in the Sun are converted to a different kind of neutrino, probably muon neutrinos, either in the solar interior or on the way to Earth. Muon neutrinos are impossible or difficult to observe, hence leading to an apparent deficit of solar neutrinos. This idea will be tested by new-generation experiments in the near future.

23 February 1987 will be remembered as the day when a real instance of the gravitational collapse and the subsequent birth of a NEUTRON STAR were first observed with neutrinos. Two large water Cherenkov detectors, Kamiokande and IMB, observed 11 and eight neutrino events, respectively. Although the observed neutrinos were few, these observations beautifully demonstrated that the underlying theory of the explosion of a type II supernova is correct, namely that the explosion was initiated by the gravitational collapse and the total energy released was about 3×10^{53} erg, which roughly corresponds to 500×solar luminosity×4.6 billion years.

These are the only successful observations of astronomical neutrinos. Large under-ice and under-water detectors are being built and tested for high-energy cosmic ray neutrinos with energies above 10^{12} eV. It will still take several more years before these neutrinos are first observed.

There is absolutely no idea how to detect relic neutrinos born in the early universe. They are expected to have an average energy of only 0.000 17 eV which is too low to have a meaningful interaction probability (cross section) with matter.

What neutrinos are

Particle physics tells us that the ELEMENTARY PARTICLES (or simply called particles) are classified in four types: up-quark (u), down-quark (d), electron (e) and electron neutrino (ν_e). These particles are said to form a family. Three families have in fact been found in nature and hence there are 12 elementary particles altogether. They are listed in table 1. Three neutrino species are called the electron neutrino (ν_e), muon neutrino (ν_μ), and tau neutrino (ν_τ), corresponding to charged counterparts, electron (e), muon (μ) and tau lepton (τ), respectively.

The unique characteristics of neutrinos are as follows.

Table 1. Table of elementary particles. Rows in the second column correspond to u-quark, d-quark, electron and electron neutrino. They are classified by electric charge. The columns correspond to families. Families are distinguished only by the masses of the particles.

Charge			
2/3	u	c	t
−1/3	d	s	b
−1	e	μ	τ
0	ν_e	ν_μ	ν_τ

- They are electrically neutral and fly straight even in the presence of magnetic fields.
- Only weak forces act on neutrinos and hence they have a great ability to penetrate matter.
- Neutrinos are produced in high-temperature and high-density environments such as the center of stars and easily escape out of the star and reach Earth, bringing information on nuclear processes, energy generation etc at the production site.
- Great penetrability in turn makes neutrino detection quite difficult and the target size of a detector should be as large as possible.

Solar neutrinos

According to the standard solar model the central temperature and density of the Sun are about 15 million kelvins ($kT \simeq 14$ keV) and 150 g cm^{-3}, respectively. These conditions allow protons to overcome the repelling force from their positive charges (Coulomb barrier) and to initiate nuclear reactions.

The following nuclear fusion processes are taking place in the Sun:

$$\mathrm{p} + \mathrm{p} \longrightarrow \mathrm{d} + \mathrm{e}^+ + \nu_\mathrm{e} \quad (1)$$

$$\mathrm{d} + \mathrm{p} \longrightarrow {}^3\mathrm{He} + \gamma \quad (2)$$

$${}^3\mathrm{He} + {}^3\mathrm{He} \longrightarrow {}^4\mathrm{He} + 2\mathrm{p} \quad (3)$$

or

$${}^3\mathrm{He} + {}^4\mathrm{He} \longrightarrow {}^7\mathrm{Be} + \gamma \quad (4)$$

$${}^7\mathrm{Be} + \mathrm{e}^- \longrightarrow {}^7\mathrm{Li} + \nu_\mathrm{e} \quad (5)$$

$${}^7\mathrm{Be} + \mathrm{p} \longrightarrow {}^8\mathrm{B} + \gamma \quad (6)$$

$${}^8\mathrm{B} \longrightarrow {}^8\mathrm{Be}^* + \mathrm{e}^+ + \nu_\mathrm{e}. \quad (7)$$

The product ^{7}Li further reacts with a proton and produces two ^{4}He. The product ^{8}Be* immediately decays into two ^{4}He also. The reaction chain is now complete. One can see that electron neutrinos are produced by weak interactions (equation (1) and equation (5)) and a weak decay (equation (7)). These neutrinos are called pp neutrinos, ^{7}Be neutrinos and ^{8}B neutrinos, respectively. pp and ^{8}B neutrinos have continuous energy spectra approximately given as $E_\nu^2 E_\mathrm{e} p_\mathrm{e}$, where E_ν, E_e and p_e are neutrino energy, positron energy and positron momentum, respectively. E_ν is given by $Q - E_\mathrm{e}$, where Q is the available energy for the neutrino+positron pair (Q value); the maximum E_ν are 0.42 MeV and 15 MeV for pp and ^{8}B neutrinos, respectively. ^{7}Be neutrinos have a line spectrum as equation (5) is a two-body reaction. Their energy is either 0.86 MeV (90%) or 0.38 MeV (10%).

The standard solar model calculates the neutrino flux on Earth from each source. The fluxes obviously depend on the temperature, density of each chemical element, thermal conduction of the surrounding medium, etc. The calculated fluxes are enormous: $5.9 \pm 0.06 \times 10^{10}$ cm^{-2} s^{-1}, $0.48 \pm 0.04 \times 10^{10}$ cm^{-2} s^{-1} and $5.2^{+1.0}_{-0.7} \times 10^6$ cm^{-2} s^{-1} for pp, ^{7}Be and ^{8}B neutrinos, respectively.

Neutrinos have to be detected on Earth. In general particle detectors utilize particles' electric charge to produce observable signals. Neutral particles such as neutrinos must first interact with target particles and produce charged particles that produce signals. For solar neutrinos the following reactions have been used:

$$\nu_\mathrm{e} + \mathrm{e}^- \longrightarrow \mathrm{e}^- + \nu_\mathrm{e} \quad (8)$$

$$\nu_\mathrm{e} + {}^{37}\mathrm{Cl} \longrightarrow \mathrm{e}^- + {}^{37}\mathrm{Ar} \quad (9)$$

$$\nu_\mathrm{e} + {}^{71}\mathrm{Ga} \longrightarrow \mathrm{e}^- + {}^{71}\mathrm{Ge}. \quad (10)$$

In water Cherenkov experiments, Kamiokande and Super-Kamiokande (figure 1), water is the target material and electrons emitted from reaction (8) are detected. Only electrons with $E_\mathrm{e} \geq 5.5$ MeV are detected owing to severe background problems. Thus the experiment is sensitive only to ^{8}B neutrinos. For the latter two reactions, the end products ^{37}Ar and ^{71}Ge are extracted by the radiochemical technique and their numbers counted. The pioneering experiment Homestake used reaction (9) with a threshold energy of 0.81 MeV, and was thus sensitive to ^{7}Be and ^{8}B neutrinos, and subsequent SAGE and GALLEX experiments adopted reaction (10) with a threshold energy of 0.23 MeV, sensitive to pp, ^{7}Be and ^{8}B neutrinos.

The observational results are surprising. All five experiments observed much fewer neutrinos than what the standard solar model predicts. If one takes the ratio of observed to predicted numbers, the results were 0.27 ± 0.02, 0.42 ± 0.06, 0.47 ± 0.015, 0.56 ± 0.06, 0.50 ± 0.09 for Homestake, Kamiokande, Super-Kamiokande, GALLEX and SAGE, respectively.

These serious discrepancies are called the solar neutrino problem and its solution has not been found yet, although neutrino oscillation is the most likely clue. Super-Kamiokande and coming experiments, SNO and BOREXINO, will challenge the problem further.

Supernova neutrinos

The theory of the type II supernova explosion can be summarized as follows.

A star with mass larger than $8M_\odot$ (solar mass) rapidly burns out its nuclear fuels. Nuclear ashes form an onionskin-like structure: the iron core at the center, then successively silicon, oxygen, neon, carbon, helium layers

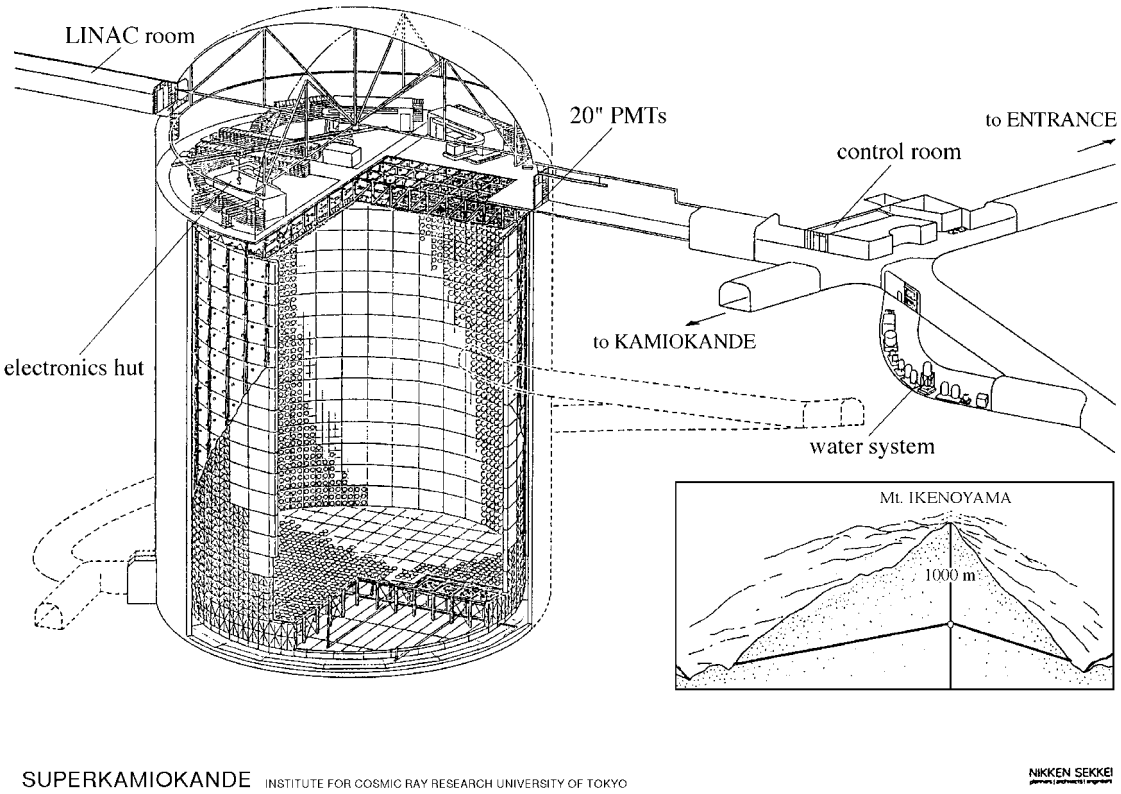

Figure 1. The Super-Kamiokande detector. It consists of inner and outer parts, each of which contains 32 000 tons and 18 000 tons of pure water, surrounded by 11 200 50 cm diameter photomultiplier tubes (PMTs) and 1800 20 cm diameter PMTs, respectively. A charged particle moving faster than the speed of light in water emits blue light named after the discoverer P Cherenkov with an opening angle of about 42°. The energy, direction and type of the particle are determined by measuring the arrival time, intensity and ring pattern of the Cherenkov light. The Super-Kamiokande experiment discovered the finite mass of neutrinos from detailed observation of atmospheric neutrinos.

and the hydrogen layer at the outermost layer. The central iron core becomes unstable when its mass exceeds the Chandrasekhar mass ($\sim 1.4 M_\odot$) and eventually collapses gravitationally. The central core is pressurized by falling matter, stiffened and bounces back. How large the bounce is depends on the elasticity or equation of state of the matter. The temperature rises above 100 billion kelvins ($kT \sim 10$ MeV) and the inverse beta decay process sets in:

$$\mathrm{p} + \mathrm{e}^- \longrightarrow \mathrm{n} + \nu_\mathrm{e}. \tag{11}$$

An electron neutrino burst of about 10 ms duration thus follows. It is called a neutronization burst and signals the real onset of the supernova explosion. A neutron-rich high-density ball forms which is called a proto-neutron star as it will later become a neutron star. The matter density is now above 10^{11} g cm^{-3}, which is high enough that even neutrinos frequently interact with matter and are trapped inside. Neutrinos are in approximate thermal equilibrium with electrons, protons and neutrons. Neutrinos of all kinds now evaporate from the surface of the neutron-rich, high-density sphere called a neutrinosphere, the radius of which was initially several tens of km. The underlying process for neutrino emission is the thermal one:

$$\mathrm{e}^+ + \mathrm{e}^- \longrightarrow \nu_i + \bar{\nu}_i \tag{12}$$

where ν_i denotes any of the three neutrino species and $\bar{\nu}_i$ its antineutrino. The hot proto-neutron star quickly cools down with a time scale of about 5 s, where neutrino and antineutrino pairs carry off thermal energy. Note that the proto-neutron star is still surrounded by thick falling matter. Hence heat cannot be transported by electromagnetic waves. The proto-neutron star shrinks to a radius of about 10 km and the density reaches $\sim 10^{14}$ g cm^{-3}, at which neutrons are packed in contact with each other. It has become a neutron star. The reverse shock produced at the core bounce, and probably the reheat caused by the outgoing neutrinos, later blow off the whole star and the explosion becomes optically visible, thus the birth of a supernova.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

The total energy carried off by neutrinos, the luminosity, is equal to the gravitational potential of a neutron star with radius $R \sim 10$ km and mass $M \sim 1.4 M_\odot$:

$$L_\nu = \frac{3}{5}\frac{GM^2}{R} \simeq 3 \times 10^{53} \text{ erg}. \quad (13)$$

The neutrino energy distribution approximately follows the Fermi–Dirac distribution,

$$\frac{\mathrm{d}N_\nu}{\mathrm{d}E} = 4\pi R^2 \frac{g\pi c}{(2\pi\hbar c)^3} \frac{E^2}{\exp[(E-\mu)/kT]+1} \frac{1}{4\pi D^2} \quad (14)$$

where E, T and R are the neutrino energy, temperature and radius of the neutrinosphere, respectively. $g(=1)$ is the helicity weight of the neutrino, μ the chemical potential and D the distance to the supernova. The average neutrino energy is, for zero chemical potential, $\langle E \rangle \simeq 3.15kT$.

The cross sections satisfy the following inequalities: $\sigma_{\nu_\mathrm{e}} > \sigma_{\bar{\nu}_\mathrm{e}} > \sigma_{\nu_\mu} = \sigma_{\nu_\tau} > \sigma_{\bar{\nu}_\mu} = \sigma_{\bar{\nu}_\tau}$. Neutrinos with a smaller cross section can leave the proto-neutron star at the denser and deeper region where the temperature is higher. The average energy of those neutrinos is thus higher. According to calculations, $\langle E_{\nu_\mathrm{e}} \rangle \sim 10$ MeV, $\langle E_{\bar{\nu}_\mathrm{e}} \rangle \sim 15$ MeV and $\langle E_{\nu_\mu} \rangle \sim 20$ MeV. It was also found that the luminosity is equipartitioned among neutrino species, $L_{\nu_\mathrm{e}} \simeq L_{\bar{\nu}_\mathrm{e}} \simeq L_{\nu_\mu} \simeq L_{\bar{\nu}_\mu} \simeq L_{\nu_\tau} \simeq L_{\bar{\nu}_\tau}$.

Neutrinos from SUPERNOVA 1987A (SN1987A) were observed using the following reactions which took place in the detector water:

$$\bar{\nu}_\mathrm{e} + \mathrm{p} \longrightarrow \mathrm{e}^+ + \mathrm{n} \quad (15)$$

$$\nu_i + \mathrm{e}^- \longrightarrow \nu_i + \mathrm{e}^- \quad (16)$$

where ν_i is any of the neutrino species, and emitted e^+ and e^- were detected. However, the cross section of equation (15) is almost 100 times larger than that of the elastic scattering (equation (16)), and hence almost all of the observed events were due to $\bar{\nu}_e$. There was no clear evidence that elastic-scattering events (equation (16)) had been detected.

Assume that the radius of the neutrinosphere R is constant in time while its temperature T behaves like $T = T_0 \exp(-t/4\tau)$. The factor 4 was introduced in order for the luminosity L_ν to take the form $\exp(-t/\tau)$, since the luminosity is proportional to T^4.

The combined Kamiokande and IMB data have been analyzed with an assumption that $\mu = 0$ in equation (14). The results are

$$kT_0 = 4.5^{+1.1}_{-0.9} \text{ MeV}$$

$$\tau = 4.2^{+2.5}_{-1.5} \text{ s}$$

$$R = 23^{+22}_{-10} \text{ km}$$

$$L_{\bar{\nu}_\mathrm{e}} = 5^{+8}_{-3} \times 10^{52} \text{ erg}.$$

$L_{\bar{\nu}_\mathrm{e}}$ was calculated from

$$L_{\bar{\nu}_\mathrm{e}} = \int E \frac{\mathrm{d}N_\nu}{\mathrm{d}E\,\mathrm{d}t} 4\pi D^2 \,\mathrm{d}E_\nu \,\mathrm{d}t$$

where $D = 50$ kpc was assumed and $\mathrm{d}N_\nu/\mathrm{d}E\,\mathrm{d}t$ is given by equation (14).

Note that the total neutrino luminosity L_tot is given as $L_\mathrm{tot} = 6L_{\bar{\nu}_\mathrm{e}}$, which leads to

$$L_\mathrm{tot} = 3^{+5}_{-2} \times 10^{53} \text{ erg}.$$

This is in excellent agreement with the naive expectation of equation (13). The cooling time τ and the temperature T_0 are also quite reasonable. Thus the observations of SN1987A beautifully confirmed the basic part of the supernova theory.

More data are obviously needed for further studies of the gravitational collapse. The new detector, SUPER-KAMIOKANDE, which is 15 times larger than Kamiokande, has been in operation since 1996. If the next supernova occurs at a distance of 10 kpc, i.e. close to the Galactic center, Super-Kamiokande will observe 4000 $\bar{\nu}_e$ events (by equation (15)) and about 250 elastic events (by equation (16)). Super-Kamiokande may be able to see about 10 neutronization-burst events, too. The only question is now when the next supernova will happen.

High-energy cosmic ray neutrinos

The CRAB NEBULA is known to emit gamma rays with energies larger than 10^{12} eV (TeV gamma rays). The energy spectrum was measured and found to obey a power law with a spectral index close to 2. Detailed studies together with other wavelength data revealed that TeV gamma rays are most likely produced by the inverse Compton process, namely collision of high-energy electrons ($\leq 10^{14}$ eV) with synchrotron photons or microwave background photons. Several other PULSARS have also been found as TeV gamma ray sources. Their production mechanism is considered to be the same as that for Crab Nebula. Nonthermal x-ray emission was found at the expanding shell of a supernova remnant SN1006. These x-rays are presumably synchrotron photons radiated by high-energy electrons ($\leq 10^{13}$ eV). TeV gamma rays were indeed found coming exactly from the same shell, indicating again that the inverse Compton process is responsible. TeV gamma rays are also coming from extragalactic objects, BL Lac sources Mkn421 (redshift 0.031) and Mkn501 (redshift 0.032). Their production mechanism is not clear but is presumably the inverse Compton process, too.

Hence acceleration sites of high-energy electrons have been identified. However, where are protons and other nuclei then accelerated? We know that they are dominant components of cosmic rays and moreover we know that their energies extend beyond 10^{20} eV. The acceleration site may be surrounded by intense photons or to a lesser extent a thick gas, i.e. optically thick, so that TeV gamma rays may have been absorbed before escaping the acceleration region. If this is the case, one expects the site to be a strong source of neutrinos, whose energies may extend as high as 10^{17} eV. Production processes of neutrinos are

$$\mathrm{p} + \gamma \longrightarrow \pi^+ + \mathrm{n} \quad (17)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$\pi^+ \longrightarrow \mu^+ + \nu_\mu \tag{18}$$

$$\mu^+ \longrightarrow \bar{\nu}_\mu + e^+ + \nu_e \tag{19}$$

where γ is an ambient photon. Muon neutrinos and electron neutrinos are produced with a ratio of 2 to 1.

The flux of these neutrinos is estimated by assuming that observed TeV gamma rays are produced not by the inverse Compton process but by the nuclear processes, namely, corresponding to equation (17),

$$p + \gamma \longrightarrow \pi^0 + p \tag{20}$$

$$\pi^0 \longrightarrow \gamma + \gamma. \tag{21}$$

By estimating somehow the optical thickness, one can relate the gamma ray flux to that of neutrinos. These estimates are, however, quite uncertain owing to the poorly known optical thickness. The energy spectrum is expected to obey a power law with a spectral index of about 2, the same as for gamma rays. The estimated fluxes of $\nu_\mu + \bar{\nu}_\mu$, F_ν, are, for $E_\nu \geq 1$ TeV, $F_\nu \sim 10^{-12}$ cm^{-2} s^{-1} TeV^{-1} for AGN 3C279 and $F_\nu \sim 10^{-11}$ cm^{-2} s^{-1} TeV^{-1} for Mkn421 and 3C273. These numbers may be quite optimistic and could be smaller by several orders of magnitude.

Muon neutrinos from astronomical objects interact with rock in Earth and produce muons:

$$\nu_\mu + N \longrightarrow \mu^- + \cdots. \tag{22}$$

Detection of astronomical muon neutrinos adopts this reaction. A large-area muon detector is deployed deep underground in order to reduce the atmospheric muon background. Rock beneath the detector is the target. A high-energy muon produced in the rock travels a long distance upward, approximately $E_\mu/(2\text{ MeV})$ g cm^{-2}, reaches the detector and is detected. Downward-going muons are completely swamped by atmospheric muons and cannot be detected. In order to overcome the huge background of atmospheric neutrinos, which are produced by cosmic rays in the atmosphere associated with atmospheric muons, a high-energy threshold must be set, say 1 TeV–100 TeV, depending on what objects are to be observed. A rough estimate of the observed rate is

$$N_\mu \sim \frac{0.5\text{ events}(E_\mu \geq 1\text{ TeV})}{10^5\text{ m}^2\text{ yr}} \frac{F_\nu(\geq 1\text{ TeV})}{10^{-12}\text{ cm}^{-2}\text{ s}^{-1}}. \tag{23}$$

The largest detector under test is the AMANDA-B (figure 2) detector which is located 1500 m under Antarctic ice. The detector has cylindrical shape with 120 m radius and 400 m height. Cherenkov light emitted in the ice is detected with a number of photomultipliers. AMANDA-B may still be too small. There is a plan to enlarge it to a size of 1 km^3, and underwater projects of similar size are being seriously considered.

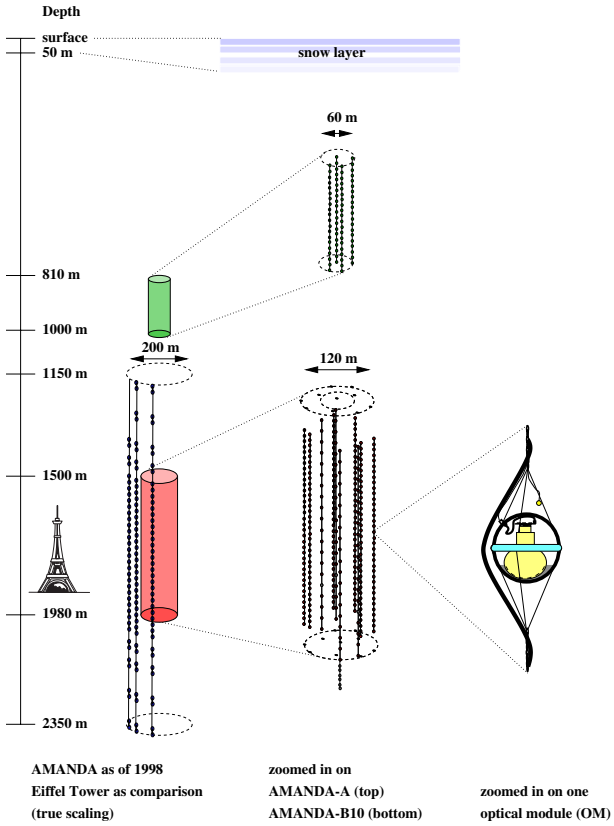

Figure 2. The AMANDA-B detector. A number of optical modules (20 cm diameter photomultipliers) are deployed within a volume 120 m in diameter and 400 m high. A high-energy upward-going muon produced by a cosmic ray muon neutrino in the rock passes through the region and emits Cherenkov light which is detected by optical modules. The direction and energy are obtained by measuring arrival time and intensity of the Cherenkov light. It could be extended to a km^3 detector.

Relic neutrinos

In the hot and dense universe up to about 1 s after the big bang, electrons and neutrinos were in thermal equilibrium. They were interacting each other,

$$e^+ + e^- \longleftrightarrow \nu_i + \bar{\nu}_i \tag{24}$$

where ν_i is a neutrino of any kind.

Surprisingly, the environment at that time was much more modest than that in the core of the supernova. The temperature was 10 billion kelvins ($kT \sim 1$ MeV), which is about 5 times lower, and the energy (or mass) density was almost 9 orders of magnitude less than those of a hot neutron star.

The universe expanded rapidly and hence cooled down (see UNIVERSE: THERMAL HISTORY). The thermal equilibrium could not hold and eventually the reaction from right to left of equation (24) ceased. Neutrinos were left behind in the universe and their energies became lower and lower until the present day. Electrons and positrons

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

rapidly annihilated into two photons whose energies were also redshifted to a wavelength of a few mm. These photons are called the COSMIC MICROWAVE BACKGROUND (CMB) and detailed studies are being carried out. Relic neutrinos and photons obey Fermi–Dirac and Planck distributions, respectively. The number densities are

$$n_\nu = 1.5\frac{\zeta(3)}{\pi^2(\hbar c)^3}(kT_\nu)^3 \tag{25}$$

$$n_\gamma = 2\frac{\zeta(3)}{\pi^2(\hbar c)^3}(kT_\gamma)^3 \tag{26}$$

where $\zeta(3)/\pi^2 = 0.121\ldots$. The neutrino number density corresponds to one species only. There is a simple relation between the two temperatures,

$$\frac{T_\nu}{T_\gamma} = \left(\frac{4}{11}\right)^{1/3} = 0.714. \tag{27}$$

The CMB temperature was measured to be 2.74 K. Hence $n_\gamma = 420\ \mathrm{cm}^{-3}$ which is in good agreement with measurement. The neutrino temperature and number density per species should therefore be 1.96 K (0.000 17 eV) and $n_\nu = 115\ \mathrm{cm}^{-3}$, respectively.

These relic neutrinos must exist in the present universe. Recently the Super-Kamiokande experiment has discovered the finite neutrino mass from a detailed study of atmospheric neutrinos. However, the experiment is sensitive only to the mass-squared difference, not to each mass value. The measured value is Δm^2 ($\equiv m^2_{\nu_\tau} - m^2_{\nu_\mu}$) $= (1.5\text{–}6) \times 10^{-3}\ \mathrm{eV}^2$. From this the tau neutrino mass is constrained as $m_{\nu_\tau} \geq 0.04$ eV, which is much larger than the temperature 0.000 17 eV. Thus the relic tau neutrinos should be nonrelativistic. Their velocity is about 300 km s^{-1} which is determined from other astronomical factors such as the Earth's motion in the Galaxy.

The neutrino mass could be as large as a few eV. If this is the case, the relic neutrinos are the hot dark matter component and could significantly contribute to the energy density of the universe.

There is at present no idea how to detect such low-energy neutrinos.

Neutrinos

Neutrinos are electrically neutral ELEMENTARY PARTICLES which experience only the weak nuclear force and gravity. Their existence was introduced as a hypothesis by Wolfgang Pauli in 1930 to explain the apparent violation of energy conservation in radioactive beta decay. Chadwick had discovered in 1914 that the energy spectrum of electrons emitted in beta decay was not monoenergetic but continuous, from zero to the maximum energy allowed by the energy balance. Pauli's hypothesis assumed that a neutral particle was emitted together with the electron. This neutral particle had never been observed; a calculation of its interaction probability with matter by Bethe and Peierls gave a mean free path for absorption of thousands of light years in lead. In the opinion of physicists in the 1930s it was therefore undetectable, a ghost.

ENRICO FERMI cast these ideas of Pauli into a theory of beta decay: he introduced a revolutionary new concept in his theory by treating the electron and the neutrino, both spin 1/2 particles, as fields which are created together, in analogy to the creation of a photon in nuclear transitions. Later this was called the Fermi interaction. The agreement between calculated and measured beta spectra and decay rates was excellent. The mass of the neutrino was apparently smaller than the electron mass.

Does the neutrino exist as a particle? It took nearly 30 yr to answer this question. The problem of the small absorption cross-section required a high-intensity neutrino source and a very massive detector which would identify the absorption of the antineutrino by a proton, i.e. $\bar{\nu}_e p \rightarrow e^+ n$, producing a positron and a neutron. After World War II high-power nuclear reactors were available which produce a flux of 10^{13} $\bar{\nu}_e$ cm^{-2} s^{-1} at a distance of 10 m from the core. Reines, Cowan and collaborators built a detector of 200 ton target mass which detected the annihilation of the positron into two prompt 0.5 MeV photons and the capture of the neutron in cadmium dissolved in water, producing several photons after a characteristic delay of about 5 μs. This signature discriminated against background induced by NEUTRONS, PHOTONS and COSMIC RAYS. The measured capture rate agreed with the theoretical cross-section within the rather large uncertainty of the calculated antineutrino flux. In 1956 they obtained evidence that the neutrino is indeed a particle. Five years later, in 1962, Ledermann, Schwartz and Steinberger discovered a second neutrino, the muon-neutrino. They invented a new research tool, a neutrino beam, by intercepting the 20 GeV proton beam of the Brookhaven National Laboratory Synchrotron with a target plate. Positively charged pions are selected by the fringing field of the accelerator; in flight a fraction of a few per cent decay into a muon and a neutrino before they are absorbed by a 5.5 m thick steel wall. The muons were brought to rest by ionization loss in the steel wall. Only neutrinos pass through the wall. They interact with matter in the detector. What kind of neutrino appears in the decay of a pion into a muon? The detector was designed to discriminate between electron-neutrinos which produce electrons and muon-neutrinos which produce muons in the absorption process by a neutron. All 30 single-track events observed had a muon. It was concluded that neutrinos exist in families. Today we know that a third neutrino flavor, the tau-neutrino, exists.

A very sensitive measurement of the number of neutrino flavors was performed at the e^+e^- collider LEP at CERN. From a measurement of the resonance shape of the Z, a mediator of the neutral current weak interaction, discovered at CERN in 1983, the number of neutrino flavors with mass lighter than one-half the Z mass (90 GeV) was determined to be

$$N_\nu = 2.998 \pm 0.029.$$

There are three light neutrinos in nature and three QUARKS.

The method of the neutrino beam created a new area of research called neutrino physics which provided a rich harvest. Because of the point-like nature of the neutrino interaction they are ideal probes. In a bubble chamber exposed to a neutrino beam at CERN (Geneva, Switzerland) it was observed that the interaction probability of neutrinos increased with energy. This observation was attributed to a point-like substructure of matter, due to the quarks which compose the nucleons. The number of quarks per nucleon was found to be three by comparing the interaction probability of neutrinos and electrons, in agreement with the quark model of matter proposed by Gell-Mann, the proton being composed of two u (up) quarks and one d (down) quark, the neutron of two d quarks and one u quark. About 50% of the neutrino interactions in matter do not take place on quarks. These interactions with matter take place on another constituent, the gluon which binds the quarks in matter. It was found that gluons produce a virtual sea of quark–antiquark pairs. Measurements with neutrino and antineutrino beams led to a quantitative analysis of the quark and antiquark structure of matter. A special class of events induced by high-energy neutrinos was found to contain two muons in the final state, a leading muon of negative charge in muon-neutrino interactions and a positively charged muon, in general of lower energy, produced at the hadron vertex. The second muon is a decay product of a heavy quark called the charmed or c quark. It is produced by the fusion of a virtual W particle, the mediator of the charged current weak interaction, and either the s quark or the d quark. The transition of a d quark to a c quark is reduced by the Cabibbo angle, compensating nearly for the smaller presence of s quarks in the sea and producing almost equal contributions. In antineutrino interactions an antiquark fuses with a virtual W^+ particle to produce a $\bar{c}$ quark with decays into μ^- and a K^0 and an anti-neutrino.

A detailed study of these processes led to the experimental determination of the quark mixing matrix which has 3×3 elements.

In neutrino events observed in the Gargamelle bubblechamber in 1973 a new phenomenon was discovered, a new weak interaction of neutral currents. The observation of muon-neutrino-induced events without a muon in the final state was the experimental evidence. Initially events of two kinds were observed, the elastic scattering of an anti-muon-neutrino on an electron and events in which all charged tracks were identified to be hadrons either by visible interactions or by decays. Soon afterwards the process was identified in general, inclusive reactions. The interaction is mediated by a neutral heavy boson, the Z, which was discovered at CERN, together with the charged boson W, in 1984 by C Rubbia and S van der Meer. A new theory of the weak and the electromagnetic interactions formulated by S Weinberg, S Glashow and A Salam unifies the description of these forces (see GRAND UNIFIED THEORY). The neutral current weak interaction is due to a mixing of the charged current weak interaction and the electromagnetic interaction. The mixing is described by an angle, the electroweak mixing angle, which was determined experimentally from the ratio of neutral and charged current weak interaction cross-sections. The value of this mixing parameter is related to the ratio of the W and the Z masses. The early measurements of the mixing parameter in neutrino experiments led to a prediction of these masses ($M_{\mathrm{W}} \sim 82$ GeV, $M_{\mathrm{Z}} \sim 90$ GeV) which was later confirmed by the direct measurements of the masses.

This agreement was an important confirmation of the unified theory of the electroweak interaction. Even more precise measurements were obtained at the e^+e^- colliders operating at the Z mass. This new theory made real progress compared with the Fermi theory. The unification is achieved by a renormalizable gauge theory which gives finite results for higher-order calculations, whereas in the Fermi theory these calculations lead to divergent results. Hence, the progress is tremendous.

The transformation properties of the fermions, leptons and quarks are given by their doublet structure. There are three lepton doublets and three quark doublets each with an 'up' state of weak isospin +1 and a 'down' state with weak isospin −1. Local gauge symmetry requires this structure.

Experimentally they can be verified by neutrino–electron scattering and by e^+e^- elastic scattering. $\nu_\mu e$ and $\nu_e e$ scattering and $\bar{\nu}_\mu e$ and $\bar{\nu}_e e$ scattering determine two coupling solutions; e^+e^- elastic scattering determines eight cones of coupling values. One solution is found to be common; it is the one which determines that the electron is the down state with respect to the neutrino, as predicted by local gauge symmetry. The measurements of $\nu_\mu e$ and $\bar{\nu}_\mu e$ scattering have been performed in the high-flux neutrino beam at CERN; those of e^+e^- elastic scattering have been performed at LEP.

Astrophysics

The reaction which fuses four hydrogen nuclei to helium by the weak interaction is the main energy source of the Sun and of similar stars. Two neutrinos are emitted in this reaction. On Earth 10^{10} neutrinos cm^{-2} s^{-1} arrive on average. Other reactions involve beryllium and boron. The flux of neutrinos from the Sun has been studied using three different neutrino detection reactions and techniques (see SOLAR INTERIOR: NEUTRINOS):

(1) $^{37}\mathrm{Cl} + \nu_e \rightarrow e^- + {}^{37}\mathrm{Ar}$, threshold $E_\nu > 814$ keV;

(2) $\mathrm{Ga} + \nu_e \rightarrow e^- \mathrm{Ge}$, threshold $E_\nu > 233$ keV;

(3) $\nu_e e$ scattering, detection of the electron by Čerenkov radiation in water; $E_{\mathrm{threshold}}$ of detection >7.5 MeV.

Method (1) was used to record solar neutrinos over ∼20 yr. It is the first experimental confirmation of neutrinos from the Sun. The measured neutrino flux is a factor of 3 smaller than the calculated flux. Only ^{8}B neutrinos are detected. Method (2) is detecting neutrinos from hydrogen fusion and from ^{7}Be and from ^{8}B. The measured flux is a factor of 2 smaller than the calculated flux.

Method (3) can reconstruct the direction of the incident neutrino and is adding the important confirmation that the detected neutrinos indeed come from the Sun. Is the missing flux due to a deficiency of the calculation? The ^{8}B neutrino flux varies with the 18th power of the temperature in the center of the Sun. Alternatively, is it due to a new property of neutrinos which changes their identity over the distance to the Earth? If they 'oscillate' into muon-, tau- or so-called sterile neutrinos they cannot be detected by any of these methods. Combining the results of the three methods and adding the constraint of the total solar luminosity, one can determine the different fluxes separately. One solution gives a strong suppression of ^{7}Be neutrinos, assuming the standard solar model is correct. Such a suppression is predicted by a resonance in the transition of $\nu_e \rightarrow \nu_\mu$; owing to the interaction of ν_e with electrons in the Sun the effective mass of the ν_e crosses the mass of ν_μ. This level crossing leads to a resonant transition $\nu_e \rightarrow \nu_\mu$. This matter-enhanced oscillation is, however, not supported by the present observation of the day/night ratio in method (3). If matter-enhanced oscillations were at work in the Sun it would enhance the ν_e flux when the Earth is between the detector and the Sun. Small changes in the energy spectrum of solar neutrinos resulting from matter-enhanced oscillation have not been detected either. The question of why solar neutrinos are missing cannot be answered at present.

The gravitational collapse of massive stars with a core of more than 1.5 solar masses at the end of the burning of light elements up to Fe is called a supernova. At the high density reached in the collapse electrons are squeezed into protons, producing a neutron core and neutrinos. The potential energy liberated by the collapse of 10^{53} erg is radiated mainly by neutrinos. The radiation of neutrinos was first detected for a supernova observed in 1987 (see SUPERNOVA 1987A).

Twenty neutrino events were detected by Čerenkov radiation of the recoiling electron from ν_e scattering in water. This rate of neutrino events is in good agreement

with a theory of supernova collapse elaborated by Bethe. The burst of neutrinos lasted for 10–15 s. The two detectors which confirmed each other, one in a mine in the USA and the other in a mine in Japan (see NEUTRINO ASTRONOMY), were originally designed to search for proton decay.

Neutrino oscillation

No other phenomenon has been searched for more intensively. This hypothetical process due to the mixing of different neutrino states was invented by Bruno Pontecorvo and by Z Maki in 1958 and in 1967 to explain the lack of solar neutrinos. Neutrinos propagate as mass eigenstates. If the propagation states have different masses, quantum mechanical interference leads to the disappearance of one neutrino flavor and the appearance of another. The oscillation length depends on the difference of the squares of the masses of the eigenstates and the fraction of neutrino flavor disappearing or appearing on the strength of mixing. A 3×3 mixing matrix describes all possible phenomena. As a theory of flavor mixing does not exist no predictions of neutrino masses and mixing can be made.

The first convincing observation, a disappearance of muon-neutrinos of atmospheric origin, was reported in 1998 by a Japanese group using a large water Čerenkov counter (40 000 ton) in an underground mine in Japan (Kamioka). Atmospheric neutrinos are born in the decay of pions produced by primary cosmic rays in the Earth's atmosphere in the ratio of two muon-neutrinos to one electron-neutrino. Because of the isotropic flux of primary cosmic rays, up- and down-going neutrinos are expected to have equal rates to within 1–2%. The Japanese experiment observed a strong up–down asymmetry; nearly 50% of the up-going neutrinos were missing. The mean disappearance length was estimated to be ∼4000 km at 1 GeV, corresponding to a difference of mass squares of 3×10^{-3} eV^2 or a mass difference of ∼0.05 eV. The mixing appears to be maximal.

The appearance of the corresponding number of neutrinos of another flavor, supposedly tau-neutrinos, has not yet been observed. The water Čerenkov detector cannot identify them. A new experiment has to be built to make this observation. It will use a muon-neutrino beam from the CERN SPS and will be located in the Gran Sasso underground laboratory near Rome at a distance of 730 km. It is planned to start in the year 2005.

Open questions

The phenomenon of a finite neutrino mass cannot be described within the standard model of electroweak interaction. The theory has to be extended to a larger symmetry scheme. The most puzzling feature observed is the nearly maximal mixing of flavors in the case of $\nu_\mu \rightarrow \nu_\tau$ oscillation. This does not seem to be the case for $\nu_e \rightarrow \nu_\tau$ oscillation. A mass difference has not yet been observed for these flavors.

Since neutrinos have a finite mass they can also have a magnetic dipole moment which remains to be detected. The cosmological consequences of the finite neutrino mass have still to be elaborated.

Neutron

An uncharged subatomic particle that is composed of three quarks. With a mass of 1.6748×10^{-27} kg (which is equivalent to a rest-mass energy of 939.6 MeV), it is slightly heavier than the proton. It has an intrinsic angular momentum, or spin, of 1/2 (in units of the Planck constant, h, divided by 2π).

The neutron is a nucleon, one of the two basic constituents of all atomic nuclei apart from the normal form of hydrogen (which consists of a single proton). The total number of protons and neutrons in an atomic nucleus defines its mass number. An isolated neutron decays into a proton, an electron and an antineutrino on average after about 15 minutes, this process being called 'beta decay'. This process is responsible for the most common form of radioactivity (beta radioactivity), in which the emission of an electron and antineutrino accompanies the conversion of a bound neutron into a proton. This changes the atomic number of the nucleus (and therefore changes, or 'transmutes', it into a nucleus of a different element) but leaves the mass number unchanged. In many other nuclei, a bound neutron is a stable, long-lived, particle.

Neutron Stars

Neutron stars are small compact stars with densities comparable to that inside nuclei, $\rho_0 = 2.8 \times 10^{14}$ g cm^{-3}, and radii $R \simeq$ 10–15 km. They consist predominantly of NEUTRONS and a few percent of PROTONS and ELECTRONS. These huge neutron-rich 'nuclei' are bound by gravitation and require a minimum neutron star mass of $\sim 0.1 M_\odot$. Above a maximum (Chandrasekhar) mass of order $2–3 M_\odot$ neutron stars are unstable towards gravitational collapse to BLACK HOLES.

Neutron stars are formed in type II or Ib SUPERNOVA explosions when massive stars ($M \geq 10 M_\odot$) run out of nuclear fuel after burning for millions of years. When the iron core in the center of the aging stars exceeds its Chandrasekhar mass, $\sim 1.5 M_\odot$, the star undergoes gravitational collapse in just seconds and suffers violent death. Gravitational and kinetic energy of the order $\sim 10^{53}$ ergs is released mainly by neutrino emission that blows off the outer layers. Only ~1% of the energy is actually seen in a brilliant burst, the supernova. Measurements of isotopic abundances of various elements (*r*- and *s*-processes) give some insight into the densities and temperatures during certain stages of the explosion in which all heavier elements in the universe were made. Supernova explosions occur at a rate of one to three per century in our Galaxy. Historically, the Crab supernova was first recorded by the Chinese in AD 1054, and could be seen in daylight. The discovery in 1967 of a rotating neutron star (a radio pulsar) in the CRAB NEBULA supernova remnant confirmed the 1933 hypothesis of Baade and Zwicky, formulated a year after Chadwick discovered the neutron, that neutron stars are formed in supernova explosions. In our Galaxy astrophysicists expect a large abundance, $\sim 10^8$, of neutron stars but they only manifest themselves if powered by rotation, accretion, nuclear power or residual heat.

Radio PULSARS were first discovered by Bell and Hewish in 1967 and extensive searches have led to ~1200 known pulsars at present. Pulsars are rotation powered neutron stars where the magnetic B and rotational $\boldsymbol{\Omega}$ axes are misaligned by an angle θ. Consequently they emit dipole radiation in the form of radio waves that appear to pulse on and off like a lighthouse beacon as the pulsar beam sweeps across the Earth with the spin frequency of the neutron star. The rotational energy loss for dipole radiation is

$$\dot{E} = I\Omega\dot{\Omega} = -\frac{B^2 R^6 \Omega^4 \sin^2\theta}{6c^3} \quad (1)$$

where the moment of inertia for a typical neutron star is $I \sim 10^{45}$ g cm^2. The radio pulses are extremely regular with periods in the range 1.5 ms $\leq P \leq$ 8.5 s and the pulsars are spinning down slowly with period derivatives of the order $\dot{P} \sim 10^{-12}$–10^{-21}. The pulsar age is from equation (1) given by $t \simeq P/2\dot{P}$ and the magnetic field $B \sim 10^{12} G(\dot{P} \times 10^{15} P \text{ s}^{-1})^{1/2}$. The resulting magnetic fields of the order of $B \simeq 10^{12}$ G are independently confirmed by cyclotron absorption lines found in x-ray spectra. Most pulsars are old (~10 million years) and slowly rotating with relatively small period derivatives. In a (P, $\dot{P}$) diagram they cluster around $P \simeq 1$ s and $\dot{P} \simeq 10^{-15}$. A few young pulsars, e.g. those such as the CRAB and VELA PULSARS, have short periods and large period derivatives.

Table 1. Properties of a typical neutron star.

Mass	M	$\sim 1.4 M_\odot$
Radius	R	10–15 km
Central densities	ρ_c	$\sim 10^{15}$ g cm^{-3}
Moment of inertia	I	$\sim 10^{45}$ g cm^{-3}
Rotation period	P	0.0015–8.5 s
Spin down	$\dot{P}$	$\sim 10^{-15}$
Magnetic fields	B	$\sim 10^{12}$ G
Temperatures	T	$\lesssim 5 \times 10^6$ K

The nearest known neutron star, RXJ185635-3754, located in the southern constellation Corona Australis, was imaged by the Hubble Space Telescope in 2001. Its distance is estimated by parallax at only 200 light years. From its black body spectrum, a surface temperature of half a million Kelvin is found, and from its flux a radius of order 10 km is inferred. Circumstantial evidence indicates that it was born in a supernova explosion a million years ago. Such an age and surface temperature is compatible with standard cooling predictions.

Binary pulsars were discovered by Hulse and Taylor in 1973. They form a distinct subclass of mainly millisecond radio pulsars with periods 1.56 ms $\leq P \leq$ 100 ms. The period derivatives are very small corresponding to very small magnetic fields $B \sim 10^8$–10^{10} G. They are believed to be old recycled pulsars, which have been spun up by mass ACCRETION. In this process the magnetic fields of the pulsars have decayed. After the recycling the spun-up millisecond pulsars are expected to emit radio waves for billions of years. About 30—more than half of the known millisecond pulsars—are found in BINARY STARS where the companion is either a WHITE DWARF or a neutron star. Six double neutron stars are known so far. By measuring the inward spiralling or orbital decay one can determine many parameters in the binary systems such as the neutron star and companion masses, orbital periods and period derivatives, orbital distances and inclination. Parameters are overdetermined and provide a test of general

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

relativity to an unprecedented accuracy. The PERIASTRON advance in PSR 1913 + 16 is 4.2º per year as compared with 43 arcseconds per century for Mercury, which was originally used by Einstein to test his theory of general relativity. Binary neutron stars all have masses in the narrow range $1.35\pm0.07M_\odot$. This number is suspiciously close to the Chandrasekhar mass of the iron core, $M_{ch} \simeq 1.5M_\odot$, when subtracting the gravitational energy loss, $\sim GM^2/R \sim 0.1M$, that dissappears by neutrino emission in the collapse.

X-ray pulsars and X-RAY BURSTERS are accretion powered neutron stars (see figure 1). Almost 200 have been discovered within the last three decades by satellite borne x-ray detectors. The orbital period has been determined for about 60 of these X-RAY BINARIES. The x-ray pulsars and bursters are believed to be neutron stars accreting from high-mass ($M \gtrsim 10M_\odot$) and low mass ($M \lesssim 1.2M_\odot$) companions respectively. The former systems are fed by wind accretion whereas the latter are the result of ROCHE-LOBE overflow from a giant companion star. The x-ray pulses are most probably due to strong accretion on the magnetic poles emitting x-rays (as northern lights) with orbital frequency. The x-ray bursts are due to slow accretion spreading all over the neutron star surface before igniting in a thermonuclear flash. The resulting burst time-scales depend on accretion rates rather than orbital periods. One bursting pulsar has recently been discovered. The radiation from x-ray bursters is not blackbody and therefore only upper limits on temperatures can be extracted from observed luminosities in most cases. Masses are less accurately measured than for binary pulsars but a few, for example, the x-ray pulsars Vela X-1 ($M \simeq (1.9\pm0.2)M_\odot$) and the x-ray burster Cygnus X-2, seem to be heavier than the binary pulsars which could be due to accretion.

Recently, a subclass of half a dozen anomalous x-ray pulsars have been discovered. They are slowly rotating, $P \sim 10$ s, but rapidly slowing down. This requires huge magnetic fields of $B \sim 10^{14}$ G and they have appropriately

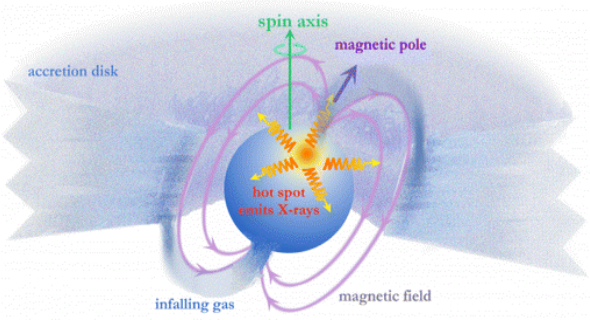

Figure 1. An accreting neutron star with misaligned spin and magnetic axes.

been named 'magnetars'. Four gamma-ray repeaters discovered so far are also slowly rotating. The anomalous x-ray pulsars, and probably also the gamma-ray repeaters, appear to reside inside SUPERNOVA REMNANTS. Together they constitute just as many galactic neutron star candidates inside supernova remnants as the radio pulsars—in spite of the extensive searches for the latter. Of the ~1200 discovered radio pulsars only about ~10 are associated with the 220 known supernova remnants.

Quasi-periodic oscillations (QPO) have very recently been discovered in low-mass x-ray binaries. QPOs provide a promising new method for determining masses and radii of neutron stars. The QPO are brightness oscillations in the x-ray luminosity. In many systems two kHz QPO peaks appear with frequencies that increase with accretion but with almost constant frequency difference. The pair is most likely the orbital frequency of accreting matter in Keplerian orbits around the neutron star and its beat frequency with the neutron star spin. In the case of 4U 1820-30 the accretion may have been tracked to its innermost stable orbit, since the QPO frequency displays a distinct saturation with accretion rate. From the corresponding maximum frequency $\nu_{QPO} = 1060$ Hz, one deduces a neutron star mass of $M \simeq 2.25M_\odot$. The existence of such heavy neutron stars would restrict the equation of state for neutron star matter severely.

X-ray bursts are thermonuclear explosions of accreted matter on the surface of neutron stars. After accumulating hydrogen on the surface for hours, the pressure and temperature become sufficient to trigger a runaway thermonuclear explosion seen as an x-ray burst. The energy involved is of the order of typical nuclear binding energies, ~7 MeV per hydrogen atom. Slow accretion from a small mass companion generates a continuous background of x-rays. Each nucleon radiates its gravitational energy of $\sim m_n GM/R \simeq 200$ MeV. The burst energy is therefore only about a per cent of the time integrated background but is released in only a few seconds. In the case of 4U 1728-34 x-ray modulation due to the neutron star spin frequency of 364 Hz has been found. It decreases, however, to 362 Hz during the first 1–2 s of the burst. A simple explanation is that the thermonuclear explosion elevates the surface of the neutron star. Conserving angular momentum, $L \propto MR^2\nu$, leads to a decrease in rotation by $\Delta\nu/\nu \simeq -2\Delta R/R$. With a frequency change of $\Delta\nu \sim -2$ Hz and typical neutron star radius of order $R \sim 10$ km, an elevation of order $\Delta R \sim 20$ m is found, which is roughly in agreement with expectations but much less than on Earth due to the much stronger gravitational fields on neutron stars.

The structure of a typical $1.4M_\odot$ mass neutron star is to first approximation a ~1 km thick crust and a nuclear liquid in the interior. At terrestrial densities the ground state of matter consists of ^{56}Fe nuclei in a solid body-

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

centered cubic lattice and electrons. With increasing density, the atomic cores begin to overlap and matter becomes pressure ionized. At a density $\sim 10^6$ times terrestrial density, or of order 10^6 g cm^{-3}, electrons become relativistic. At a density of about 10^7 g cm^{-3} it becomes energetically favorable to reduce the number of electrons by electron capture, converting protons to neutrons and form ^{62}Ni. At higher densities, the equilibrium nuclei become even more neutron rich, and eventually, at a density of about 4×10^{11} g cm^{-3}, all bound neutron levels in nuclei are occupied, and neutrons 'drip'. The inner crust consists of neutron-rich nuclei embedded in a gas of neutrons and relativistic electrons. As densities approach the density of nuclear matter the nuclei may merge into intricate rod-, plate- and bubble-like structures. The sizes of the structures are determined by a competition between Coulomb and surface energies. The inner crust terminates at a density close to nuclear matter density at $\rho \simeq 2 \times 10^{14}$ g cm^{-3}, where the transition to a spatially uniform state occurs which is believed to be a superfluid (see figure 2).

In the core of neutron stars many other problems arise. The basic difficulty in predicting neutron star properties is that matter at supernuclear densities is not well understood. There are a number of possible states for matter. The simplest is a uniform liquid of neutrons and protons in β-equilibrium, with a neutralizing background of negative charge from electrons, and, when the electron chemical potential exceeds the muon rest mass, also muons. There could be other particles present, such as hyperons. Another class of possibilities is Bose condensation of mesons, either pions or kaons. Yet another is quark matter, in which the nucleons are broken down into quarks. To make progress it is necessary to develop a better understanding of many aspects of physics (see e.g. PARTICLE ASTROPHYSICS). One is the basic interactions between hadrons. While two-particle interactions between nucleons are well characterized from scattering data, the corresponding interactions for strange particles are less secure. Knowledge of many-body interactions is much more rudimentary.

The equation of state (EoS) of dense matter, e.g. pressure versus energy density $P(\epsilon)$, can therefore only be calculated reliably up to a few times normal nuclear saturation densities by using measured nucleon–nucleon scattering data and binding energies and saturation density of nuclei. At higher densities causality provides some constraint on the EoS. Given the EoS, the structure of non-rotating neutron stars can be calculated from the Oppenheimer–Volkoff equation

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -G\frac{(P+\epsilon)(m+4\pi r^3 P)}{r^2(1-2Gm/r)} \qquad (2)$$

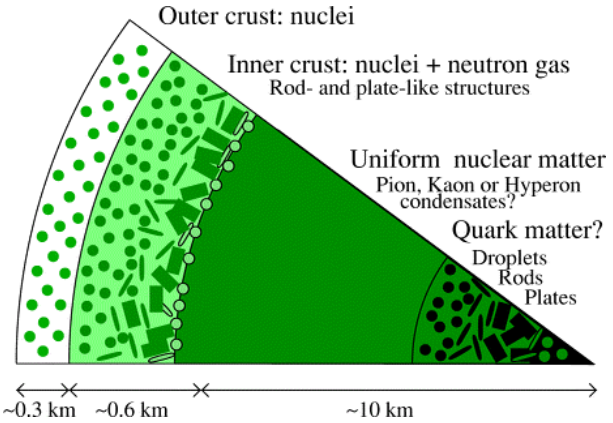

Figure 2. Schematic cross section of a neutron star. Possible components are listed, and estimates of radial dimensions are drawn (not to scale).

where $m(r) = 4\pi \int_0^r \epsilon(r')r'^2\,\mathrm{d}r'$. Rotation was included by Hartle. The maximum (Chandrasekhar) mass is expected to be below $\sim 2.5 M_\odot$ depending on the stiffness of the nuclear EoS, but it could be lower if phase transitions take place. Observations of large neutron star masses of order $\sim 2.3 M_\odot$ would therefore restrict the equation of state (EoS) severely for dense matter.

Glitches are sudden speed-ups in the rotation rate observed in a number of younger pulsars, e.g. the Crab and Vela. Glitches occur due to quakes in solid structures such as the crust, superfluid vortices or possibly a quark matter lattice in the core. As the rotating neutron star gradually slows down and becomes less deformed, the rigid component is strained and eventually cracks/quakes and changes its structure towards being more spherical. The moment of inertia of the rigid component, I_c, decreases abruptly and its rotation and pulsar frequency increase due to angular momentum conservation resulting in a glitch, $\Delta\Omega/\Omega \sim 10^{-6}$–$10^{-8}$, which slowly relaxes on a time scale of days as the rigid and fluid components approach a common rotational frequency.

Surface temperatures may provide information about the interiors and thermal evolution of neutron stars. In recent years much effort has been devoted to measuring neutron star temperatures, especially with the Einstein Observatory and ROSAT. Neutron stars are born with interior temperatures of the order of 10^{12} K, but cool rapidly via neutrino emission to temperatures of the order of 10^{10} K within minutes and $\lesssim 10^6$ K in 10^5 yr. The only information on neutron star temperatures stems from surface temperatures observed in x-ray or UV bands. Most observations are for pulsars, and it is unclear how much of the observed radiation is due to pulsar phenomena, to a synchrotron-emitting nebula or to the neutron star itself. Surface temperatures of neutron stars have been measured in a few cases or upper limits have

Dirac House, Temple Back, Bristol, BS1 6BE, UK

been set. These seem to be compatible with predictions from standard modified URCA cooling processes. Non-rotating and non-accreting neutron stars are virtually undetectable but the Hubble Space Telescope has observed one single thermally radiating neutron star RX J185635-3754. Its surface temperature is $T \simeq 6 \times 10^5$ K $\simeq 50$ eV and its distance is less than 120 pc from Earth. Circumstantial evidence indicates a distance of ~80 pc which leads to a neutron star radius of 12–13 km in good agreement with modern EoS.

Gamma ray bursters (GRB) have recently been associated with afterglows from which very high REDSHIFTS ($z \geq 1$) could be determined. An enormous energy output of $E \sim 10^{53}$ ergs can be inferred, if isotropically emitted, but there is evidence for beaming or jets and the GRB therefore 'only' requires a total energy of $E \sim 10^{51}$ ergs in gamma rays. Candidates for such violent events include neutron star mergers or, as indicated by recent observations of coinciding supernovae, a special class of type Ic supernova (hypernovae) where cores collapse to black holes.

NEUTRINO and GRAVITATIONAL WAVE detectors on Earth will look into the formation and cores of neutron stars. LIGO will be able to detect gravitational waves from core collapse in supernova and coalescence of binary neutron stars. Neutrinos carry away ~99% of the energy in supernova explosions and their abundance, timing and spectra reveal detailed information about the explosion and the proto-neutron star. Nineteen neutrinos were detected from SN-1987A in the Large Magellanic Cloud. Modern neutrino detectors should catch several thousand neutrinos from future supernovae in our galaxy or the neighboring Magellanic Clouds.

The future of neutron stars looks bright as new windows are about to open. A new fleet of x- and gamma-ray satellites will be launched. With upgraded ground-based observatories and detectors new classes of neutron stars will be discovered and our understanding of neutron star properties will be improved.

New General Catalog of Nebulae and Clusters of Stars (NGC)

A basic reference list of star clusters, nebulas and galaxies compiled in 1888 by Danish astronomer Johan Ludvig Emil Dreyer. Dreyer worked at the Armagh Observatory in Northern Ireland. Here he based his work on lists made earlier by the Herschel family of British astronomers and John Herschel's General Catalog of Nebulae, published in 1864. Dreyer included 7840 celestial objects. He later extended the list by 5386 objects with his first and second Index Catalogs (IC), published in 1895 and 1908 respectively. With these supplements the NGC covers the entire sky, although many objects visible with modern instruments are not listed.

Newcomb, Simon (1835–1909)

Mathematical astronomer, born in Wallace, Nova Scotia, Canada, moved with his family to Maryland and self-studied mathematics. Worked at the US Nautical Almanac Office (then in Cambridge, MA), studied at Harvard, and was appointed to the US Naval Observatory at Washington, DC, becoming director. In his own words, because of the 'confusion which pervaded the whole system of exact astronomy, arising from the diversity of the fundamental data made use of by the astronomers of foreign countries and various institutions in their work' he started 'a systematic determination of the constants of astronomy from the best existing data, a reinvestigation of the theories of the celestial motions, and the preparation of tables, formulae, and precepts for the construction of ephemeredes, and for other applications of the same results'. He thus used careful measurements of stellar and planetary positions to compute formulae for their future motions, with an analysis of the constants in the formulae (such as the masses of the Sun, Moon and planets), and the speed of light. This set in train a century of astronomical activity focused in the work of the International Astronomical Union to define the astronomical constants.

Newton

Isaac Newton (1642–1727) is known pre-eminently for discoveries in mathematics (binomial theorem and fundamental theorem of the calculus), optics (the heterogeneity of white light) and mechanics (laws of motion and universal gravitation). Not undisputed are some questions of priority and how in detail to characterize these achievements. Beyond question, however, is the foundational character of Newton's chief works for all later physical science: his *Principia* (editions in 1687, 1713 and 1726) and *Opticks* (English editions in 1704 and 1717, Latin editions in 1706 and 1719). Various understandings of Newton's methodology played an important role in Enlightenment thought.

Newton's paternal forebears were illiterate Lincolnshire yeomen. His grandfather, prospering, purchased Woolsthorpe Manor. His father on inheriting the estate married Hannah Ayscough, then died six months later before his son Isaac was born. When Isaac was three, his mother remarried and went to live with her new husband, the Rev. Barnabas Smith, leaving Isaac till age ten (when Smith also died) in the care of his maternal grandmother at Woolsthorpe. Newton's boyhood was lonely and punctuated by fits of anger against his mother and step-father. Neurotic isolation remained characteristic into his middle years.

Between ages 12 and 17 Newton attended grammar school in Grantham, becoming fluent in Latin. Put then to managing the Woolsthorpe estate, he was a disaster, interested only in bookish learning. His mother at length relented, sending him back to Grantham to prepare for university entrance. He matriculated at Trinity College, Cambridge, in July 1661.

The Cambridge curriculum was a moribund Aristotelianism, but Newton's solitary reading by 1664 had led him beyond the prescribed course to GALILEO's *Dialogue*, DESCARTES' *Principia*, Walter Charleton's epitome of Gassendi's writings, and other proponents of new philosophy. He discovered the new mathematics in Schooten's second Latin edition of Descartes' *Geometry* and in John Wallis's *Arithmetic of Infinites*.

Despite the aberrancy of his studies, Newton in 1664 was elected scholar at Trinity, and in 1667 Minor Fellow, then Major Fellow in 1668. In 1669 Isaac Barrow saw to it that Newton became his successor as Lucasian Professor of Mathematics. To continue as a Fellow required taking holy orders within seven years, but study of Scripture and the Church Fathers convinced Newton that the Trinity was a hoax. By royal dispensation, obtained through Isaac Barrow's intercession, he was freed from the requirement. Newton would remain in Cambridge till 1696 when he moved to London to become Warden of the Mint, then Master of the Mint in late 1699; he resigned his Trinity College fellowship and professorial chair in 1701. His scientifically most fruitful years were over.

Newton's discoveries in mathematics

Newton's most intense study of the new mathematics began sometime in 1664, and lasted until November 1665, by which time he had made his principal discoveries. Quickly he assimilated the central insight of DESCARTES' *Geometry*: curves were to be understood through their equations. He reduced to formula Descartes' method of finding a tangent to a curve (it involved constructing the normal). He then considered normals at two nearby points on the curve with abscissas x and $x + o$. The limiting position of the intersection of the two normals as o went to zero gave the center of curvature, and thence the radius of curvature—a result beyond anything in the texts he was studying.

Wallis's *Arithmetic of Infinites* introduced him to the definite integral, an area under a curve between fixed ordinates, computed by dividing the area into infinitesimal rectangles and summing them as an infinite series. Newton made the upper limits variable, and so arrived at indefinite integrals, for instance (in our symbolism):

$$\int_0^x y\,\mathrm{d}x = \int_0^x x^3\,\mathrm{d}x = x^4/4.$$

Wallis often solved problems by a kind of induction, and Newton used just such a process in solving one of the problems Wallis had posed: to find the area under a circle, that is, to integrate $\int(1 - x^2)^n\,\mathrm{d}x$ where n is $1/2$. If n were a positive integer the integral would be obtainable by expanding the binomial and integrating the resulting polynomial term by term. The successive terms of the integral in this case, Newton observed, are given by multiplying x, $-x^3/3$, $x^5/5$, $-x^7/7$, etc, respectively by the successive binomial coefficients. Discerning the rule by which the binomial coefficients are produced, and extending it to the cases in which $n = 1/2, 3/2, 5/2$, etc, Newton obtained the integrals $\int(1 - x^2)^n\,\mathrm{d}x$ for these fractional values of n as infinite series; thus for $n = 1/2$ the integral is

$$1x + (1/2)(-x^3/3) + (-1/8)(x^5/5) + \cdots.$$

In this manner all radicals could be integrated. Here and elsewhere Newton intuited general rules and illustrated them in specific examples, without strictly demonstrating them or expressing them in a general symbolism.

Dissatisfied with the concept of infinitesimals, Newton shifted to a kinematic view: areas were swept out by a moving ordinate, its length giving the momentary rate of areal increase. Likewise, a curve could be viewed as produced by a moving point, the tangent at a point being determined by the limiting ratio of the component speeds in the x and y directions. To these 'speeds' in the production of an area or curve Newton gave the name 'fluxions'. The determination of the tangent now appeared as the inverse of the finding of an area under a curve. This inverse relation is the fundamental theorem of the calculus. Here again, Newton illustrated the theorem in examples without expressing it in a general symbolism.

After mid-November 1665, Newton's interest in mathematics lapsed. In autumn 1666 he produced a summary of his discoveries, and in 1669, at Barrow's urging, he set himself to producing a full-fledged treatise on his methods of series and fluxions. Fatefully, he abandoned the unfinished treatise in 1671, apparently overcome by fear of criticisms that publication could bring. The incomplete treatise was not published until after his death.

Newton's optical discoveries

Newton's work in optics began in early 1666 when he obtained a prism 'to try the celebrated *Phaenomena of Colours*'. Descartes, Boyle and Hooke had taken color to be a modification of white light—the traditional view. Newton's understanding of color grew gradually, in tandem with experiments. A circular beam of white light, on passing through the prism, gave an elongated spectrum, implying different refractions of its different parts. Other experiments showed the separate rays to have unalterable degrees of refrangibility. These rays on being recombined gave white light. White light was thus a mixture composed of individual rays of constant refrangibility.

Newton devoted his first series of professorial lectures (in 1670) to the theory of colors. The phenomena implied, he believed, the corpuscularity of light: he saw no way in which a wave theory could agree with distinctive natures in the rays. HOOKE in his *Micrographia* (1665) had investigated the colors of thin films, and Newton now carried Hooke's investigation further, determining the varying thickness of the film between a spherical lens and a plate glass to hundredths of an inch, and thereby establishing a periodicity associated with the successive rings of color and darkness that presented themselves ('Newton's rings'). He attempted to explain the periodicity as due to vibrations set up in the aether by the impact of the light corpuscles; the aether at the second interface between glass and air was thus put into 'alternate fits of easy reflection and refraction'.

By his own labor Newton designed and constructed a reflecting telescope. Completed in early 1669, it was six inches long, magnified 40 times, and was free of the chromatic aberration affecting refractors. Newton showed it off in Cambridge; word of it spread to London. Members of the Royal Society asked to see it, and in late 1671 Barrow presented it to the Society. It caused a sensation. Flattered, Newton agreed to provide an account of his theory and experiments. His 'New Theory about Light and Colors' appeared in the *Philosophical Transactions* in February 1672.

With this, his first publication, Newton's worst fears came true. The force of his experiments was not understood. Hooke took his main point to be the corpuscular nature of light, and was unpersuaded by Newton's attempt to separate the issues of corpuscularity and heterogeneity. When HUYGENS referred to the theory as 'an hypothesis', Newton bridled. Most wearying of all were the objections and experimental incompetence of three English Jesuits in Liège. By 1678 Newton had had enough. Now immersed in alchemical experiments, he wanted no part in further controversy. Only after his death, he said, would his further writings be published.

Newton on the laws of motion and gravitation

Newton's study of the laws of impact began in the mid-1660s. From Descartes he accepted the law of inertia: bodies persist in their state of rest or motion unless acted upon by an exterior cause. Descartes' rules of impact, derived by *a priori* thinking, were contradicted by experiments; Newton by thought and experiment derived correct rules. The center of mass of two bodies must move uniformly whether they impact or not. Implicit here was the equality and oppositeness of action and reaction, and the constancy of the ratio of the inertias or masses determining how the two bodies exchanged or shared speeds. Unlike Descartes, Newton took account of the vectorial character of the motions. He verified his rules in both inelastic and elastic impacts.

In the same period, Newton quantified Descartes' concept of the 'endeavor to recede' of a body whirled in circular motion. The acceleration, which Newton like Descartes thought of as radially outward, was $v^2/r = 4\pi^2 r/T^2$, where v is the body's linear speed, r its distance from the center and T its period of circulation. In Streete's *Astronomia Carolina* (1661), Newton had met with Kepler's harmonic law for the planets, $T^2 \propto r^3$, and this substituted into the formula showed the 'endeavor to recede' of the planets to vary inversely as the squares of their mean solar distances.

Like most of his contemporaries, Newton during the 1660s and 1670s conceived the planets to be borne about in a Sun-centered vortex of aether, and the Moon to be borne in a smaller, Earth-centered vortex. To balance the endeavor to recede developed in these circulations, he imagined a subtler variety of aether rushing into the central body. This aether might serve, in the solar case, as fuel to conserve the Sun's shining, and in the terrestrial case, after chemical transformation within the Earth's body, as nutriment for living things. All things, he proposed, may be composed of different kinds of aether that transform into one another: 'Nature is a great circulatory worker'. In a paper sent to the Royal Society (though not for publication) in late 1675, Newton cited numerous phenomena in support of this aethereal philosophy.

In November 1679 Hooke as a secretary of the Royal Society sought to engage Newton in correspondence, and asked him, in particular, what he thought of Hooke's idea of 'compounding the celestial motions of the planets of a direct motion by the tangent & an attractive motion towards the central body'. This idea had emerged for CHRISTOPHER WREN and Hooke out of their reflections on GILBERT's magnetic philosophy. There is no clear evidence that Newton had seriously entertained it before.

In perhaps August 1684 HALLEY visited Newton in Cambridge to ask what path a planet would follow if

Dirac House, Temple Back, Bristol, BS1 6BE, UK

subject to an inverse-square force toward the Sun. By now the inverse-square variation of the solar force was accepted by Wren, Hooke and others as deducible from Huygens' formula for centrifugal force (published in 1673 and equivalent to Newton's unpublished formula) and the Keplerian rule $T^2 \propto r^3$. Newton reportedly answered 'an ellipse!', and promised to produce a demonstration. His response, sent to the Royal Society in November, was a small treatise *On the motion of bodies in gyres*, giving quantitative expression to Hooke's conception of orbital motion. A centripetal force, Newton showed, implies equable description of areas. Given the proportionality of time to area, he derived a formula for the planet's instantaneous radial acceleration. Applying this to an elliptical orbit with center of force in a focus, he showed that the force would be inverse square—the converse of the theorem he had promised. 'Therefore the major planets revolve in ellipses having a focus in the centre of the Sun…'. The logic was less than clear.

In the next two and a half years the small treatise expanded into the 510 pages of the *Principia*. But a critical threshold of substantiation had first to be crossed: 'Now I am upon this subject I would gladly know the bottom of it before I publish my papers' (Newton to FLAMSTEED, 12 January 1685). Flamsteed's data for the satellites of Jupiter helped: their periods and distances (measured by micrometer) were as exactly in accord with the $T^2 \propto r^3$ rule 'as it is possible for our senses to determine'. Taking the inverse-square law to be universally exact, Newton could compare the absolute attractive powers of the Sun and the planets having satellites (Jupiter, Saturn, Earth), by comparing the accelerations they would produce in satellites at a fixed distance. Identifying the attractive powers with the masses, Newton found that the center of mass or gravity of the system fell within the Sun or remained close to it, thus demonstrating the Copernican system *a priori*.

In another basic confirmation of his 'mathematical way', Newton carried out the earliest version of what is now called the 'Eötvös experiment'. In contrast to the changes of motion produced in impacts, gravitational accelerations appeared to be independent of the masses of the bodies accelerated; implying a proportionality of mass to gravitational force. Using pendulums with bobs of nine different materials (gold, silver, lead, glass, etc), Newton tested this proportionality, and found it to hold to within one part in a thousand. Hence aethereal mechanisms for gravity could be dismissed.

Newton's method demanded universalization of any rule found to hold in all known cases; results thus arrived at, however, were subject to correction or refutation from further experiments or observations. The law of universal gravitation had therefore to be tested unendingly. In an analysis of the three-body problem (*Principia* I.66) Newton derived qualitatively all the known inequalities of the Moon, and claimed to derive the tides and the precession of the equinoxes (the latter two derivations were flawed). Newton's procedure for fitting orbits to comets enabled Halley to predict the return of Halley's comet in 1759. In the late nineteenth century the anomalous precession of Mercury's perihelion was at length recognized as requiring modification of Newton's law; Einstein in 1915 accounted for the anomaly by his Theory of General Relativity.

Newton failed to generate a following of applied mathematicians able competently to pursue the testing of his theory. His mathematical methods, partly geometrical and partly algebraic, were too various and special to lend themselves to successful imitation. Wrongheadedly and fiercely Newton and Leibniz wasted energy charging each other with plagiarism in the invention of the calculus. The systematic attack on the THREE-BODY PROBLEM would come only after Newton's death, when EULER combined Leibnizian symbolic mathematics with the calculus of trigonometric functions that Newton had known. The resulting science, known today by LAPLACE's name for it, CELESTIAL MECHANICS, led to new mathematics and eventually to new understandings of the scope and limits of rational mechanics; but its agenda had been set by Newton's *Principia*.

Newton Mission

The European Space Agency's long-term plan for its science program is called 'Horizons 2000' and is designed to provide a balanced combination of satellite missions in astronomy, space science and fundamental physics. One of the cornerstones of this program is the XMM–Newton x-ray observatory, launched on 10 December 1999 from the European spaceport in French Guyana on the first commercial flight of the Ariane 5 rocket. In order to observe x-rays from astronomical objects it is necessary to be above the Earth's atmosphere since this absorbs incident x-rays. XMM–Newton was launched into a highly eccentric orbit, which takes the satellite once around the Earth every 48 h. The reason for this highly eccentric, long-duration, orbit is that it allows for long and uninterrupted observations (which are often required in x-ray astronomy) free of the radiation belts around the Earth. XMM–Newton cannot operate within the radiation belts since they disturb the measurements and can even damage some of the sensitive instrumentation (if left unprotected).

Originally, XMM–Newton was called the 'High-Throughput Imaging X-ray Spectroscopy Mission', which accurately describes its capabilities. 'High throughput' is provided by the three largest x-ray telescopes ever flown in space. Each telescope consists of 58 tightly nested grazing-incidence x-ray mirrors with a focal length of 7.5 m. Grazing-incidence optics are necessary because most materials simply absorb x-rays, rather than reflecting them, and only at very small incidence angles will ultrasmooth gold reflect x-rays. The mirrors focus the x-rays with a precision of about 15 arcsec which accounts for the 'imaging'. The 'spectroscopy' is provided by the instruments on board XMM–Newton:

EPIC — European Photon Imaging Camera (principal investigator, Dr M. Turner, Leicester University, UK);
RGS — Reflection Grating Spectrometer (principal investigator, Dr A. Brinkman, SRON, Utrecht, The Netherlands);
OM — Optical Monitor (principal investigator, Professor K. Mason, MSSL, UCL, UK).

The EPIC instrument provides the medium spectral resolution and simultaneous imaging capability through three cameras using two different technologies. The EPIC–MOS is geared towards lower energies, while EPIC–PN excels at unparalleled throughput and timing capabilities, especially at higher (5–10 keV) x-ray energies. The RGS is a dispersive instrument (much like a prism is for visible light), which provides medium- to high-resolution dispersive spectroscopy only. The concept of grazing incidence has once more been applied here in two arrays, each consisting of 182 grating plates, mounted behind two of the three x-ray telescopes. The co-aligned Optical Monitor provides the capability to observe the x-ray sources at visual and ultraviolet wavelengths, a concept that has proven its worth in the past. It is one of the great strengths of the XMM–Newton observatory that all of the above instruments work in parallel.

The first results from the XMM–Newton Observatory have seriously changed our understanding of many astrophysical sources of x-rays: from the extraction of energy from a black hole, through the distribution and state of the hot gas pervading clusters of galaxies to the accretion disks of material swirling around collapsed stars. It is clear that XMM–Newton is paving the way in x-ray imaging spectroscopy, so much so that astronomers are already seriously thinking about the potential successor which is called XEUS. This will be even larger than XMM–Newton, able to observe the first massive black holes as they were formed when the universe was only a small fraction of its current age.

Web update (31 July 2002)

New results from the XMM–Newton suggest a supernova was responsible for the gamma-ray burst that occurred on 11 December 2001. Observing the afterglow of the gamma-ray burst GRB 011211, XMM–Newton has produced the first ever evidence of the presence of chemical elements which were the unmistakable remnants of a supernova explosion which had occurred just a few days before. The observations revealed two important facts: first, the material in the source was moving quickly towards Earth, at a tenth percent of the speed of light; and second, chemical analysis of this material showed that it had to be the remnant of a supernova explosion.

Gamma-ray bursts are the most powerful explosions ever detected in the universe. So far there has been no conclusive evidence to prove what causes them. Until now, there have been two prime suspects for what makes gamma-ray bursts: the collision of neutron stars—dead, ultra-dense stars—or the death of very massive stars in supernova explosions.

Newton's Laws of Motion

Laws governing the motion of all bodies which were set out by Isaac Newton (1642–1727) in 1687. They form the basis of Newtonian mechanics. The three laws are as follows:

First law. Every body continues in a state of rest or uniform motion in a straight line unless acted upon by a force.

Second law. If a body is acted upon by an external force, it accelerates, the acceleration being directly proportional to the force and inversely proportional to the mass of the body; the acceleration takes place in the direction of the force. This may be expressed as the rate of change of *momentum* of a body is proportional to the applied force. This can be written as:

$$F = ma$$

where F is the applied force, m is the mass of the body and a the acceleration.

Third law. To every action there is an equal and opposite reaction; in other words, if a force acts on one body an equal and opposite force must act on another body. For example, a person standing on the Earth is pressing down on its surface with a force equal to his weight; the Earth's surface in resisting this force (so preventing the person from falling towards the center of the Earth) exerts a reaction, an upward force equal to that person's weight.

The essence of some of these laws was appreciated by other workers prior to and contemporary with Newton (e.g. Galilieo), but he was the first fully to appreciate and to formalize them. Newton's laws of motion express a completely different point of view from the earlier belief that force is necessary to maintain motion; in Newtonian theory force is only required to *change* the state of motion of a body.

Newtonian Telescope

A reflecting telescope in which the converging cone of light from a concave parabolic primary mirror is reflected to the side of the telescope tube by a small flat mirror set at an angle of 45° to the optical axis. The light is brought to a focus at the side of the tube, at the opposite end of the tube from the primary mirror, and this is where the eyepiece is located. Originally devised by Isaac Newton (1642–1727), who built the first working reflecting telescope to this design in 1668, this optical system is still widely used today in small reflecting telescopes, since the observer's head does not block incoming light. The design is less practical when the telescope focal length is large, say larger than a person's height.

Newton's first reflector had an aperture of 2.5 cm (1 inch) and its mirrors were made from speculum metal (an alloy of various metals, predominantly copper and tin) which, even when freshly polished, reflected no more than 60% of the incident light. With two such mirrors, a tiny aperture, and a magnification of about 25 times, it produced very faint images. Furthermore, because the curve of its primary mirror was spherical rather than parabolic, it suffered from an optical defect called spherical aberration.

See also: aperture, focal length, mirror, reflector, spherical aberration, telescope.

Next Generation Space Telescope

The Next Generation Space Telescope (NGST) will be an 8 m class deployable, radiatively cooled telescope, optimized for the 1–5 μm band, with zodiacal background limited sensitivity from 0.6 to 10 μm or longer, operating for 10 yr near the Earth–Sun second LAGRANGIAN POINT (L2). It will be a general-purpose observatory, operated by the SPACE TELESCOPE SCIENCE INSTITUTE (STScI) for competitively selected observers from the international astronomy community. NASA, the European Space Agency (ESA) and the Canadian Space Agency (CSA) will build NGST, with construction to start in 2004 and a planned launch of 2009.

NGST will be able to observe the first generations of stars and galaxies, including individual starburst regions, protogalactic fragments and supernovae out to REDSHIFTS of z = 5–20. NGST will resolve individual stars in nearby galaxies, penetrate dust clouds around local star-forming regions and discover thousands of isolated substellar and KUIPER BELT objects.

NGST science goals

The primary science goals for NGST have been generated by the astronomical community through reports to NASA headquarters and science working group studies. Although NGST will be a general-purpose observatory capable of a variety of investigations, several types of observational problems are being examined in detail to help design the mission. The following sections highlight these programs.

The origin and evolution of galaxies

Motivated by the spectacular success of the HUBBLE SPACE TELESCOPE (HST) in pioneering the exploration of high-redshift (z > 1) galaxies and clusters, the HST & Beyond Committee foresaw the enormous potential of a scientific successor to HST, optimized for the near infrared (NIR, 1–5 μm). Such an instrument would be especially powerful in studying the origin and evolution of galaxies. In 2008, NGST will be poised to complete our understanding of the formation and early evolution of galaxies such as the Milky Way by doing the following.

- The earliest phases of star and galaxy formation—the end of the 'dark ages'—will be detected (figure 1). This requires superb NIR sensitivity (> 1 nJy (1.0 × 10^{-35} W m^{-2} Hz^{-1}), 1–5 μm) in deep-broadband imaging (in a ~10^5 s exposure).
- The first galactic substructures larger than individual star clusters (whose diameters are typically ~300 pc (~9 × 10^{16} km) for 0.5 < z < 5.0) will be resolved. This requires HST-like resolution in the NIR (~0.060 arcsec at 2 μm).
- The fundamental properties of individual galaxies will be quantitatively measured. This will be enabled by emission-line and absorption-line spectroscopy, with broad spectral coverage and low-to-moderate spectral resolution ($R = \lambda/\delta\lambda$): R ~ 300 (0.6–5.0 μm) for redshift confirmation, cluster membership and ages of stellar populations; R ~ 1000 (0.6–5.0 μm or longer) for star formation rates, metallicity and reddening; R ~ 3000 (1.0–10 μm) for dynamics (mass).
- Dust-enshrouded regions hiding massive star formation or active galactic nuclei during the epoch of greatest star formation to a minimum of z~2 will be detected and diagnosed.

The structure and chemical enrichment of the universe

The geometry and structure of the universe, as well as its history of element formation, are intimately related to the formation of galaxies. Future microwave telescope missions will measure the power spectrum of the COSMIC MICROWAVE BACKGROUND (CMB) at z ~ 1300 and, using standard models, will provide or constrain important cosmological constants. NGST will play a powerful complementary role in determining the distribution of mass and light on small scales. Large MICROLENSING imaging surveys will use the wide field, superb angular resolution and excellent 0.6–5.0 μm sensitivity of NGST to measure the mass structure of the universe at z = 1–5 on scales smaller than those probed by CMB measurements from space or possible from the ground or HST.

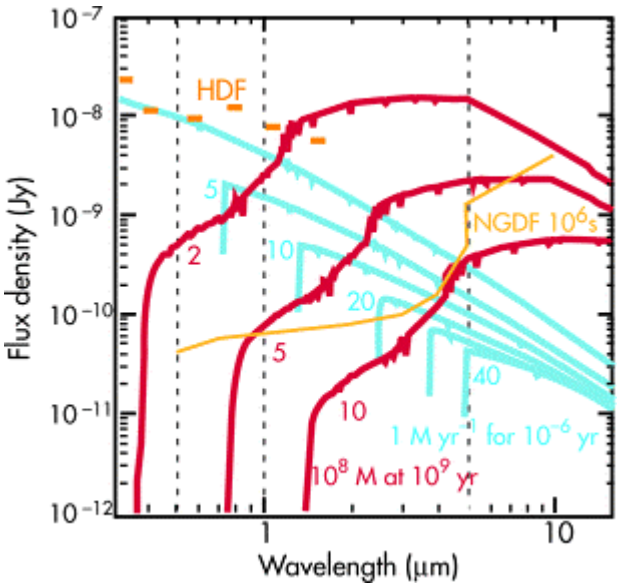

Figure 1. The sensitivity of an NGST deep field (10^6 s in 30% bandwidths, 10σ detection). Also indicated are the spectra of starburst regions (10^6 solar masses (2 × 10^{36} kg) in 10^6 yr) and established populations (10^8 solar masses at 1 Gyr age) at various redshifts (Ω_m = 0.2). Comparable sensitivities also are shown for the Hubble Deep Field (HDF) using NICMOS.

Expected science programs include the following.

- The dark matter halos of galaxies to redshifts of z~5 will be weighed statistically by deep imaging of selected fields.
- The growth of galaxy clusters to redshifts of $z \sim 1$–3 will be measured using multicolor deep imaging of selected high-redshift clusters and protoclusters discovered in other surveys.
- The statistical properties of the distribution of matter on scales of 1–10 Mpc (~$3 \times 10^{19–20}$ km) can be found from wide-area, high-resolution NGST imaging surveys (>1 deg^2).

These imaging programs are comparable in depth and required field of view with those used for the study of GALAXY EVOLUTION. Such surveys also provide an excellent method for discovering type Ia and type II SUPERNOVAE at redshifts in the range $1 < z < 5$. Measuring the rates and galactic associations of type Ia and type II supernovae will provide an independent assessment of the history of element production. We expect that NGST will be crucial in extending the observations of type Ia supernovae beyond z~0.9 to z~5. Only at the higher redshifts is it possible to distinguish between the behavior of type Ia supernovae with cosmologies involving only H_0, Ω_m and Γ and models with significant supernova evolution or smoothly distributed gray obscuration. Such data will provide measurements of the cosmological parameters, which are independent of and complementary to those derived from the CMB missions.

The processes of star and planet formation

The potential studies in this arena are essentially limitless and depend crucially on the available spectral resolutions and mid-infrared (MIR; defined here as ~5 μm < λ < ~30 μm) wavelength coverage. Examples include the following.

- The infall and outflow processes through which stars are built and their final masses determined will be characterized. MIR spectroscopy will diagnose the accretion shocks in protostellar systems, while NIR imaging will reveal outflow shocks and jets near their source, with a resolution of ~2 astronomical units (~300 million kilometers).
- The structure and evolution of circumstellar material will be traced, from the massive envelopes of class 0 protostars to the protoplanetary disks of pre-main-sequence stars, and finally to the dissipation of these disks into mature debris disks of main sequence stars. NIR and MIR spectroscopy of gas and dust features, their excitation and their radial variation within the circumstellar region will permit study of the growth of dust grains toward planetesimals, the chemical processing of disk gas and the disk dissipation mechanisms that define the time available for planet formation.
- Substellar objects will be detected and characterized. Ground-based sky surveys and adaptive optics programs are now beginning to discover significant numbers of isolated and companion brown dwarf stars. However, these observations will be limited to the bright (high mass–low age) end of the substellar luminosity function and to wide binary companions. NGST will have the needed combination of high angular resolution, high sensitivity and a stable PSF for high-contrast imaging of faint substellar companions in planetary orbits. Observations at 5 μm with a graded-mask coronagraph would be able to directly detect planets with Jupiter's mass, age and orbital semimajor axis in more than 90% of the single stars within 8 pc (2.4×10^{14} km) of the Sun (>50 systems). By detecting planetary photons directly, NGST could provide the first opportunity to spectrally characterize exoplanet atmospheres.

NGST mission concept

The science goals for NGST require a telescope with high sensitivity covering the wavelength range from 0.6 to 10 μm with capability out to 28 μm, and with NIR angular resolution comparable with that of HST at visible wavelengths. Industry and NASA have studied several mission architectures. While they differ in details the concepts share an overall similar design. For simplicity, the NASA version, referred to as the Reference Architecture, is discussed here. Figure 2 shows the observatory and its main components: the Optical Telescope Assembly (OTA), the Integrated Science Instruments Module (ISIM) and the Spacecraft Support Module (SSM). Details for the Reference Architecture may be found in the book *Visiting a Time When Galaxies Were Young*.

The optical telescope assembly

The Reference Architecture optical configuration is a three-mirror anastigmat that provides a real, accessible pupil and permits a relatively fast primary mirror to minimize telescope length. This design provides excellent imaging over a field of more than 20 arcmin with achievable alignment tolerances. A real pupil permits the use of a deformable mirror (DM) for wavefront correction and a fast-steering mirror for fine pointing using image compensation. The primary mirror is a compact 8 m diameter segmented aperture. It is composed of a central mirror segment, with a diameter of 3.3 m, surrounded by eight petals.

The Reference Architecture mirror is made of beryllium, thermally controlled with very-low-power heaters so that its figure remains insensitive to rapid or

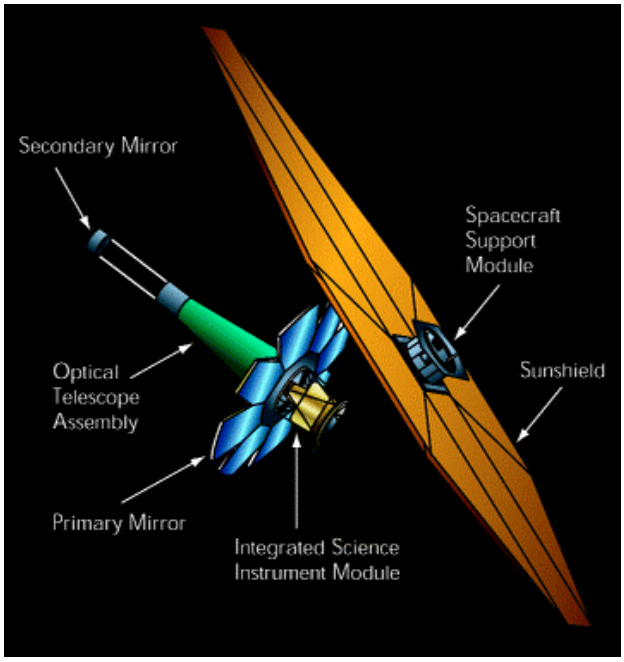

Figure 2. The elements of the Reference Architecture concept.

large positioning slews. The areal density of the primary mirror assembly (mirror, actuators and backup structure) is 13 kg m^{-2}. This represents over an order of magnitude improvement over the HST mirror areal density. The DM provides a design margin for figure errors in the primary mirror, including those due to gravity release, thermal gradients or edge effects.

Unlike telescopes such as HST that are launched fully assembled, NGST must be able to compensate for errors in deployment position, long-term dimensional changes and on-orbit thermal variations. Optics are aligned and phased by observing the image of a star and deriving mirror position corrections. Wavefront errors are determined by obtaining defocused star images and analyzing the image with a 'phase retrieval' computer algorithm.

The Reference Architecture Integrated Science Instrument Module

The ISIM consists of a cryogenic instrument module integrated with the OTA, and processors, software and other electronics located in the Spacecraft Support Module. The ISIM provides the structure, environment and data handling for several science instruments.

This ISIM design is illustrative and is not intended to define NGST's final complement of instruments. The Reference Architecture instrument suite includes the following.

- An NIR camera covers 0.6–5 μm, critically sampled at 2 μm. Efficient surveying capability, as well as guiding requirements, set the field at about 4 arcmin × 4 arcmin, apportioned over four subcameras each 2 arcmin on a side. The NIR detectors (InSb or thinned HgCdTe) are radiatively cooled to 30 K.
- An NIR multi-object spectrometer, with spectral resolutions of 300 and 3000 and a spatial resolution of 100 marcsec, covers a field of 3 arcmin × 3 arcmin. Multi-object capability is enabled by an array of 2048^2 micromirrors used to form a reflective slit mask, directing light into or away from the spectrometer.
- An MIR camera–spectrometer covers a field of 2 arcmin × 2 arcmin with a spectral range of 5–28 μm using a 1 K × 1 K Si:As array as detector and a long-slit cross-dispersed grism. Its spectral resolution is ~10^3. The camera employs a selection of slits and a no-slit option to enable direct imaging with filters. The MIR detector is cooled to 6 K by a miniaturized reverse turbo-Brayton cooler; open-cycle solid hydrogen cooling has been identified as a viable alternative.

Passive cooling and thermal control

NGST designs solve the problem of cooling to the cryogenic temperatures required for NIR and MIR operation passively by (a) protecting the observatory from the Sun with a multilayer shield, (b) using a heliocentric orbit to decrease the Earth's thermal input and (c) configuring the telescope to have a large area exposed to space to improve radiative cooling.

To make the thermal emissivity negligible compared with the zodiacal light, the back of the sunshield must be below 100 K. This is accomplished by adding five low-emissivity layers behind the surface of the shield facing the Sun. The main optics then reach very low temperatures (<40 K) and do not contribute significantly to the overall emissivity of the observatory.

Sky coverage

The observatory can be pitched ±25º off the sunline and rolled 360º about the sunline. The portion of the sky accessible is a 50º wide spherical band centered 20º away from the perpendicular to the sunline. This represents ~40% of the entire sky. Full sky coverage is achieved in slightly less than 6 months. At any time, any target in the accessible zone can be tracked for a minimum of 7 weeks.

Launch and orbit

The overall mass of the Reference Observatory NGST is approximately 3300 kg, within the capability of an Atlas IIAS or the next generation of medium launchers (EELV Medium). Deployment of the OTA occurs soon after launch, before the sunshield is deployed, while all the mechanisms are still relatively warm. Optics alignment can then begin, followed by science calibration as the telescope cools. The halo orbit at L2 is reached about 3 months later.

Science and mission operations

NGST's Science and Mission Operations will be simple and efficient because of the telescope's location at L2. Operations for NGST will be based on an optimized long-range observing plan that consists of sequenced science programs ranging from large imaging surveys, often with pre-planned spectroscopic follow-ups, to intensive studies of individual objects.

Discovery potential

NGST will be an observatory with enormous discovery potential both at 0.6–10 μm and at longer wavelengths. This is illustrated in figure 3, which shows the time to achieve a broadband, high-resolution wide-field image with a variety of facilities: NGST, HST, GEMINI OBSERVATORY (representing IR-optimized ground-based 8 m telescopes) and SPACE INFRARED TELESCOPE FACILITY (SIRTF). NGST enjoys a significant background advantage over the ground at all wavelengths, a larger field of view over which high-resolution images can be obtained (4 arcmin × 4 arcmin assumed) and a significant aperture advantage over SIRTF. The shorter times required to achieve a given threshold sensitivity can translate into larger fields observed (more targets) or greater sensitivities.

At wavelengths between 2.2 and 10 μm, NGST is many orders of magnitude faster than any other planned facility. In practice, it will have sensitivities several orders of magnitude better than even SIRTF because of source confusion in very deep observations. In this regard, SIRTF is a superb instrument for surveys of 10–100 square degrees. NGST is best used for deeper observations of smaller pre-selected fields. At wavelengths longer than 10 μm, NGST will surpass SIRTF by an order of magnitude in sensitivity despite a much higher MIR background. For NIR and MIR spectroscopy, it will be unsurpassed between 0.9 and 28 μm (28 μm is the cutoff for Si:As detectors) because NGST's thermal background is much reduced at high spectral resolution.

The 'uniqueness space' for NGST is defined relative to the many large ground-based telescopes that will be operating by 2009. The criterion is that NGST be at least 100 times faster than an optimally operated and equipped 8 m telescope with laser guide stars and adaptive optics. In the NIR, the NGST imaging uniqueness space is very large. For moderate spectral resolution 2D spectroscopy the effects of detector noise significantly narrow the uniqueness space. At this resolution and detector dark current, ~0.02 e^- pixel s^{-1}, NGST is no longer background limited in the visible or NIR (< 4 μm). For spectroscopy of single faint targets, for instance, NGST would be used primarily in the NIR (>0.9 μm). For high-resolution spectroscopy in the visible and J(1.25 μm) and K(2.2 μm) bands (R > 5000) or for visible imaging of large fields with 0.4 arcsec resolution, large ground-based telescopes are competitive with NGST. This is where the large telescopes planned for the next decade will make major contributions.

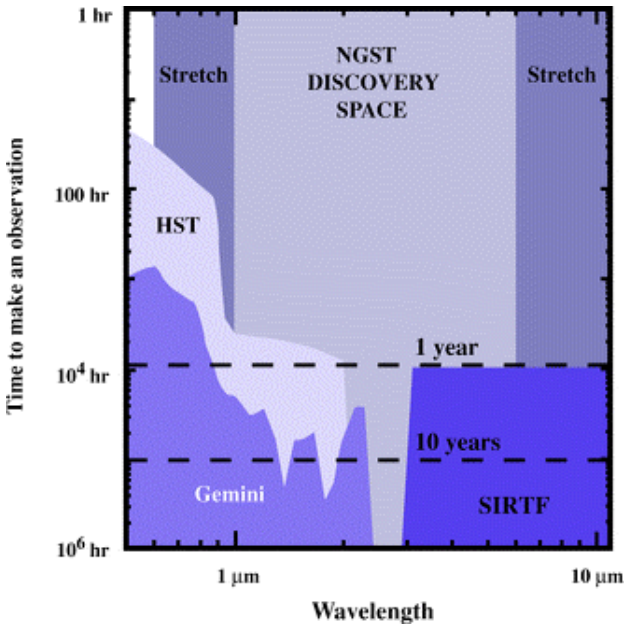

Figure 3. NGST Discovery Space: the relative speed of broadband NGST high-resolution, wide-field imaging compared with other observatories (HST, ACS, NICMOS, Gemini and SIRTF).

It is instructive to consider the relative power of NGST compared with that of HST. HST is currently unique in the windowed ultraviolet (0.1–0.3 μm, a factor of 3 in wavelength). It has comparable sensitivity but superior resolution over ground-based telescopes in the visible and NIR (0.3–1.8 μm, a factor of 6). NGST will have 10–100 times more imaging sensitivity than HST and superior resolution at 2.5 μm (a factor of 4 or comparable with HST at 0.6 μm). It will be unique in imaging and spectroscopy from 2.5 to 28 μm (a factor of 10 in wavelength). It is clear from this simple analysis that NGST will have at least as great an impact on astronomy as HST.

NGC 1068: Prototypical Seyfert 2 Galaxy

NGC 1068 is a nearby spiral galaxy which harbors the prototypical example of a Seyfert type 2 nucleus. However, all evidence points to the conclusion that its active nucleus is completely hidden to our view by dense obscuring material. If we could see NGC 1068 along an unobscured line of sight it would appear radically different. This unveils the importance of orientation of the observable properties of ACTIVE GALACTIC NUCLEI. The extended emission line region in NGC 1068 bears a strong morphological connection with the radio emitting plasma. This close association suggests that nuclear outflows play a fundamental role in the origin of narrow line regions in SEYFERT GALAXIES.

Basic data

NGC 1068 is an early type, BARRED SPIRAL GALAXY located in the Cetus–Aries group. It lies very close to the celestial equator and this makes it visible from both hemispheres (RA $02^h42^m\ 40.711^s$ DEC-$00^d00^m47.81^s$, J2000). Its recessional velocity is 1148 ± 5 km s^{-1} which corresponds, after correction for the Virgocentric infall and adopting $H_0 = 75$ km s^{-1} Mpc^{-1}, to a distance of 14.4 Mpc. At this distance an angular separation of $1''$ translates to 72 pc. NGC 1068 is very bright over the whole electromagnetic spectrum. For this reason, and for its many peculiarities, it belongs to several catalogs of galaxies. Table 1 lists the most common aliases for NGC 1068.

Table 1. NGC 1068 aliases

Messier 77	UGC 2188
ARP 37	IRAS 02401-0013

The optical appearance of NGC 1068 is dominated by a 13 kpc oval bulge elongated on a NS orientation from which originate two spiral arms (see figure 1). The most vigorous star formation, however, occurs in a ring-like region with a diameter of ∼2 kpc (see figures 2(*a*) and 2(*b*)). On a smaller scale HUBBLE SPACE TELESCOPE (HST) observations shown a bright compact knot which stands out from the diffuse emission of the central regions of the stellar bulge (see figure 2(*c*)). Active star formation is often associated with nuclear activity in Seyfert galaxies (see the article on STARBURST GALAXIES). Several absorption features form a filamentary spiral-like structure around the nucleus and a dust lane (extending over $\sim 180 \times 35$ pc) is projected just south of the brightest knot.

Infrared images reveal a quite different morphology. In particular they are dominated by the presence of a conspicuous stellar bar which extends over ∼3 kpc along position angle $\sim 50^\circ$. Furthermore, a bright central source is also seen at these longer wavelengths but, as will be discussed later, it is not coincident with the optical knot.

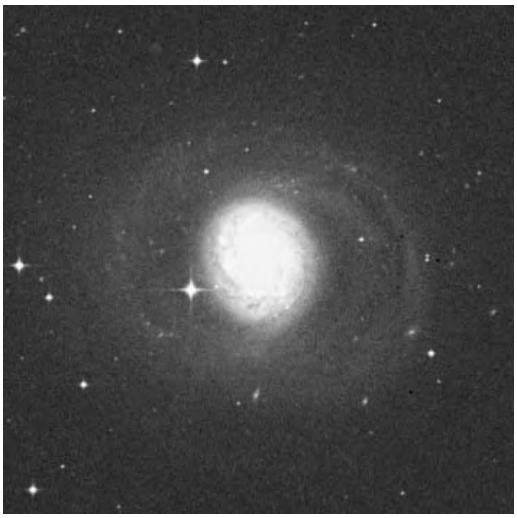

Figure 1. Digital Sky Survey optical image of NGC 1068. The field of view is 10×10 arcmin.

NGC 1068 hosts one of the most studied active galactic nuclei (AGN) in the sky. It is the first object listed in the original discovery paper by SEYFERT containing galaxies with strong ultraviolet excess and in this sense it represents the prototypical Seyfert galaxy. Its optical spectrum is characterized by prominent emission lines. Since permitted and forbidden lines share a similar width (∼1000 km s^{-1}) NGC 1068 is classified as a Seyfert type 2 galaxy (as opposed to Seyfert type I in which permitted lines are broader than the forbidden ones). Ground-based studies have shown that the region where the narrow emission lines are produced is extended and covers several arcsec north of the nucleus. Deep spectroscopy and imaging also revealed a much fainter and more extended (50 arcsec) emission line region with a well defined conical morphology.

A bright radio source (16 Jy at 178 MHz) is also associated with NGC 1068. The radio emission is dominated by a central component which, in high resolution images, reveals a jet-like morphology originating from the nucleus and extending towards the north. Two radio lobes form a bipolar structure which extends over $\sim 15''$.

NGC 1068 harbors a hidden active nucleus

Since the discovery of significant optical POLARIZATION in Seyfert nuclei the study of their polarized flux has proved to be a powerful tool for probing the properties and the geometry of their inner regions.

Three astrophysical processes are known to produce polarized emission: synchrotron radiation, transmission of light through aligned dust particles, and scattering. However, in Seyfert galaxies, synchrotron radiation at optical wavelength is negligible and dichroic transmission has a relatively low efficiency and thus cannot account for the high degree of polarization observed (as high as 60%) in NGC 1068. Conversely, when a photon is scattered

(*a*) (*b*) (*c*)

Figure 2. NGC 1068 as seen by HST: (*a*) Visual continuum, (*b*) Hα emission line image showing the 2 kpc ring of star formation, (*c*) innermost nuclear regions of NGC 1068. Fields of view are 50 arcsec for (*a*) and (*b*) and 15 arcsec for (*c*).

it acquires a net linear polarization which, for a right angle scattering, can be as high as 100%. This indicates that scattering is the dominant polarization mechanism in Seyfert galaxies. The degree of polarization in NGC 1068, after correction for the starlight contribution, is essentially constant ($\sim$16%) over the UV and optical wavelength range. This strongly argues that electrons, whose scattering cross section is independent of wavelength, represent the dominant scattering medium, at least in the innermost nuclear regions.

Polarization observations represent a unique tool to distinguish scattered light from light produced *in situ*. In particular, optical spectropolarimetry revealed that the spectrum of the *polarized* light of NGC 1068 is radically different from that observed in traditional spectroscopic observations. The polarized spectrum of NGC 1068 closely reproduces the spectrum of a type I Seyfert galaxies with the presence of broad permitted hydrogen and iron lines. The simplest interpretation is that NGC 1068 harbors a Seyfert I nucleus which is hidden to our view by obscuring material, probably arranged in a torus or on a highly warped disk. The minimum vertical height of the torus is set by the requirement that the whole region in which the broad lines are produced must be covered, $\sim$0.1–1 pc. Light produced from the nucleus can reach us only after it has been scattered into our line of sight and is therefore polarized.

Imaging polarimetry has been particularly useful to confirm this scenario (see POLARIMETRY: IMAGING POLARIMETRY). From two-dimensional mapping of polarized light it is possible to derive the location of the illuminating sources and of the scattering medium. In fact, the plane of polarization is perpendicular to the direction of the last free path before the scattering and this enable us to trace this path back to the source of illumination. The polarization vectors are thus expected to be tangential to circles drawn around the nucleus and to form a centro-symmetric pattern. This behavior has been indeed clearly observed in NGC 1068 which, in this sense, can be described as a giant REFLECTION NEBULA. By modeling such a pattern it is possible to accurately locate the hidden nucleus as the center of the polarization circles. In agreement with the proposed unified model, there appears to be no visible counterpart at this location since the nucleus is not seen directly. Conversely, the hidden nucleus lies at the center of the nuclear dust lane which probably mark the location of the obscuring torus.

The distribution of polarized light also provides evidence that the nuclear radiation field is anisotropic, as expected if the torus intercepts the nuclear light over a substantial solid angle. Indeed, the polarized emission is concentrated within a region which cover an angle of $\sim 70^\circ$ as seen from the nucleus. This is reminiscent of the conical distribution of the large-scale ionized gas. The torus is 'shading' a large portion of the galaxy from the illumination of the nuclear radiation field. While in the optical the scattering nebula and the emission line region is strongly asymmetric and essentially only the northeastern side is visible (as well as the extended line emission), at IR wavelengths they are clearly seen also on the southwestern quadrant.

The strongest direct evidence in favor of the presence of dense obscuring nuclear material comes from high resolution interferometric radio observations. When looked at with a resolution of $0.002''$($\sim$1.5 pc) the radio component closest to the hidden nucleus shows an elongated morphology, approximately 20 mas in size, oriented *perpendicularly* to the radio jet. Its radio spectrum is well accounted for as thermal emission from hot ionized gas at a temperature of 10^6 degrees. However, water maser emission has been detected associated to the same physical region and this requires the presence of warm ($\sim$400 K) high density ($\sim 10^8$–10^{10}) gas. These two results, combined, point to the idea that we are indeed seeing the inner portion of an edge-on dense disk or torus.

Is the NGC 1068 active nucleus hidden at all wavelengths?
As already discussed the nucleus is completely obscured from ultraviolet to optical wavelengths. The region of

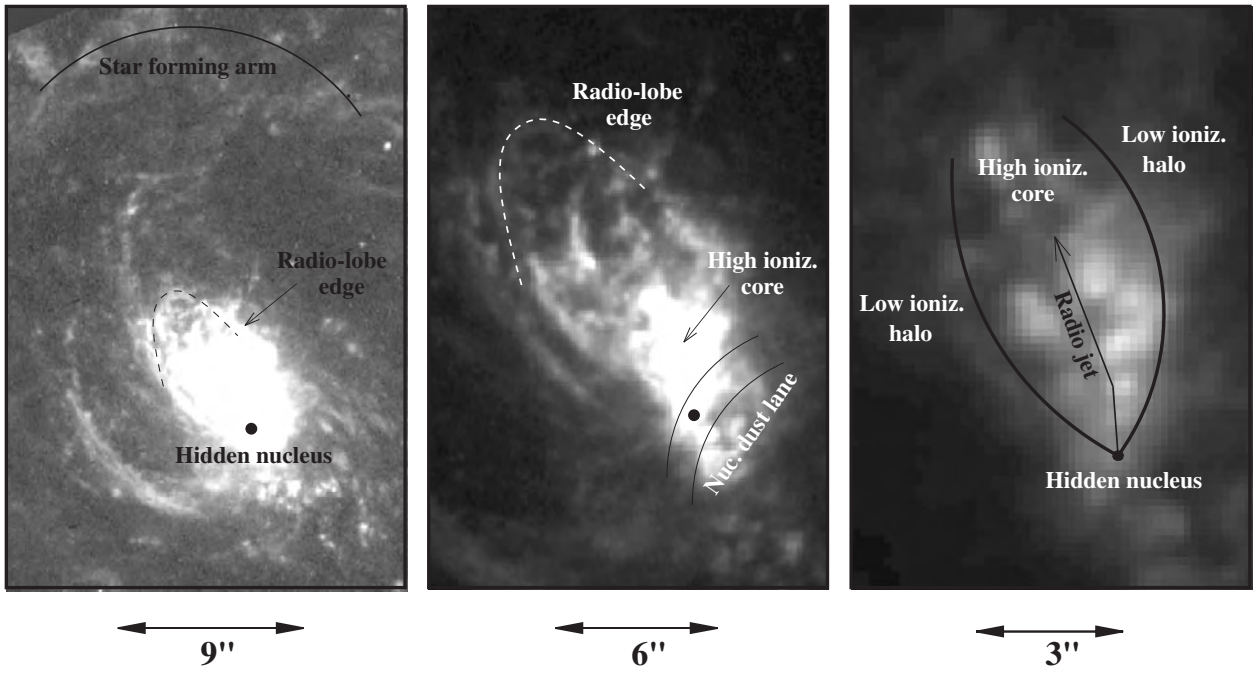

Figure 3. Schematic representation of the various components of the NLR and other features of interest in NGC 1068 overlaid on Hα+[N II] HST images. The black circle indicates the location of the hidden nucleus.

brightest optical emission is located ∼20 pc north of the hidden nucleus as determined by imaging polarimetry and radio observations. In the near-infrared, where dust extinction is less severe, there is a compact central source (smaller than 2 pc) coincident to the location of the nucleus. However, this emission is produced by the hot dust located in the innermost regions of the obscuring torus rather than by the nucleus itself. This is confirmed by the lack of detection of infrared permitted broad lines which, if the nucleus was seen directly at these wavelengths, should be associated with the nuclear emission as in the case of Seyfert I galaxies. Similarly, radio observations of the nuclear region do not show the presence of radio continuum emission near the center of the torus.

X-ray observations seem to represent our best chance to see the nucleus directly. In fact, the amount of material needed to absorb the x-ray emission is much larger that in the optical band, particularly in the hard x-ray band (∼2–10 keV) where a gas column density of the order of $N_H \sim 10^{25}$ atom cm^{-2} is needed. As a comparison, in the optical band a column density of $\sim 5 \times 10^{21}$ atom cm^{-2} produces an absorption depth of 1 and typical galactic column densities are $\sim 10^{21}$ atom cm^{-2}. Indeed, NGC 1068 is a strong x-ray emitter and its hard x-ray spectrum is similar to those of Seyfert I with one important exception: no variability is seen over a timescale of 10 yr. Another puzzling result is that the x-ray spectrum does not show the effects of significant absorption; if we were seeing the x-ray nucleus, these high-energy photons should cross the same material which is responsible for the obscuration in the optical and infrared bands, and thus produce easily detectable absorption features. These results can be understood if the x-ray nuclear emission is not seen directly but is scattered, similar to what is seen in the optical. In this picture the scattering region is not affected by absorption from the nuclear torus and it is extended so that the intrinsic variability of the incident nuclear continuum is smoothed out. In support of this interpretation the hard x-ray spectrum of NGC 1068, and in particular the prominent iron emission lines, can be successfully modeled by scattering over a combination of neutral and ionized reflectors. Recent observations moved the limit in photon energy at which only the scattered component can be seen, to ∼100 keV, consequently increasing the minimum column density of the torus to $\sim 10^{26}$ atom cm^{-2}.

We can conclude that we have no direct view of the nucleus of NGC 1068 but only through a small fraction of nuclear light which is scattered or reprocessed into our line of sight. Interestingly, the detection of scattered light implies that light *can* escape the nuclear regions, although not in our direction. If we could see NGC 1068 from these unobscured lines of sight it will probably look like an ordinary Seyfert I galaxy.

The key relevance of these obserations of NGC 1068 is that they clearly show that the properties of an active galaxy depend critically on its orientation. This prompted the development of a unified model for Seyfert galaxies in which the two Seyfert classes are intrinsically identical and differ only for their orientation with respect to the observer and this scheme is now proving to be widely applicable

also to other classes of AGN.

The origin of the emission line region in NGC 1068

The large-scale distribution of line-emitting gas in NGC 1068 shows a sharp conical morphology, clearly indicative of illumination from an anisotropic source of ionizing photons. Recent HST imaging shown that such a cone-like morphology is also seen on a smaller scale, ∼4 arcsec, but the axis of symmetry of this inner 'cone' is rotated some 30° clockwise from the outer one. The changing orientation with distance suggests that the gas does not fill uniformly the region illuminated by the nucleus.

In this respect, particularly intriguing is the relationship between the emission-line region and the radio emission (see figure 3). The inner radio jet lies in a region of relatively low optical emission and is surrounded by most prominent line-emitting clouds. Similarly, on a larger scale, a network of line-emission filaments completely envelop the northeastern radio-lobe. These results can be understood as due to the interaction between the outflowing radio plasma and the surrounding medium: in this scenario the outflowing plasma is sweeping, compressing and heating the interstellar gas. As a result of this interaction and compression the gas takes the form of dense shells and the line emission is highly enhanced along the edges of the radio-jet and lobes.

Strong support to this scenario comes from the velocity field of the narrow line region (NLR). Within 0.5 arcsec of the radio-jet the emission lines are kinematically disturbed and split into two components whose velocity separation is 1500 km s^{-1}, while the filaments associated with the radio lobe are redshifted by 300 km s^{-1}. This is clearly a consequence of the acceleration of the ionized gas driven by the expansion of the radio plasma.

The radio outflow might also be important for the ionization properties of the gas. In fact, the material along the radio-jet is in a much higher ionization state than the remaining of the NLR. Because the electron density is substantially larger in this region compared to the surrounding gas, these results can only be explained if there is a more intense ionizing continuum associated with the jet. This can be accomplished in a variety of ways which include an intrinsically anisotropic nuclear radiation field but also the presence of a local ionization source such as thermal emission from hot gas heated by the interaction with the radio-jet.

It therefore appears that the morphology of line-emitting region in NGC 1068 is dominated by the presence of a radio outflow, which sets the distribution of ionized gas, rather than to the anisotropy of the nuclear illuminating source and it may also play a crucial role in determining its ionization properties.

Bibliography

In 1996, a four-day workshop was dedicated to the discussion of the latest results on NGC 1068. The proceedings of this meeting, published in 1997 in the 248th volume of *Astrophysics and Space Science*, provide a valuable source of additional information and further reading on this galaxy.

NGC 4151

NGC 4151 is one of the nearest and brightest active galaxies, being among the original six 'Seyfert' galaxies singled out by Carl Seyfert in 1947 for the unusually strong, broad emission lines in their spectra (see SEYFERT GALAXIES). NGC 4151's rather anonymous designation as the 4151st entry in Dreyer's 1888 *New General Catalogue* belies its prominence in modern astronomical studies. Its proximity and brightness make possible detailed observations with good spatial resolution using a wide variety of techniques across the entire electromagnetic spectrum from the radio through the gamma ray. These observations have provided valuable insights into the general workings of all active galaxies (see ACTIVE GALAXIES: OVERVIEW, QUASISTELLAR OBJECTS: OVERVIEW and ACTIVE GALAXIES: OBSERVATIONS).

NGC 4151 is located in the constellation Canes Venatici (the Hunting Dogs), and it is visible through a modest-size telescope in the northern spring sky. As shown in figure 1, it is a spiral galaxy with a moderately bright bulge (Sab on the Hubble classification sequence). The most prominent feature of its visual appearance, however, is the bright, point-like nucleus that is the center of activity. The whole galaxy has an integrated visual magnitude of 10.8, and 35% of this light is emitted by the nucleus itself.

Modern surveys have catalogued thousands of Seyfert galaxies, and astronomers have subdivided these unusual galaxies into two major classes. The nuclei of Seyfert 1 galaxies display unusually broad emission lines as well as some narrower lines. (These 'narrow' lines are typically much broader than the emission lines seen in normal galaxies or Galactic nebulae.) In Seyfert 2 galaxies, all the emission lines have similar widths comparable to the narrow lines in Seyfert 1s. The nuclear spectrum of NGC 4151 displays both broad lines and unusually strong narrow lines, and occasionally the broad lines are so faint that they are difficult to see. It is therefore often classified in an intermediate category, 'Seyfert 1.5'.

Owing to the expansion of the universe, NGC 4151 is receding from us at a velocity (relative to the Sun) of $cz = 995$ km s^{-1}, as measured by the neutral hydrogen gas that fills its galactic disk. For a Hubble constant of 65 km s^{-1} Mpc^{-1}, this places it at a distance of 15 Mpc, or 50 million light years. At this distance, features 0.1 arc seconds across, capable of being resolved by the Hubble Space Telescope (HST), span a physical distance of 7.4 pc, or 24 light years.

Visual appearance

NGC 4151 has a visual size of 4.5 × 6.3 arc minutes, bounded by a set of outer spiral arms that merge into a faint ring. The plane of the spiral disk is inclined to our line of sight by 21°, and the major axis of the disk is oriented at a position angle of 26°. As is usual for active galaxies, the nuclear light is bluer than that of the surrounding galaxy. The galaxy has an integrated color of $B - V = 0.73$, while the nucleus has $B - V = 0.58$. Spectra of the nucleus reveal broad emission lines and a non-stellar, power law continuum, but, depending on the size of the aperture used, galactic starlight is seen in varying degrees as well.

Figure 1. Visible light image of NGC 4151 from the Digital Sky Survey. The image covers an area of 160 × 160 square arc seconds on the sky.

Figure 2. Emission-line image of NGC 4151 in the light of [O III] obtained with WFPC2 on HST. The image size is 15 × 12 square arc seconds.

HST images of NGC 4151 resolve the narrow-line emission in the nuclear region on the sub-arc second scale. As shown in figure 2, its morphology is biconical, similar to that seen in Seyfert 2 galaxies (like the prototype NGC 1068). The cones have an opening angle of 75°, and they are oriented at a position angle of 60° on the sky. Long-slit spectroscopy of this emission using the Space Telescope Imaging Spectrograph (STIS) on HST shows that the gas is outflowing from the nuclear region. Images with ground-based telescopes trace the narrow-line emission in filaments extending up to 30 arc seconds from the nucleus. This is often called the 'extended narrow-line region.'

Ultraviolet properties

At shorter ultraviolet wavelengths, the starlight of the galaxy proper in NGC 4151 nearly disappears, and its

Dirac House, Temple Back, Bristol, BS1 6BE, UK

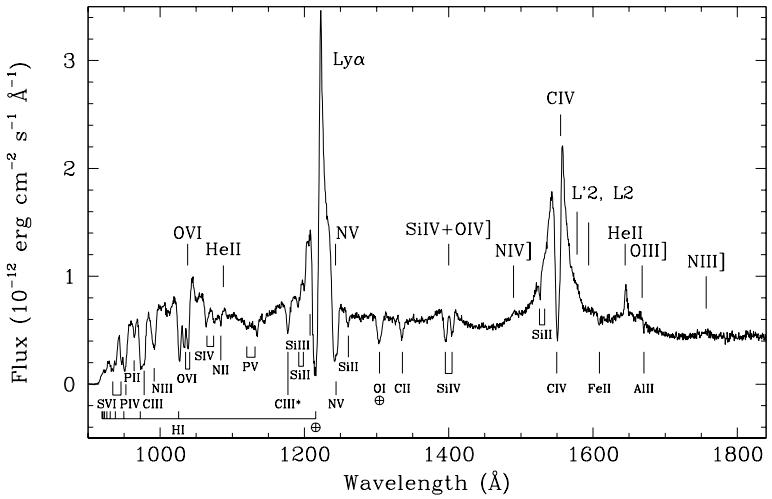

Figure 3. Far-ultraviolet spectrum of NGC 4151 obtained with the Hopkins Ultraviolet Telescope during the Astro-2 mission.

appearance is completely dominated by the bright, point-like nucleus. As in visible light, the nuclear spectrum shows a non-stellar continuum and prominent broad absorption lines. This spectrum, shown in figure 3, is similar to that seen in other Seyfert 1 galaxies (and in quasars) except for one unusual characteristic, which is the strong, complex assortment of absorption lines. While weak UV absorption lines are seen to be common in HST spectra of Seyfert galaxies, these are usually restricted to the transitions of highly ionized atoms and the Lyman α transition of hydrogen. In NGC 4151 absorption lines are associated with nearly all ionization levels, and they are particularly strong, broad (200–300 km s^{-1}), and blue shifted, indicating that the absorbing gas is outflowing from the nucleus.

X-ray characteristics

At x-ray energies, NGC 4151 is one of the brightest sources in the sky outside our own Galaxy. The 2–10 keV x-ray flux is variable on time scales as short as days, and it roughly averages 2.5×10^{-10} ergs cm^{-2} s^{-1}. This corresponds to a luminosity of 7×10^{42} ergs s^{-1}, making NGC 4151 one of the intrinsically least luminous Seyfert galaxies. The x-ray emission is dominated by the point-like nucleus, but there is some surrounding faint extended emission.

The x-ray spectrum of NGC 4151 is complex, and it displays a variety of features that have both illuminated and puzzled our understanding of active galaxies. The 2–10 keV spectrum is dominated by a power law continuum showing strong, variable absorption at energies below 4 keV. The power law continues to higher x-ray energies before showing an exponential cutoff beyond 100 keV. A strong 6.4 keV emission line attributed to Fe Kα emission is also present.

The most unusual aspect of the low-energy absorption is that x-ray emission is still visible at low energies at levels above what would be predicted by simple absorption by cold gas at the required column densities of $\sim 10^{23}$ cm^{-2}. When this was first noticed in observations obtained with the Solid State Spectrometer on the Einstein Observatory, it was interpreted as 'partial covering' of the x-ray source by the absorbing material, as might happen when a myriad of individual small clouds each obscured only a small portion of the x-ray emitting region, thereby allowing some of the x-ray flux to leak through holes between the clouds. More recent and detailed x-ray observations with the Japanese ASCA satellite show that the excess emission is more complex. Matching the observations requires the absorbing material to be partially ionized, thereby making it more transparent at x-ray energies, having a small percentage of the original x-rays scattered into our line of sight, and adding a soft thermal component at energies below 0.7 keV. In this model the ionized absorber could also serve as the scattering medium as well as the source of the soft thermal emission.

The shape of the hard x-ray spectrum and the presence of the iron emission line are signals of Compton x-ray reflection. This type of emission is generally seen in Seyfert galaxies, and it arises when the primary x-ray source illuminates surrounding colder material covering a large solid angle, such as an accretion disk (see ACCRETION DISKS). The Fe Kα emission shows both a narrow component as well as one that is relativistically broadened with the shape expected for material in an accretion disk orbiting the central black hole. Once the effects of the Compton reflection are taken into account, the intrinsic x-ray spectrum can be modeled as the emission produced when a hot (60 keV), optically thick plasma cloud Compton scatters low-energy seed photons. A natural source for these low-energy photons is the ultraviolet and optical radiation from the outer portions of the accretion disk. Thus Compton scattering is operating in two regimes and in two separate locations here—first, at high temperatures in the production of the primary x-rays, and second, in the reflection of those x-rays from cold surrounding material.

Radio morphology

Among active galaxies, NGC 4151 belongs to the class known as 'radio quiet.' Radio quiet doesn't mean radio invisible, however. At radio wavelengths, NGC 4151 also displays unusual activity compared to a normal galaxy. The nuclear region has a total radio flux of 145 mJy at 6 cm (5 GHz). This is resolved on arc-second scales into a two-sided radio jet oriented at a position angle of 77° and extending about two arc seconds from the nucleus. The radio core coincident with the nucleus is itself extended, and it is resolved with very long baseline interferometry (VLBI) into an elongated structure that is misaligned with the larger scale radio jet, but at an orientation (position angle 57°) that is nearly aligned with the biconical narrow-line region imaged with HST.

Unified models

Unified models that link the Seyfert 1 and Seyfert 2 classes of active galaxies rely on a combination of geometrical factors to explain the disparate appearance of what are intrinsically identical objects (see ACTIVE GALAXIES: UNIFIED MODEL). The basic Seyfert galaxy of either type has a 'central engine' in which material accreting onto a central black hole generates the radiation that we see and which illuminates the surrounding material in the host galaxy. Fast-moving gas clouds near the central engine emit the characteristic broad lines seen in Seyfert 1 galaxies; this is called the 'broad-line region'. Slower moving clouds at distances of 10–100 pc in the 'narrow-line region' produce the narrower lines typical of Seyfert 2 galaxies. An opaque ring, or torus, surrounds the central engine and the broad-line region. This torus blocks radiation from escaping in its plane. Thus, the narrow-line region is illuminated by radiation that has been collimated into two opposing cones. In Seyfert 2 galaxies, our line of sight lies in the plane of the torus. Our view of the central engine and broad-line region is blocked, and what we see is dominated by the extended, conically shaped narrow-line region. In contrast, our view of Seyfert 1 galaxies is from above the plane of the torus, where we have a clear line of sight to the broad-line region and the central engine. Since our line of sight lies within the cone of collimated radiation, any extended narrow-line structure has a symmetrical distribution about the point-like nucleus rather then the twin cones often seen in Seyfert 2s. In addition, the brilliance of the radiation from the nuclear region often makes the much fainter narrow-line clouds difficult to see.

The appearance of NGC 4151 presents a challenge to the simple unified model outlined above. The biconical narrow-line region imaged with HST and shown in figure 2 is typical of what one would expect in a Seyfert 2 galaxy, and it implies that our line of sight lies in the shadow of whatever structure is collimating the radiation. Yet, we clearly have a direct view of the central engine and broad-line region since the broad lines characteristic of a Seyfert 1 are prominent in its optical and UV spectra. Thus the collimation cannot be provided by an optically thick torus. Two possible explanations have been discussed in the literature.

The narrow-line region can still take on the appearance of a cone if the illuminated material lies in a thin plane parallel to the disk of the galaxy rather than uniformly filling the conical region of collimated nuclear radiation. Since the conical structure has sharp edges that can be traced down to distances less than 0.5 arc second from the nucleus, the plane must be no thicker than 35 pc and have sharp upper and lower boundaries. The virtue of this explanation is that the difference between the observed axis of the ionization cone and the radio jet is simply due to a projection effect. There are two difficulties, however. First, the ionization cone must have an intrinsic opening angle of 130°, much higher than the $\sim 90°$ inferred for other Seyferts. Second, the vertical distribution of the gas is unusually thin compared to our own Galaxy, and it must be sharply bounded rather than have a smooth vertical gradient.

The other alternative notes that while our line of sight to the central engine in NGC 4151 is fairly clear, it is not completely unobstructed. The x-ray spectrum shows heavy (but partial) low-energy absorption, and the UV and optical spectrum is rich in absorption features, including an optically thick Lyman limit. These absorption features are unusual for Seyfert 1 galaxies, and they are only found in those Seyfert 1s in which a biconical narrow-line region is visible. (NGC 3516 is the only other known case.) A slight modification of the unified model in which the obscuring torus is surrounded with a thin atmosphere can explain the absorption features and the biconical appearance of the narrow-line region. The gas in this atmosphere will be photoionized by the central source, and radiation pressure may drive it in an outflowing wind as seen in the high luminosity broad absorption-line quasars. This can produce the blue-shifted, ionized UV absorption features. For lines of sight through the atmosphere in which the total column density is $\sim 10^{21}$ cm^{-2}, the view is clear at all wavelengths longer than the Lyman limit of neutral hydrogen (912 Å), but it is optically thick throughout the ionizing UV and into the soft x-ray region of the spectrum. This atmosphere can then effectively collimate the ionizing radiation and still provide a clear line of sight to the central regions. One can then explain the unusual characteristics of NGC 4151 within the context of unified models by simply requiring a special line of sight for this unique object.

NGC 5128/Centaurus A: 150 Years of Wonder

Just over 150 years ago, in 1847, Sir John Herschel saw in the southern sky 'a most wonderful object ... cut asunder ... by a broad obscure band' (see HERSCHEL FAMILY). At the time, there was no clue as to the nature of this celestial object. It took well over half a century for observational astronomy to advance to the point where it could hypothesize that it was extra-galactic, and only in the last 50 years have advances in radio, infra-red, x-ray, γ-ray and optical astronomy permitted us to think we understand this unusual and visually spectacular object.

We now know it as the galaxy NGC 5128. We know that its dominant visual feature is a dust lane, a large, edge-on disk of gas and dust around the galaxy, with areas of recent star formation, thought to have resulted from a past merger with another galaxy—updating the very early model for the morphology of a collision between two ELLIPTICAL GALAXIES. We know that it is a strong radio source, and hosts an ACTIVE GALACTIC NUCLEUS (AGN) which is a powerful source of emission at many wavelengths—AGN are thought to be SUPER-MASSIVE BLACK HOLES, accreting interstellar material from the host galaxy. In fact, we more commonly use its radio designation CENTAURUS A. Finally, we also know that Centaurus A is not unique. There are untold numbers of galaxies with significant dust lanes and features; dust is thought to play a major role in the evolution of galaxies and in star formation. We know that mergers play a major role in galaxy evolution and star formation. And we know that there is a broad variety of nuclear activity in galaxies, that massive black holes may be present at the centers of most, if not all, galaxies, that mergers may also be related to the presence of nuclear activity and/or massive black holes, and that nuclear activity may in turn affect star formation.

The phenomena we see in Centaurus A are thus, in fact, quite common, and Centaurus A is likely representative of many galaxies. Much of its uniqueness, and its spectacular appearance, arises from its proximity to us. At a distance of 3.5 Mpc, it is one of the nearest galaxies outside the LOCAL GROUP—the nearest giant elliptical galaxy, the nearest radio galaxy, the nearest active galactic nucleus, and the nearest example of a recent merger. The unprecedented detail potentially visible in Centaurus A due to its proximity allows us to learn more about all these phenomena: it should be an excellent laboratory for investigating the nature of active galactic nuclei, of radio and x-ray jets, of mergers, and of the relation among these phenomena. But in one of nature's perversities, the very dust lane which gives the galaxy its spectacular appearance also blocks visible investigations of the nuclear region. We must rely on all of modern astronomy's observational tools to understand this object.

The galaxy as a whole—its optical appearance

Optically, NGC 5128 appears as an elliptical galaxy with a dark lane cutting through the central region (figure 1). The obvious visual image stretches out some 5–10 arcmin, although intensity contours can be traced several times further out. Kinematic studies and dynamic modeling suggest a triaxial geometry. Estimates for the distance to NGC 5128 have varied though the years, ranging up to 8 Mpc, but it is now widely accepted to be between 3 and 3.5 Mpc away; we use the value of 3.5 Mpc—11 or 12 million light years away. At this distance, one arcsec corresponds to 17 pc; an arcmin is just about a kpc.

If we ignore the dust lane and inner region, NGC 5128 actually appears visually as a fairly normal giant elliptical galaxy. Most of the light comes from an older stellar population, and the light distribution follows a de Vaucouleurs law. The integrated visual magnitude of about 7 makes it one of the brightest galaxies in the sky, even without compensating for the obscuring dust lane (the intrinsic magnitude is ~ -22). Outside the dust lane, the light has an R-I color $\simeq$0.7, average for an elliptical. Inside the dust lane, the color varies generally from 0.9 to 1.5, with occasional higher peaks. Correcting for the estimated extinction reveals a relatively smooth brightness distribution, confirmed by near-infrared observations which are less affected by the dust. Within the dust lane, polarized red and infrared emission is seen, with spatially variable polarized intensity proportional to extinction, but with a relatively constant position angle of $\sim$110°. This suggests that the POLARIZATION is caused by dichroic transmission through aligned dust grains. The highest polarization region at the center has a different angle and coincides with a flatter spectrum compact knot, interpreted as a scattering knot very close to the active nucleus.

In the outer regions, NGC 5128 has a faint blue shell structure. These shells are interpreted as being caused by a galaxy merger—a small, gas and dust-rich disk galaxy colliding with the existing giant elliptical galaxy some 10^8–10^9 yr ago. The outer shells are debris of the intruder galaxy—stars and gas stripped from the small galaxy during the interaction. The blue color suggests the shells include new stars formed as a result of the collision. Neutral hydrogen is also seen near the shells.

The dust lane itself comprises the remaining gas and dust of the tidally disrupted incoming galaxy, having formed a disk around the center of the original giant elliptical galaxy. Molecular (e.g. CO, HCO^+, HCN), Hα, and H I kinematic mapping of the dust lane in emission and absorption are well modeled by a warped, twisted gas disk around the nucleus, viewed nearly edge-on. This disk, with a projected width of approximately an arcmin, effectively obscures the nucleus and the inner half-kiloparsec of the galaxy in the optical. The outer parts of the warped disk reflect the orbital plane of the incoming galaxy, the inner portion having settled into a principal plane of the elliptical galaxy. Sub-millimeter and recent ISO mid-infrared observations (see INFRARED SPACE MISSIONS) have shown a 5 kpc structure along and within the dust lane, symmetrical around the nucleus. This structure resembles a barred spiral associated with the thin disk

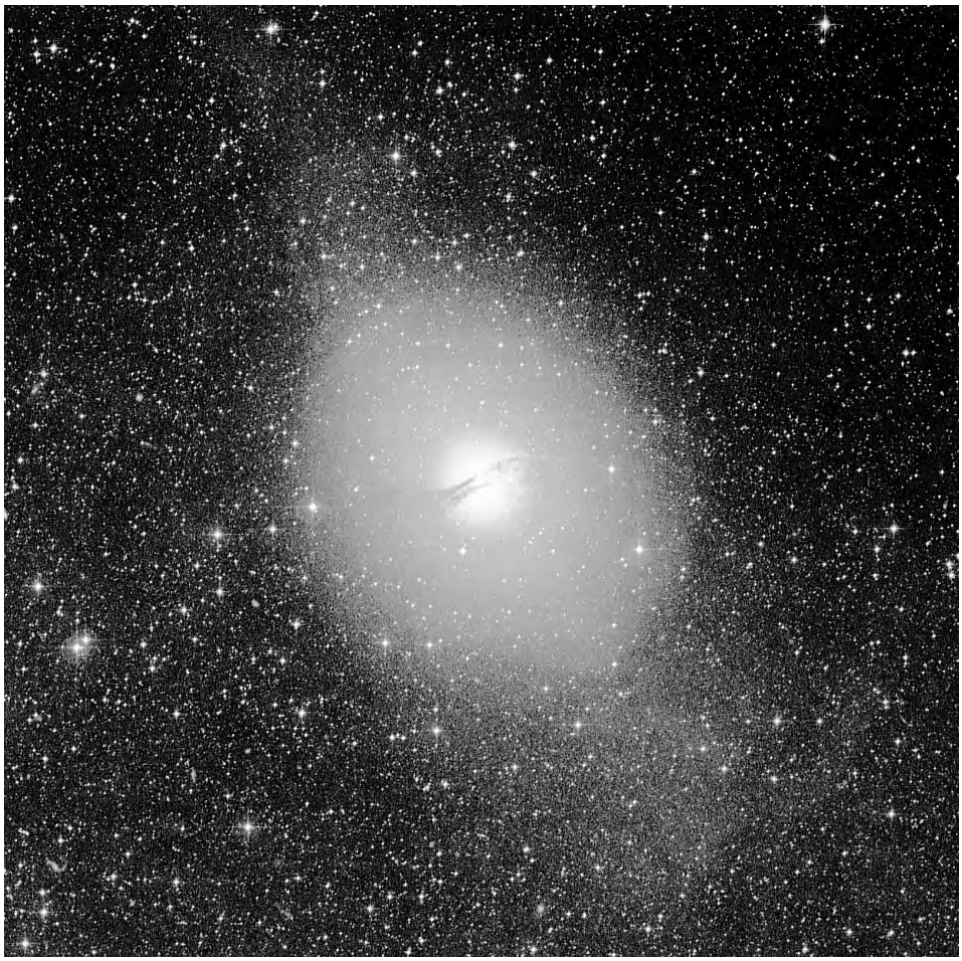

Figure 1. Deep visible light image of NGC 5128, showing the large (50′ ∼ 50 kpc) low-luminosity extent of the elliptical galaxy, the bright bulge, and the warped dustlane.

formed by tidal debris; it is, perhaps, related to the transfer of material into the central region around the AGN.

Associated with the edges of the dust lane are young blue stars, stellar associations, globular clusters, and H II regions. Early HUBBLE SPACE TELESCOPE (WFPC1) observations revealed some 74 sources above detection limits (23.0, 22.6 in R, I) along the northern edge of the dust lane, much larger than the density in neighboring parts of the galaxy. The luminosities of many of these objects exceed that expected for single stars, and many were resolved on the several parsec scale. A large color dispersion, with many blue objects dominated by spectral type A or earlier stars, is consistent with recent star formation along the dust lane. The blue stars, stellar associations and globular clusters, also studied with HST/WFPC2, indicate that new stars were likely formed along the dust lane as a result of the merger.

The active galaxy—Centaurus A in radio, x-rays and infrared

Centaurus A was one of the earliest powerful discrete radio sources discovered, and is, of course, the nearest of the giant RADIO GALAXIES (see figure 2). It was the identification of NGC 5128 with Centaurus A in 1949 that sparked interest in the galaxy, suggesting that it was indeed an unusual object. One of the well-known early optical images of the galaxy was labeled 'NGC5128—peculiar galaxy, source of radio noise'. Baade and Minkowski confirmed its extragalactic nature by radial velocity measurements in 1954. Early radio observations revealed giant outer lobes on a scale of several degrees and intermediate and smaller scale structure down to the scale of several arcmin. It was only in 1980, however, that high resolution observations with the VLA revealed the detailed morphology of the inner lobes, nucleus and jet (see below).

The nucleus itself, although invisible in the optical, has by now been studied for years via radio, x-ray, gamma ray, infrared, and mm observations. It was one of the first

active galactic nuclei identified, even before we recognized AGN as a major category of astrophysical phenomena. A strong x-ray source was found in the vicinity of Centaurus A in 1970. The x-ray source was confirmed to be associated with the nucleus of the galaxy by UHURU and ANS. Its luminosity is about 10^{42} erg s^{-1}, not particularly unusual for AGN. It shows a simple power law spectrum in the few keV to tens of keV range, similar to that of Seyferts seen in the same energy range. Strong absorption is seen at low x-ray energies, historically thought to derive from the optically obscuring dust lane, but now better interpreted via the so-called standard model of AGN, in which we are looking through a dense accretion torus around a black hole. OSSE gamma-ray data show a slightly flatter power law out to 120 keV, and other gamma-ray observations have shown some steepening again at higher energies. Fe K-line emission has been detected by ASCA, consistent with reprocessing by the 10^{23} H cm^{-2} column, and some other Hα lines are seen at lower x-ray energies, suggesting scattering and fluorescence in a thinner, cooler medium outside the nucleus. An infrared hotspot was reported as the nucleus in 1971, but modern observations reveal a lot of structure in the nuclear region (see below).

When x-ray imaging with the Einstein Observatory became possible in 1979, a jet and other diffuse features were discovered in addition to the nucleus. The spectacular jet was the first such discovered via its x-ray emission, and only subsequently studied in radio with the VLA. Extended x-ray emission on the scale of the galaxy as a whole, at the level of about 10^{39}–10^{40} erg s^{-1}, originally

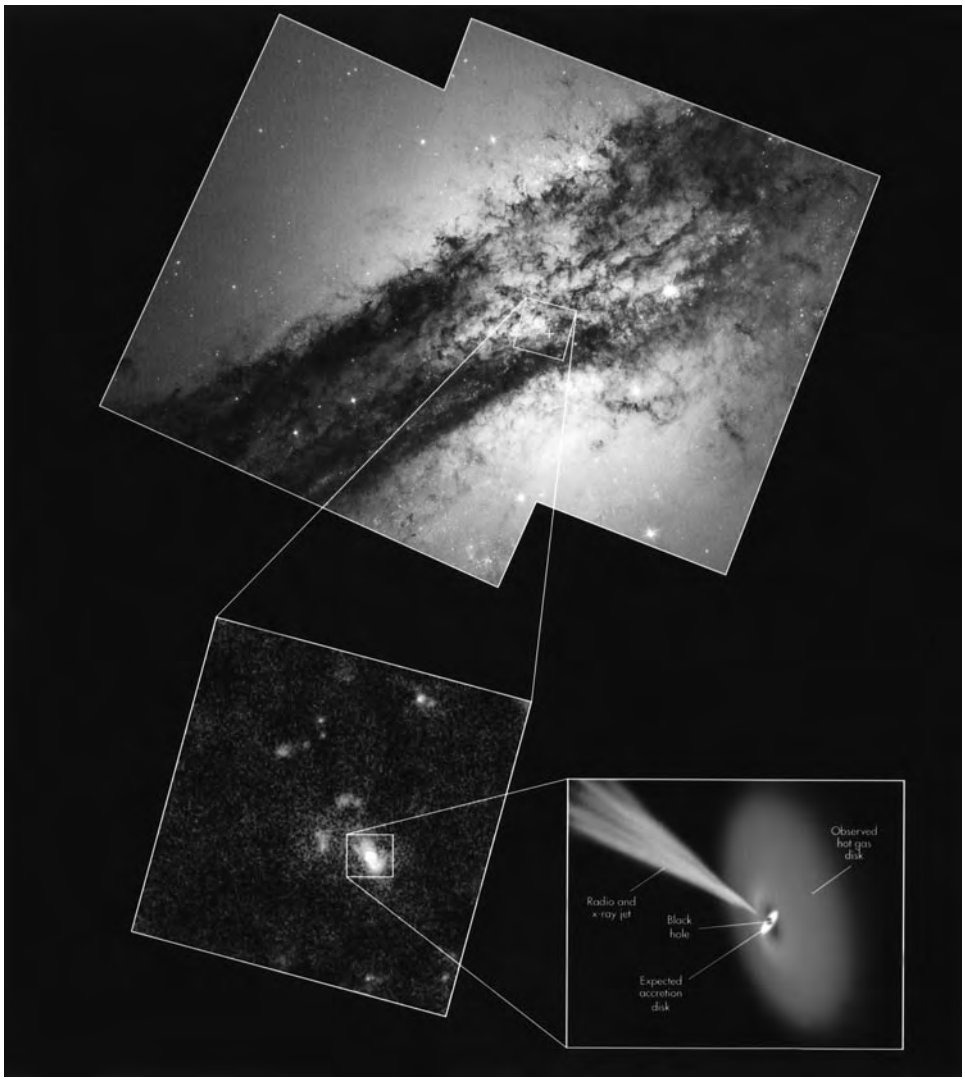

Figure 3. Upper panel: HST WFPC2 image of the core of NGC 5128. Note the bright young stars along the edge of the dustlane. Lower left: HST NICMOS image of the ionized gas at the nucleus of the galaxy. Lower right: Schematic model of the hot gas disk around the active nucleus and the radio/x-ray jet.

hypothesized as inverse Compton emission from the radio lobes, was later found to be common in other galaxies, and is likely due to emission from hot gas produced by stellar mass loss. Ridges of x-ray emission parallel to but outside the dust lane have been interpreted as being associated with the young population in the disk of the galaxy, possibly the integrated emission of massive x-ray binaries.

The radio source in general, and the jet in particular, is not unusual. The large-scale structure is typical of the large class of medium power, double-lobed radio sources, although the presence of both inner and outer sets of lobes suggests at least two different epochs of radio activity. Possibly related to this, the symmetry axis changes progressively from the outer to inner lobes, and in to the observed jet, suggesting changes in the jet direction over time, caused, perhaps, by precession. The jet morphology is rather similar to that of M87, with constant opening angle and knots, having an inner core and an outer halo. The nucleus has an inverted spectrum ($\alpha = -0.55$), and jet shows a synchrotron spectrum, steepening slightly with distance ($\alpha \simeq 0.48 \rightarrow 0.72 \rightarrow 0.86$ in the lobe) and with rather good correlation between radio and x-ray morphology in the inner knots, suggesting that the x-ray emission might also be synchrotron. Unfortunately, x-ray spatial and spectral resolution has not yet been adequate to unambiguously distinguish among synchrotron, thermal, and inverse Compton emission mechanisms. A synchrotron model would require continuous re-acceleration of electrons to replenish their energy, since the x-ray emitting electron lifetimes would only be $\sim$50 yr or less, far less than the light

travel time along the jet. Then again, in a perverse 'catch 22' of nature, if there is indeed re-acceleration, we might also expect to see shocks, which could in turn produce thermal x-rays.

In addition to the jet components seen in x-rays, there are also several radio components within 1–5″ of the nucleus, a VLBI jet on the scale of 100–150 mas, showing sub-luminal motion, and a VLBI counterjet. The VLBI observations, on the one parsec scale, are consistent with Centaurus A being an FRII source; the jet is not relativistically beamed toward us—it is close to the plane of the sky. VLBA observations limit the size of the nucleus to $\sim$0.5 mas $\simeq$0.01 pc $\simeq$10 light days, the smallest known extragalactic radio source. X-ray variability suggests an even smaller size, since the source is known to vary on scales ranging down to less than a day.

Optical emission from the jet has been variously reported through the years at different places in the galaxy. There are indeed faint blue filaments of line-emitting gas and stars about 8′ from the nucleus along the line of the jet, but outside the radio lobe. These suggest jet interaction with the interstellar medium, but are not

Dirac House, Temple Back, Bristol, BS1 6BE, UK

directly correlated to specific x-ray/radio features. There is also a faint linear optical feature along the position angle of the jet near the nucleus seen by HST, but there have been no confirmed detections of optical counterparts to any radio or x-ray knots.

The active galactic nucleus—a black hole

The proximity of this nearest active galaxy, in which 1″ corresponds to only 17 pc, presents the expectation that it would be a good test bed to explore the standard model for AGNs at the parsec scale. Nonetheless, the obscuring dust lane, with its high extinction, has hindered high resolution studies of the innermost regions around the presumed BLACK HOLE. X-ray spectroscopy has suggested the presence of thermal components near the nucleus in addition to the highly cut-off, non-thermal emission from the nucleus itself, and AXAF is expected to further improve our understanding of the high energy emissions from the AGN. High resolution imaging and spectroscopy in the near-infrared, made possible by HST and by the new generation of ground-based 8 m telescopes, are rapidly remedying our lack of insight into the immediate environment of the massive black hole, as we write. HST has produced diffraction-limited images in U, V, I, H and K bands, and HST and VLT are likely to soon produce spectra with spatial resolutions on the 0.1″ scale in R through K.

HST/WFPC2 visible light images have not only revealed new detail of the morphology within the dust lane, but have finally revealed the unresolved nucleus in V and I (see figure 3). HST/NICMOS near-infrared images also show the nucleus and extended galaxy emission, but in addition reveal an elongated ionized structure, interpreted as a gas disk emitting in Paschen α and [Fe II]λ1.643 μm. This inclined disk is approximately 20 pc in radius and roughly perpendicular to the larger dust lane, perhaps on another principal plane of the galaxy. Notably, the disk is not perpendicular to the jet, despite the fact that the standard model suggests that the central torus around a black hole would be perpendicular to a jet. The ionized feature is thought to be an extended ACCRETION DISK, aligned with the gravitational potential of the galaxy, perhaps transferring material from the dust lane and the barred structure seen in the mid-infrared into the dense torus around the black hole at the center. Ground-based near-infrared spectroscopy has revealed broadened lines at the nucleus in the 1–2.5 μm range, likely dominated by the integrated emission from this disk, leading to hopes that we will indeed be able to use HST or the 8 m telescopes to map the velocity structure in the disk, measure the mass of the black hole, and perhaps better understand the details of the accretion process itself (see figure 4).

Summary

NGC 5128—Centaurus A—is indeed a wondrous object, as first noted more than 150 years ago. We now know that its wonder goes far beyond its visual appearance. It gives us a close-up look at a number of astrophysical phenomena which are fundamental to our current world view of the universe and its evolution: the nature of AGNs and the presence of super-massive black holes at the centers of galaxies; the role of mergers in star formation, in the building of elliptical galaxies, and in the presence of activity in galaxies; and the presence of dust and its relation to all these processes. The spectacular appearance is due merely to its proximity and orientation—it is otherwise representative of a large class of giant elliptical galaxies with nuclear activity. It illustrates the fact that the nearest objects of a class often do not initially fit into canonical models—their proximity allows us to see far more detail and more strictly test standard models and interpretations of phenomena derived from observing more distant objects, seen with fuzzier vision. Our growing understanding of our close neighbor Centaurus A will allow us to extrapolate our understanding to galaxies at much greater distances and ages, gaining new insight into the evolution of galaxies and of the universe.

The author gratefully thanks Anton Koekemoer for help in preparing this article.

Nicholas of Cusa [Nicolaus Cryffts, Chrypffs or Krebs, Nicolaus de Cusa, Cusanus] (1401–64)

Cardinal and philosopher, born in Cues or Cusa, Germany. He studied at Heidleberg and Padua, and became a cardinal in 1448. He marks the end of the philosophy of the Middle Ages. In his writing on astronomy, he denied the finitude of the world and its enclosure by crystal walls, suggesting instead that the universe was 'interminate'—'without boundaries'—and that the Earth therefore cannot be at the center of the universe.

Nicholson, Seth Barnes (1891–1963)

Astronomer, born in Springfield, IL, joined the staff of the Mount Wilson Observatory. While photographing the recently discovered eighth moon of Jupiter with the 36 in Crossley reflector, he discovered the ninth, whose orbit he computed. He discovered three more of Jupiter's satellites, as well as a Trojan asteroid. He observed the Sun, including its sunspot activity and magnetism. With Edison Pettit he used a thermocouple to measure the temperature of the Moon (illuminated and eclipsed) and the planets.

Nicolaus Copernicus

Nicolaus Copernicus (1473–1543) was a Polish astronomer whose *De Revolutionibus Orbium Coelestium* (1543) was the final achievement under the agenda of the ancient Greek astronomers and—by its claim that the Earth orbits the Sun—provided a major contribution to the later development of a dynamics of inertial motion.

Mainstream Greek astronomy conceived the universe as being bounded by the spherical heavens, in the midst of which was the spherical (and motionless) Earth. Astronomers attempted to 'save the appearances' (to reproduce the observed movements) of the planets by means of calculations based on geometrical models centered on the Earth; these models comprised circles on whose circumferences the center of another circle, or the planet in question, moved (PLANETARY THEORY FROM EUDOXUS TO COPERNICUS). Since Venus (for example) orbits the Sun which appears to us to orbit the Earth, and since the orbits are in each case not very different from circles and the speeds of the two bodies not very far from uniform, a model of the motion of Venus in which the planet moves on a circle whose center moves uniformly in a circular though somewhat eccentric orbit about the Earth can give an encouraging first approximation to the observed behavior of Venus. On the other hand, the desire for accuracy (on the part of astronomers and astrologers alike) guaranteed that no such model, nor any elaboration of it, would ever prove completely satisfactory: there would always be an incentive to develop and refine further.

In the second century AD, PTOLEMY in his *Almagest* and elsewhere had developed models that came near to saving the appearances. However, in these models Ptolemy had found it necessary to introduce non-uniform motion, namely motion that appeared uniform when viewed from an off-center 'equant' point that we recognize as analogous to the empty focus in a Keplerian ellipse. This violated a fundamental truth about the cosmos, and so brought about a rift between natural philosophers interested in understanding the universe and astronomers glad to have models that, whatever their defects, gave good predictions.

Another limitation of the Ptolemaic models was their *ad hoc* character. In the *Almagest*, which was to dominate astronomy for 14 centuries, Ptolemy used devices that had no rationale other than that they worked. Thus, faced with the observed fact that Venus and Mercury are never seen far from the Sun, he simply required the centers of the models for Venus and Mercury to be aligned with the mean Sun, without offering any explanation of why this should be so. Furthermore, in the *Almagest* Ptolemy made no attempt to combine the individual models into a unified system with a common scale. In the Renaissance, when both Aristotle's concentric nested spheres model was recovered, and the competing detailed mechanisms of Ptolemy understood, an integrated and intellectually satisfying picture of the cosmos became once more an important desideratum, and this came to be seen as a serious defect.

By the fifteenth century, Latin scholars were in the later stages of assimilating the achievement of Ptolemy, as mediated and elaborated by Islamic astronomers (see ISLAMIC ASTRONOMY). They recognized that the Western planetary tables based on the *Almagest* and named for the thirteenth-century Alfonso X of Castile, were of good, though by no means perfect, accuracy. On the other hand, Ptolemy's use of the equant violated a basic truth of natural philosophy, and his failure in the *Almagest* to offer an intellectually satisfying view of the cosmos as a whole was becoming increasingly troubling.

The man who developed geometrical models that more than matched Ptolemy's in predictive accuracy and achieved this without resorting to equants, and who also provided an elegant and convincing picture of the cosmos, was born in Toruń on the Vistula on 19 February 1473. Nicolaus Copernicus was the son of a prosperous merchant who died a decade or so after his son's birth. Copernicus then came under the protection of his uncle, who was to become bishop of Warmia in 1489. From 1491 to 1495 Copernicus studied at Cracow, where his purchases included a volume of the Alfonsine Tables. In 1495 his uncle obtained for him a canonry of the chapter of Warmia (a position that did not necessitate his being ordained priest), but he did not formally take up the post until 1497. In 1496 he enrolled at Bologna, the leading university for law, where he studied both canon and civil law, though he resided with the professor of astronomy. In 1497 and (twice) in 1500 he made astronomical observations that he was later to use in his major publication, and about 1500 he is reported to have lectured in Rome on astronomy. In 1501, after Copernicus had returned to Poland, the chapter agreed to his studying medicine at Padua for two years. This done, he again returned to Poland, where he was to remain for the rest of his life. At first he became personal physician and administrative assistant to his bishop uncle, but in 1510 he moved to Frauenberg, the headquarters of the chapter.

Meanwhile Copernicus's interests in astronomy had developed, and somewhere he had encountered the planetary theory of the Islamic astronomers of Maragha, elements of which were to appear in his own mature planetary models, to the wonderment of modern historians. The catalog of the library of a Cracow professor dated 1 May 1514 contains an entry, 'Next a quire of six leaves of a *Theorica* maintaining that the Earth moves while the Sun is at rest', and this must refer to a copy of the little treatise that Copernicus was circulating anonymously and in manuscript and is known as the *Commentariolus*. Its modern editor thinks it 'may have been written in a momentary burst of enthusiasm, perhaps immediately upon devising the heliocentric theory'.

Already in this sketch we encounter the problem that would bedevil the later acceptance of his developed theory: he was attempting two different tasks, the promulgation of a new cosmology in which the Earth was

in orbit about the Sun, and the provision for mathematical astronomers of a new set of planetary models purged of the equant, that philosophically suspect device employed by Ptolemy.

Of his great *De Revolutionibus Orbium Coelestium Libri VI (Six Books on the Revolutions of the Heavenly Spheres)*, which eventually appeared in 1543, only the first 10 chapters of Book I, or about 6% of the whole, were dedicated to cosmology. The remaining 94% was densely mathematical and inpenetrable to all but a handful of specialists. These specialists would for the most part focus on what interested them and ignore the preliminary cosmology, while the many who might have debated the cosmology would pass by so forbidding a volume—especially since (as we shall see) an anonymous preface explained that the motion of the Earth was proposed merely as a mathematical device to facilitate computational accuracy.

The problematic nature of this assertion, that the book was intended merely to save the appearances, would have been clear to anyone willing to master its contents; but, as Copernicus was well aware, it was indeed formally impossible, simply by means of applied geometry, to *demonstrate* the motion of the Earth. Only when Kepler taught astronomers to think dynamically would it become clear that the Sun must be the focus of the planetary system. All Copernicus could do was to argue that the harmony and simplicity of the heliocentric vision was convincing, and not only to him but to anyone who shared Plato's sense of cosmic beauty.

The planets had worried Greek astronomers not only by moving against the background of the 'fixed' stars—which was bad enough—but by coming to a halt from time to time and temporarily reversing their direction of movement. But on the heliocentric approach such retrogressions were to be expected; indeed, it would be worrying if they did *not* occur. For if the Earth is one of several planets orbiting the Sun, then we will expect the Earth from time to time to overtake each of the outer planets, and the outer planet will then appear to retrogress, not because it is in fact moving backwards, but because the Earth is moving forwards faster. We will expect this to occur when the outer planet is in opposition to the Sun—and in fact this is exactly what we observe. Similarly, when the Earth is overtaken by an inner planet, the planet will appear to reverse its normal direction; and this will happen when it is in inferior conjunction with the Sun.

A problem with Ptolemaic astronomy had been that while Saturn was slower than Jupiter in circuiting the sky, and therefore was plausibly further away, while Mars was quicker and therefore nearer, the Sun, Venus and Mercury all took one year to go round against the background of the stars; the order of their respective distances from Earth was therefore moot. In other words, in Ptolemaic astronomy even the very order of the planets was open to debate. But on the heliocentric view, not only the order of the planets but the actual radii of their orbits could be determined. If we observe the angle Sun–Earth–Venus (and Sun–Earth–Mercury) when the planets are at maximum elongation from the Sun, then elementary trigonometry will give us the radii of their orbits as fractions of an astronomical unit. Observations of the outer planets can likewise yield the radii of their orbits, and in this way we can envision a true system of the planets, which we may depict with the (basic) orbits all drawn to scale.

Furthermore, the annual period of the Sun, Venus and Mercury was revealed as no more than a reflection of the annual period of the Earth: Venus and Mercury had quite different periods which could now be determined. It then emerged that the order of the planets by distance exactly matched the order of the planets by period—not a formal proof of the heliocentric hypothesis, but thoroughly persuasive to those of a certain cast of mind. Indeed, given this geometry it was easy to predict just when a planet would appear to stop its forward movement, and when it would subsequently resume this forward movement once more: the phenomena that had given the 'wandering stars' their name had been shown to be thoroughly lawlike and amenable to prediction, no more than a natural consequence of the Earth's status as one planet among several.

The merits of a heliocentric cosmology are sketched in the *Commentariolus*. The author also offers geometrical models for the motions of the various planets, in longitude and in latitude. The models for longitude are modified from the Maragha models, but referred to the center of the Earth's orbit, while those for latitude derive more directly from Ptolemy. These models are no more than outline, and would require elaboration before becoming the basis for computations of sufficient accuracy. The parameters involved in this elaboration would depend upon observations to be made when the planets concerned were in particular configurations, and the opportunities for such observations would be spread over many years.

Copernicus's interest in astronomy had to take second place to his duties as a canon. So for three years, and later for a part of a fourth, he was Administrator of Benefices, required to travel throughout the chapter's estates collecting revenues and administering justice. During these three years he drew up a set of recommendations for the reform of the coinage, whose debasement he ranked as a disaster alongside civil strife, disease and famine. For much of 1523 he was Administrator General of the diocese between the death of one bishop and the appointment of his successor.

Furthermore, he lived in troubled times; and even in the rare intervals of peace his medical skills were much in demand. But by about 1530 the necessary astronomical observations for the determination of parameters had been made, and soon his treatise was taking shape. By the middle 1530s he was able to compute an almanac (now lost), as a demonstration that the heliocentric approach was more than empty rhetoric. By 1539 the work was essentially complete, and in May of that year he allowed sight of it to a young visitor, Georg Joachim RHETICUS

(1514–74). Rheticus was a professor of mathematics at the University of Wittenberg, and he brought with him as gifts a number of mathematical and astronomical books that had been published in Nuremberg by Johann Petreius. By this time, despite Copernicus's isolation, word of his astronomical work had spread in the German-speaking world, and even as far as Rome, and Rheticus's curiosity had been aroused. Copernicus allowed Rheticus to summarize his treatise in a *Narratio Prima*, or *First Account*, which appeared in 1540. By then the elderly canon was revising his work for publication, while Petreius had indicated a strong interest in being the publisher.

In October 1541 Rheticus returned to Wittenberg to resume his teaching, and he either took Copernicus's manuscript with him or had it sent to him soon thereafter. In May 1542 Rheticus was able to deliver the fair copy to Petreius, and in the coming months he corrected the proofs, until he was appointed to a post at Leipzig. The task of seeing the book through the press then passed to a Lutheran clergyman, ANDREAS OSIANDER, who took it upon himself to forestall criticism of Copernicus by adding an unsigned preface to say that the motion of the Earth was not being proposed as a truth of nature but merely for purposes of calculation. Rheticus was involved in an attempt to persuade the Nuremberg town council to compel Petreius to issue a corrected edition in which Copernicus's true position on the question was clearly stated, but this failed, and the misleading preface was taken to be the author's until KEPLER revealed Osiander's role after the turn of the century.

Late in 1542, Copernicus suffered a cerebral hemorrhage and paralysis of his right side, but he lingered on until 24 May of the following year. We are told he received the final pages of *De Revolutionibus* on the day of his death; but if so, he would hardly have been aware of it.

For the remainder of the century Copernicus's treatise was mined by mathematical astronomers for the ingenuity of its planetary models. Not until 1596 did Kepler publish an unabashedly heliocentric cosmology, and not until 1610 did GALILEO's telescopic observations lead him to embark on a reform of physics that would make it possible for Earth-dwellers to accept the notion that they inhabited a spinning, orbiting planet without feeling any sensation of movement.

Nicolaus Copernicus Astronomical Center

Nicolaus Copernicus Astronomical Center is the largest astronomical institution in Poland, located in Warsaw and founded in 1956. At present it is a government-funded research institute supervised by the Polish Academy of Sciences and licensed by the government of Poland to award PhD and doctor habilitatus degrees in astronomy and astrophysics. In September 1999 staff included 21 senior scientists with permanent or tenure-track positions; 13 post-doctorates; 16 PhD students. The main research fields are theory and observations of binary stars; stellar structure and pulsations; stellar atmospheres and circumstellar matter; cosmology and large-scale structure of the universe.

A PhD program in astronomy and astrophysics is taught and there is international cooperation with various observational projects: Integral (a gamma-ray telescope to be launched in 2001); SALT (South-African Large Telescope) and WET (Whole Earth Telescope); French–Polish program Jumelage (collaboration in theoretical astrophysics). Main achievements are the structure of and mechanisms operating in cataclysmic binaries; evolution of single and binary stars; theory of thick accretion disks; helioseismological models of the Sun's interior; limits on the equation of state of neutron stars; Compton reflection in AGNs.

Nitrogen (N)

The element that is the principal constituent of the Earth's atmosphere (making up, at ground level, 78.08% by volume). By number of atoms, it is the fifth most abundant element in the universe (by mass, it is seventh). The chemical symbol for nitrogen is N, and its normal molecular form, N_2 (i.e. a molecule made up of two nitrogen atoms). Its atomic mass is most commonly 14 and its atomic number is 7. Although nitrogen makes up the major part of the Earth's atmosphere, it comprises only 3.5% of the atmosphere of Venus and 2.7% of the atmosphere of Mars.

See also: cosmic abundance of elements.

Nobel Prize Winners in Astronomy

One of the greatest honours which can be bestowed upon any human being is the Nobel Prize. It is named after Alfred Nobel, a Swedish physicist who was particularly noted for his work on explosives. Nobel was born in 1833, and had a long and successful career, so that, when he died, on 10 December 1896, he left a large sum of money. This was to be put into a trust to establish an annual prize to those who, in the preceding year, shall have conferred the greatest benefit on mankind; there were to be prizes for physics, chemistry, physiology or medicine, literature and peace. Note that there was to be no specific Nobel prize for astronomy, but it is impossible to separate astronomy from any other branch of science, and several Nobel laureates have earned their prizes for work which is mainly astronomical.

The decisions are made by four institutions, three Swedish and one Norwegian; the prize involves a gold medal, a diploma and a sum of money.

The first prizes were awarded in 1901, five years after Alfred Nobel's death. An early laureate was SVANTE AUGUST ARRHENIUS, a Swedish chemist (1859–1927). The citation read that he received the prize 'in recognition of the extraordinary services he has rendered to the advancement of chemistry by his electrolytic theory of dissociation', but he was also very much concerned with astronomy; he studied cosmic physics, and was particularly concerned with radiation pressure on comet tails. He also put forward the 'panspermia' theory, according to which life on Earth did not originate here, but was brought to our world by a meteorite. The theory never gained wide acceptance, and neither has a much more modern theory, due to Sir Fred Hoyle and Chandra Wickramasinghe, that life was brought here via comets. However, it caused a great deal of discussion, and in his own field Arrhenius certainly deserved the Nobel Prize.

In 1907 the Physics Prize went to ALBERT A MICHELSON (1852–1931), German by birth but who spent most of his career in America. He was awarded the prize for his work on designing optical instruments and carrying out experiments with them. He is best remembered for his part in the Michelson–Morley experiment, in which it was demonstrated that the velocity of light is constant and is independent of the Earth's motion in space—a result which finally disproved the existence of the hypothetical 'aether', a medium which was supposed to permeate all space. He also designed an interferometer, which was used with the Mount Wilson 100 in reflector to make the first direct measurements of the angular diameters of some nearby giant stars such as Betelgeuse.

Obviously we cannot forget ALBERT EINSTEIN (1879–1955), widely and justifiably regarded as the world's greatest mathematician since Newton. In 1905, while still working at the Patent Office at Berne in Switzerland, he published three theoretical papers—and in retrospect any one of these was good enough to earn a Nobel Prize. In 1915 he produced his general theory of relativity, on which all subsequent work has been based. He was finally awarded the Nobel Prize for Physics in 1921.

It seems strange that Einstein had to wait several years for this recognition, but an even longer delay was experienced by the two American physicists ARNO PENZIAS (1933–) and ROBERT WOODROW WILSON (1936–), who shared the 1978 Physics Prize with the Russian, Peter Kapitsa. The story here goes back for more than a dozen years.

It began with some theoretical work in the United States by R H DICKE, who was investigating the very early stages of the universe. According to the 'big bang' theory, the universe as we know it came into existence around 12 000 million years ago; space, time and matter were created simultaneously. (One cannot ask what happened before the big bang, because if time started at this moment there was no 'before'.)[1] The temperature at this moment was of the order of 10^{32} K, but cooling was rapid, and 3 min after the big bang the temperature was down to a few thousand million kelvins. By now, according to Dicke's calculations, the overall temperature of the universe should have fallen to 3 K—that is to say, 3 degrees above absolute zero, the coldest temperature that there can possibly be ($-273\,^{\circ}$C). In this case, a background radiation should be detectable at radio wavelengths.

Meanwhile, Arno Penzias and Robert Wilson had been carrying out work with a specially built radio telescope, not to search for any background radiation but for quite different reasons. They found a steady, persistent signal coming from all directions and could not explain it; for a time they even put it down to pigeon droppings in the antenna of their radio telescope. When Dicke learned about this, it took very little time to establish that what Penzias and Wilson had found was in fact the expected radiation—the last remnant of the big bang. There can be little doubt that this was one of the most important cosmological discoveries of the 20th century, and it finally disposed of the steady-state or continuous creation theory, according to which the universe has always existed and will exist for ever.

The Austrian physicist VICTOR FRANZ HESS (1883–1964) shared the 1936 Physics Prize with CARL D ANDERSON. Hess' main contribution to science was his discovery of cosmic rays, in 1911–1912. He was then at the university of Vienna, specializing in studies of the upper atmosphere, and he made ten balloon ascents, establishing for the first time that cosmic rays are bombarding the Earth from all directions all the time (in fact the name is misleading; cosmic rays are not rays at all, but atomic particles). In modern times many cosmic ray satellites have been launched, and cosmic ray astronomy has become of immense importance, but it all dates back to the balloon ascents made by Hess.

Another early investigator of cosmic rays was Arthur Holly Compton (1892–1962), professor of physics at the University of Chicago. He discovered what is now known as the Compton effect—the interaction between

[1] The term 'big bang' was scornfully introduced much later by Sir Fred Hoyle, who does not believe in the theory.

a photon and a charged particle, so that the photon is scattered with lower energy and the particle is given extra energy. Compton shared the 1927 Nobel Physics Prize with Charles Wilson. The important Gamma-Ray Observatory satellite (GRO), launched on 5 April 1991, was named the Compton Observatory in his honor.

Several physics laureates have carried out work which is of vital importance in astronomy as well as in other branches of science, for example Professor Patrick Blackett (1948), Sir John Cockcroft and Ernest Walton (1951) and Pavel Čerenkov (1958). In the field of what may be called pure astronomy, we must note HANS BETHE (1906–). For many years the source of stellar energy was not known; initially it was thought that a star shone because it was slowly contracting, and then came a theory that atomic particles were simply annihilating each other with the release of energy. The key to the whole problem was found by Bethe in 1939—it is said that he actually worked it out during a train journey between Washington and Cornell University. The essential 'fuel' of a normal star is hydrogen. Deep inside the star, where the temperatures are very high and the pressures are immense, nuclei of hydrogen are combining to form nuclei of helium; it takes four hydrogen nuclei to make one nucleus of helium, and in the process a little energy is set free and a little mass is lost. (In the case of the Sun, the mass loss amounts to 4 000 000 tons s^{-1}; fortunately there is plenty of material left.) The process is not straightforward, and Bethe worked out a whole series of reactions on which future investigations have been based. His Nobel Prize for Physics did not come until 1967, a lapse of over a quarter of a century, so that one can hardly accuse the Nobel Committees of being over-hasty. (It is only fair to add that similar work was carried out at around the same time by GEORGE GAMOW.)

Two more pioneers in studies of stellar evolution shared the Nobel Physics Prize in 1983; the Indian astrophysicist SUBRAHMANYAN CHANDRASEKHAR (1910–1995) and WILLIAM A FOWLER (1911–1995). At one stage Chandrasekhar came into conflict of ideas with SIR ARTHUR EDDINGTON, the great British astrophysicist. A star such as the Sun will end its main career by collapsing into the white dwarf condition—that is to say it will become very small and very dense, as the companion of Sirius is at present. Chandrasekhar calculated that if the mass of the star is more than 1.4 times that of the Sun, a white dwarf cannot be formed, and the whole evolutionary sequence will be different. Eddington disagreed, but it is now known that Chandrasekhar was right, and the value of 1.4 times the mass of the Sun is still known as the Chandrasekhar limit.

In 1967 a team of radio astronomers at Cambridge University (England), led by Professor A HEWISH, was carrying out a sky survey with a special form of radio telescope which, it was said, looked rather like a collection of barbers' poles. One member of the team was a graduate student, JOCELYN BELL (now Professor Jocelyn Bell Burnell). Examining the records, she found a weak radio source which was fluctuating so quickly and so regularly that it seemed to be 'ticking'. For a while it disappeared, but then returned. At first it was regarded with scepticism and was dismissed either as instrumental fault or terrestrial interference, but eventually it was found to be real, and it had to be explained. It was even suggested that it might be an artificial transmission from an alien civilization far out in the Galaxy—and this was treated so seriously that no official announcement of the discovery was made until the LGM or little green men theory had been discounted. It is now known that the object was a rapidly rotating neutron star. As it spins, it sends out pulses of radio energy and is therefore known as a pulsar. Pulsars are now known to be very common, and a few have been optically identified; for example the Crab Nebula, known to be the remnant of the supernova seen in 1054, contains a pulsar which is seen optically as a very faint, flashing object.

In 1974 Hewish, leader of the team, shared the Nobel Prize for Physics with another outstanding radio astronomer, SIR MARTIN RYLE (who was also Astronomer Royal). That Hewish and Ryle deserved the prize is not in doubt, although it was also suggested that recognition should also have been given to Jocelyn Bell as the actual discoverer of the first pulsar.

Pulsars were again to the fore in 1993, when the Nobel Prize for Physics went jointly to RUSSELL HULSE and JOSEPH TAYLOR, of Princeton University, for their discovery of binary pulsars. In a system of this sort there are two pulsars, separated by a distance of only a few million miles. Each component is around 6 miles in diameter, but is as massive as the Sun, and they are so close that their movements can give valuable clues as to the nature of gravitation, attributed by Einstein to the curvature of space–time close to very massive bodies.

These are only a few of the Nobel laureates who have made outstanding contributions to astronomy. Yet there are also some notable omissions, and of these two are particularly curious. EDWIN HUBBLE, the American astronomer who was the first to prove that the so-called 'spiral nebulae' are outer galaxies, and who was also the first to show that the universe is expanding, never received a Nobel Prize; the Hubble Space Telescope is, of course, named after him. Neither did Sir BERNARD LOVELL, who masterminded the 250 foot radio telescope at Jodrell Bank in Cheshire (England). One could also advance the claims of Sir Arthur Eddington, HARLOW SHAPLEY (who made the first good measurements of the size of the Galaxy), GEORGE ELLERY HALE (who was responsible for the world's first really large reflecting telescopes) and the first radio astronomer, KARL JANSKY. Like the 20th century Nobel laureates, they will not be forgotten.

Nobeyama Radio Observatory

Nobeyama Radio Observatory has telescopes at millimeter and submillimeter wavelengths. It was established in 1982 as an observatory of Tokyo Astronomical Observatory (NATIONAL ASTRONOMICAL OBSERVATORY, JAPAN since 1987), and operates the 45 m telescope, Nobeyama Millimeter Array, and Radioheliograph. High-resolution images of star forming regions and molecular clouds have revealed many aspects of first stages of stellar evolution, chemical evolution of molecular clouds, and galaxy evolution. Activities of very long baseline interferometry (VLBI) made it possible to realize the first space VLBI mission VSOP, and discover one of the most reliable black hole candidates in NGC 4258.

Node

Either of the points at which an orbit intersects a reference plane. On the celestial sphere, a node is either of the points at which the great circle representing the orbital plane intersects the great circle corresponding to the reference plane (usually the ecliptic or the celestial equator). In the context of planetary motion, the reference plane is the ecliptic. The point at which the orbiting body crosses the reference plane from south to north is called the ascending node, and the point at which it crosses from north to south, the descending node. The line joining the two nodes, which is the line of intersection between the orbital plane and the reference plane, is called the line of nodes.

In the case of the Moon, the gravitational influence of the Sun causes the line of nodes to rotate slowly around the Earth in a westerly direction, this motion being called the regression of the line of nodes. The line of the nodes of the lunar orbit makes one complete circuit of the Earth in 18.61 years.

Non-gravitational Force

A force which is not gravitational in origin that acts on a celestial body to alter its orbit. The term is used in connection with comets, in which the outgassing of volatile material through vents leading to the surface of the nucleus can give rise to jets. Strong jets can behave as rockets and alter comets' orbits, in much the same way as the gravitational perturbations to which they are also susceptible. Such non-gravitational forces are believed to have changed the orbit of Comet 109P/Swift–Tuttle, which was calculated on its observation in 1862 to have a period of 120 years, but did not return until 1992. The Poynting–Robertson effect may also be regarded as a non-gravitational force.

Non-radial Stellar Pulsations

Non-radial STELLAR PULSATIONS are complex, non-radially (non-spherically) symmetric pulsations of a star in which part of the stellar surface moves outward (expands) while other parts of the stellar surface move inward (contract). Therefore, differential changes (displacements) in state variables (e.g., pressure, temperature) would follow the expansion and compression of different regions and would have positive values in some areas and negative values in others. There exists a wave equation for non-radial oscillations, just as in radial oscillations. Moreover, the angular variation of solutions is represented in terms of spherical harmonics as is the case with other important physical equations, e.g., the Schrödinger equation, Laplace's equation and others. The non-radial patterns are characterized by two integers, l and m, and correspond to the real parts of the spherical harmonic functions, $Y_l^m(\theta, \phi)$, where l is a non-negative integer, m is equal to any of the $2l + 1$ integers between $-l$ and l, and θ and ϕ are the polar and azimuthal angles, respectively. The spherical harmonics are defined as

$$Y_l^m(\theta, \phi) = (-1)^m \left(\frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!} \right)^{1/2} P_l^m(\cos\theta)\, \mathrm{e}^{\mathrm{i}m\phi}. \quad (1)$$

Thus, the patterns can be described by l nodal circles, where the radial displacement $(\delta r) = 0$, with $|m|$ of these circles passing through the poles of the star and the remainder parallel to the star's equator. For $l = m = 0$, the pulsation is purely radial.

Since physical information is propagated with the velocity of small amplitude (sound) waves, non-radial pulsations correspond to sound waves travelling horizontally as well as radially, producing waves that travel around the star. Since pressure provides the restoring force for sound waves, then pulsations of this type are known as *p-modes*. The p-modes, as with radial modes of pulsation, undergo most of their motion near the stellar surface. The non-radial p-modes have their largest relative displacements, $\delta r/R$, in the outer envelope of a star.

The other major class of non-radial stellar pulsations are the *g-modes* or gravity modes. Here, gravity is the source of the restoring force for these modes, which are produced by internal gravity waves. These oscillations are intimately related to the buoyancy of the stellar gas since they involve small blobs of material exhibiting small pressure and density variations and are largely transverse in their physical dsplacement. Accordingly, g-modes can be understood by considering the displacement of a gas bubble from its equilibrium position upward by an amount $\mathrm{d}r$. If the motion occurs sufficiently slowly that its pressure remains the same as the ambient pressure and if its motion is adiabatic (no heat exchange with the surrounding gas), then the net restoring force per unit volume is

$$f_{\mathrm{vol}} = \left(\frac{1}{\rho} \frac{\mathrm{d}\rho}{\mathrm{d}r} - \frac{1}{\gamma P} \right) \rho g \, \mathrm{d}r \quad (2)$$

where P is the pressure, ρ is the gas density, γ is the ratio of specific heats, g is the gravitational acceleration (GM_r/r^2) and $\mathrm{d}r$ is the displacement.

If the quantity in the parentheses in (2) is positive, then the gas is unstable toward convection. The bubble will continue to rise. If the quantity in parentheses is negative, then the bubble will sink back toward its equilibrium position. The restoring force is proportional to the displacement and the bubble will execute oscillations about its equilibrium position in the form of simple harmonic motion. The force per unit mass or acceleration is given by

$$\frac{f_{\mathrm{vol}}}{\rho} = -N^2 \mathrm{d}r = \left(\frac{1}{\rho} \frac{\mathrm{d}\rho}{\mathrm{d}r} - \frac{1}{\gamma P} \right) g \, \mathrm{d}r \quad (3)$$

where N is the angular frequency of the bubble about its equilibrium position and is called the Brunt–Väisälä frequency:

$$N = \sqrt{\left(\frac{1}{\gamma P} - \frac{1}{\rho} \frac{\mathrm{d}\rho}{\mathrm{d}r} \right) g} \quad (4)$$

The frequency of a g-mode is determined by the average value of N in the regions of the star where the oscillations are most energetic.

The g-modes involve significant movement of the gas in the deep interior of the star whereas the p-modes have their greatest motion near the stellar surface. The use of these modes as probes of the STELLAR INTERIOR and surface layers underlies stellar seismology.

Nordic Optical Telescope

The Nordic Optical Telescope (NOT) is a 2.56 m, (Super) Ritchey–Chrétien, altitude-azimuth telescope with an actively controlled primary mirror sited at 2400 m on the Roque de Los Muchachos, La Palma, Canary Islands, Spain. It was built by Denmark, Finland, Norway and Sweden, achieving first light in 1988. Iceland joined the association in 1997. Its twelve on-site astronomers, students and technical staff use and maintain the telescope, develop new instrumentation, and provide support to visiting astronomers. Core instruments on the Cassegrain-only telescope are a high-resolution imager (HiRAC) and a faint-object spectrographic camera (ALFOSC), a photopolarimeter (TurPol) and a high-resolution spectrograph (SOFIN). An infrared spectrographic camera (NOTCam) will be commissioned in 2000.

Norma

(the Level; abbrev. Nor, gen. Normae; area 165 sq. deg.) A southern constellation which lies in the Milky Way between Lupus and Ara, and culminates at midnight in mid-May. It was named Norma et Regula (the Level and Square) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2. The shortened form was adopted by the IAU in 1922.

A small, inconspicuous constellation, the brightest star in Norma is γ^2 Normae, magnitude 4.0, which forms a naked-eye double with γ^1 Normae, magnitude 5.0. Other interesting objects include ε Normae, a wide binary with components of magnitudes 4.8 and 7.5, separation 23″, the Mira-type stars T Normae (range 6.2–13.6, period about 241 days) and R Normae (range 6.5–13.9, period about 507 days), NGC 6067, an open cluster of more than 100 stars fainter than eighth magnitude, NGC 6087, another open cluster, which contains about 40 stars between sixth and tenth magnitude (including the Cepheid variable S Normae, range 6.12–6.77, period 9.75 days), and NGC 5946, a tenth-magnitude globular cluster.

North America Nebula (NGC 7000)

An emission nebula in the constellation Cygnus, position RA $20^{h}\ 58.8^{m}$, dec. $+44^{\circ}\ 20'$. It is large, measuring $120'$ by $100'$. In outline it bears a strong resemblance to the North American continent, delineated by surrounding dark nebulae, including one known appropriately as the Gulf of Mexico. NGC 7000's main source of illumination is believed to be the hot blue star HR 8023. The adjacent Pelican Nebula is part of the same nebulosity.

North American Indian Astronomy

As one distinguished astronomer observed more than 20 years ago, North American Indian astronomy seems to hold a particular fascination for the North American audience 'who now occupies the land once held by a race of people so long regarded as distant noble savages' (Aveni 1980, p294). This interest has been both sustained and expanded on in the last decade or so, particularly in the case of those indigenous people who, in historic times (*c*.1600–1900), occupied the very heartland of North America — the Plains Indians.

This is a land of sun, wind and vast grasslands, stretching from north to south more than 3000 km from the Saskatchewan River in Canada almost to the Rio Grande in Mexico. The western and eastern boundaries are approximately those of the foothills of the Rocky Mountains and the Mississippi–Missouri valleys. In all, the region encompasses an area of some 2.5 million km^2.

During the 18th and 19th centuries, when contact was first made with the white man, the Great Plains were largely dominated by Siouan and Algonquian linguistic groups although others, such as Uto-Aztecan and Athapaskan, were also represented. In the northern part of the region (now Alberta, Saskatchewan and Montana) lived such tribes as the Blackfeet, Cree, Plains Ojibwa and Gros Ventre; to their south (present-day Wyoming, southern Montana and the Dakotas) were the Sioux, Cheyenne, Crow, Mandan, Hidatsa and Arikara; the Southern Plains (present-day Texas, Nebraska and Oklahoma) were occupied by the Comanche, Kiowa, Wichita and Pawnee. Most of these tribes had migrated into the region after the introduction of the horse by the Spaniards in the southwest and of the gun by the English and French in the northeast — a gradual process which started in about 1650. It brought together peoples of great diversity of background and history — not least the way their ancestors incorporated astronomical knowledge into their culture.

There is considerable evidence which suggests that many tribal groups who occupied the various cultural areas of North America (it is convenient to consider nine cultural areas in North America, north of Mexico; see Sturtevant and Taylor 1991) and led largely sedentary lifestyles did accurate timing relating to planting and harvesting by observation of the regular celestial events. Hunters and gatherers, however — and this would include the Plains Indians — put more emphasis on use of the changing sky largely to order ritual and religious activities.

Other phenomena, such as comets, solar and lunar eclipses, meteor showers as well as terrestrial events — the thunder and lightning in particular — were not infrequently incorporated in religious and ceremonial activities. Symbols of such phenomena also adorned artefacts of various kinds.

The North American Indians, however, viewed the canopy of complex stellar patterns which nightly unfolded above them (in an ever changing but largely cyclic pattern) somewhat differently to the professional astronomer. Sophisticated reflective, refractive and radio instrumentation tends to sample but relatively small regions of the sky. In contrast, naked eye astronomy, as practiced by American Indians, led to the idea of constructing accurate calendars or patterns which could give order to planting and harvesting, hunting, ceremonial, ritual and religion.

A common form of religious activities throughout the Americas — and indeed a theme common to all humanity — was annual renewal ceremonials. Many were complex, lasting for several days, even weeks. There is considerable evidence that astronomical phenomena played an important role in many of them.

For example, scholars who have documented the lifeways of the Mahicans (these are probably the Mohicans of James Fenimore Cooper; they were an Algonquian-speaking group who, in ancient times, occupied the Hudson River Valley of present-day Vermont) recorded that they traditionally enacted a complex world renewal ceremonial which commenced at signals from the sky. The changing sky patterns associated with the constellation Ursa Major was viewed as an annual celestial bear hunt. Four of the stars defined the body of the bear while three stars that form the handle of the Dipper represented waiting hunters, the star Alcor being their dog. This 'cosmic bear' was observed to revolve around the North Star and then, in spring, seen to leave his den — the Corona Borealis. It was now followed by seven stars representing hunters, the original three being joined by stars from Boötes and Arcturus. Throughout the summer, this bear was trailed and then finally slain in the autumn. The seasonal reddening of the forest foliage was attributed to this sky hunt, the red tinting due to that of the slain bear, and the mantle of early winter snow was some of the bear's grease, tried out by the star hunters.

The ceremonials were held at night within a special structure — the Big House, *Xwate'k'an*, which itself was replete in sky symbolism. Thus, the constellation Ursa Major was represented on the floor of the house. The furnishings and positions of officials corresponded to the positions of the stars in the constellation, while the movements and acts of the performers paralleled those of the stars. In turn, the *Xwate'k'an* was said to represent the universe. This renewal ceremonial commenced again the following spring when bear once more emerged from his celestial den.

Further west, in what is now present-day Nebraska, the Pawnee — particularly one branch of the tribe known as the *Skidi* — were much governed by the panorama of the changing sky. When the villages of the various Pawnee bands assembled for annual ceremonials, they arranged themselves according to the place of their stars in the sky and nothing on Earth could move without evoking the power of the heavens. The whole 'Spring

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

Awakening' could not be undertaken without reference to the position of the stars to guide the time relating to the commencement of the appropriate ceremonials. The earth lodge itself acted as a type of astronomical observatory, the priests viewing the sky through both the smoke hole and the oriented entrance way.

Astronomical and cyclic patterns were documented and understood by the tribal intellectuals and woven into mythology, religion and ceremonial. Thus, Morning Star, *Opirikus* — almost certainly Mars — was viewed as the leader of men who travelled with his brother, the Sun, to the land of the western stars in an attempt to overcome the power of the Moon. Credited with helping the creation of the universe and the fathering of the human race, Morning Star utilizes the power of sacred bundles (housed within the ceremonial lodges) to overcome the obstacles which Moon puts in his way and is thus able to enter the woman-star village. This aspect of Pawnee mythology was clearly based on accurate and detailed observations of the sky.

Such mythology and religious concepts, however, led to one sinister ritual. Because of his favours to mankind, and particularly to the Pawnee themselves, *Opirikus* demanded human sacrifice — the Morning Star Ceremonial. Tribal priests stated that the sacrifice not only ensured continued abundant crops and game but also, perhaps more than anything, was an acknowledgement of a celestial heritage and essential to the well-being of the tribe — although not all agreed.

While the record relating to the sky watchers' craft is far less complete for tribes north of Mexico, much significant evidence is scattered within the historical and anthropological literature. Here, there are references made by North American Indians to the nature of gravitational forces and the Milky Way, to meteor showers, eclipses of the Sun and Moon and the images of the lunar landscape. Star groups, such as the Great Bear and Pleiades, the diurnal motion of stars across the sky and the heliacal rising of such stars as Aldebaren and Sirius figured as calendrical markers for ceremonial.

Some tribes, such as the Pawnee and Lakota, did star maps as well as recognizing certain geographical features as a mirror of the sky. Others used stone alignments as markers to identify the directions of set or rise of certain celestial bodies; all this, and almost certainly much more.

As such data are drawn together and analysed, they will surely demonstrate that astronomical phenomena were, not surprisingly, an important component of the indigenous Americans' culture. (This is partly based on Taylor (2000 and 2001, in press). I am indebted to both Paul Murdin and Patrick Moore for their encouragement for me to give consideration of the astronomical knowledge of the North American Indian, in the course of my researches in American ethnology.)

Nostradamus (1503–66)

Doctor, astrologer, born in St Rémy, France. Took on the role of a prophet and wrote *Centuries*, a collection of predictions in rhyme (1555–8). The predictions are expressed in obscure and enigmatic terms, which are both difficult to interpret and open to many interpretations, and so can be interpreted as successful prophesies, including what Catherine of Medici interpreted as the manner of death in a jousting tournament of her husband King Henry II. At the royal court in France, this brought their author a fame that continues today as notoriety.

Nova V1974 Cygni

A NOVA outburst is the second most violent explosion that can occur in a galaxy. It is exceeded in violence only by a SUPERNOVA explosion, but a nova occurs much more frequently so that astronomers expect a bright naked eye nova to appear in our skies every few years. In a day or two a nova can go from an intrinsic brightness much fainter than that of the Sun to more than 10 000 times that of the Sun. At the same time it is ejecting an amount of gas that exceeds the mass of the Earth at speeds of up to 5000 km s^{-1}. The gas ejected into space by the nova explosion will then mix with other gas in the interstellar medium (ISM) and eventually become part of a new solar system. There is evidence that our own solar system contains material that was once ejected in a nova explosion.

Evolution at ultraviolet wavelengths

V1974 Cygni was first seen as a naked eye star on the morning of 19 February 1992 and rapidly climbed to a peak brightness of about 4th magnitude. Because of its brightness, it was studied by more telescopes at more wavelengths than any nova before or since. The first spectra were obtained in the ultraviolet with the INTERNATIONAL ULTRAVIOLET EXPLORER satellite (IUE). They covered the wavelength range from 1150–3300 Å. They were unlike any previous IUE nova spectra obtained early in the outburst. While energy was being emitted throughout the ultraviolet, there was an increasing amount of energy at longer wavelengths. Analysis of these spectra showed that the nova had been caught in the 'fireball' phase when the hot dense material ejected by the explosion is in its first cooling phase. Because the gas was cooling, the amount of energy emitted at ultraviolet wavelengths decreased and by the second day of observations, it had dropped by a factor of 10. The rapid decline in ultraviolet light is caused by the temperature of the hot, highly ionized, expanding material dropping below 30 000 K. The ultraviolet data show that the nova had reached this temperature at the time of the first IUE observations. Below this temperature, the electrons start to recombine with the ions and form both neutral and singly ionized atoms of the iron group elements (among others) which are capable of blocking the ultraviolet light through tens of millions of individual absorption lines.

It is the gas becoming opaque in the ultraviolet which forces the radiation from the nova to emerge at optical and infrared wavelengths and then become bright in the optical. This is the time that a nova, typically, is first discovered. Luckily, V1974 Cyg was caught before maximum brightness in the optical. By the time V1974 Cyg reached maximum brightness in the optical, its temperature had declined to below 15 000 K and it was emitting most of its energy in the optical and infrared, not the ultraviolet. This phase did not last long and within a few days the optical brightness started to decline. This decline is caused by the continuing drop in density as the ejected gases expand and the outermost layers gradually become transparent. The increasing transparency allows us to see deeper into the gas, where the material is hotter, and thus the decline in optical light goes hand-in-hand with an increase in ultraviolet light. Over the next two months of IUE observations, the ultraviolet brightness of V1974 Cyg increased to the levels seen on the first spectra. This result demonstrated that the energy radiated by the underlying star had remained virtually constant during this time. This period of the nova outburst is designated as the 'constant bolometric luminosity phase' and its existence was an early prediction of the theoretical simulations of the nova outburst.

Evolution at x-ray wavelengths

Further evidence that the heat from the underlying layers was getting through the ejected material came from observations in April 1992 with ROSAT, a joint German–British–US x-ray satellite launched in 1990. The first observations showed that the nova was faint in x-rays but in a series of observations done over the next 12 months it steadily brightened. It was later realized that ROSAT had detected the underlying hot object which was gradually appearing through the expanding shell of gas ejected by the explosion. By July 1993, V1974 Cyg had become one of the brightest objects in the low-energy x-ray sky. It was emitting nearly as much energy in x-rays as it had in the optical and ultraviolet a year earlier in the outburst. The ROSAT observations thus provided important new data on the constant bolometric luminosity phase of the outburst. It then began to fade rapidly and by December 1993 it had become too faint to observe with ROSAT.

Observations with the Hubble Space Telescope

V1974 Cyg was also observed a number of times with various instruments on the HUBBLE SPACE TELESCOPE (HST). Analyses of the first HST observations showed that the nova had not ejected material in a smooth uniform sphere but rather that the expanding gas had formed a large number of dense knots inside a lower density, more rapidly expanding gas. The ejected gas was distributed in a non-spherical hollow shell with a thickness of order 30–50% of the outer radius. In a second set of observations, it was found that the same knots were still visible and were moving at approximately the same speeds as when first seen seven months earlier. However, the fast moving, low density, material had largely vanished. This means that the HST observations were now seeing completely *through* the ejected gas. As the gaseous debris from the explosion expanded, it thinned and continued to clear so that it became possible to see completely through it to the underlying object on which the explosion took place. It then became possible to study the structure of this object and determine the cause of the explosion.

Cause of the nova outburst

Studies of V1974 Cyg after the explosion showed that it has the same structure as all other novae and the entire class of stars designated 'cataclysmic variables.' More than 40

years ago it was demonstrated that novae are CLOSE BINARY STAR systems with one component a white dwarf and the other component a larger, cooler star. The two stars have orbital periods of a few hours, about 2 h for V1974 Cyg, so that tidal forces of the WHITE DWARF are sufficient to cause material to be stripped off the larger star. Because the binary is rotating rapidly, the gas forced off the cooler star forms a torus of gas around the white dwarf called an ACCRETION DISK. The gas slowly spirals through the accretion disk and ultimately falls onto the surface of the white dwarf. Over many thousands of years the gas flowing from the companion, through the accretion disk, lands on the white dwarf star where it is compressed and heated by the continuous accretion of more and more material. It is the gradually thickening layer of accreted gas on the surface of the white dwarf that provides the fuel for the explosion. It was also realized later that the accreted material must be mixed with the core material of the white dwarf since such gas is observed in the ejected gas.

The detailed calculations of the consequences of this accretion plus mixing process show that, if sufficient material falls onto the white dwarf, then compressional heating alone can cause the temperatures in the accreted gas to reach to 10^7 K or higher. At this temperature, hydrogen nuclear fusion reactions begin in this material and, because fusion is occurring on a white dwarf, the reactions quickly increase to high temperatures, just as in a terrestrial hydrogen bomb. This type of explosion is called a *thermonuclear runaway* (TNR). The white dwarf must accrete about 100 times the mass of the Earth before the temperature in the newly added material can grow to the temperatures required for initiating the TNR. By this time, the density in this layer will exceed 10 000 g cm^{-1}. Under these conditions the hydrogen nuclei fuse into helium and release energy via the carbon, nitrogen and oxygen (CNO) cycle.

Since carbon and oxygen are catalysts in the CNO cycle, the higher the percentage of carbon or oxygen in the nuclear fusion region, the greater the energy production and the greater the ultimate violence of the explosion. Since the accreted layers mix with the core material of the white dwarf, which is mostly carbon and oxygen, a violent explosion is guaranteed. One concern was that the heat from the nuclear fusion should cause the outer layers to expand and cool and prevent an explosion from occurring. That this does not happen was explained by numerical calculations which showed that the gas at the bottom of the accreted layers had become degenerate.

A degenerate gas is so dense that the pressure comes from the inability of electrons to interpenetrate each other and, unlike an ordinary gas, the temperature does not play much of a role in determining the pressure. The gas can still become hot, but it cannot expand as one would expect if the gas were normal. It is also known that the speed at which the CNO nuclear reactions occurs depends on the temperature to a very high power (between 16 and 18). Thus, even a small increase in temperature can cause a tremendous increase in the speed of the reactions between the hydrogen nuclei and the CNO nuclei. This increase in speed of the reactions acts to release heat even more rapidly into the gas. As long as the region where nuclear fusion is occurring does not expand and cool, the rate of energy release must rise. This is a vicious cycle; as the temperature increases, the rate of energy release into the layers also increases, which in turn causes a rise in temperature and more energy to be produced.

Something new happens when the temperature in the nuclear fusion region grows to values above 30×10^6 K. Nuclear energy is being produced so rapidly that the rate of energy transport by radiation is insufficient to carry the heat away from the region of peak nuclear fusion deep in the accreted layers. Even though the material is degenerate it can still become buoyant and it starts to mix with the zones above it. This is called convection. As the temperature grows from the continuous release of nuclear energy deep within the accreted layers, the newly formed convective region grows toward the surface carrying both heat and the products of the nuclear fusion reactions. Since the accreted material mixes with core material at some timeduring the explosion, convection then mixes core material to the surface. Thus, one of the predictions was that, when these layers were blown into space by the explosion, they would carry both white dwarf core gas and the nuclear reaction products along with the accreted layers. This prediction could be tested since once the ejected material became sufficiently dispersed, it would be possible to analyse it and determine its chemical composition. If this gas actually showed that core material were present, then the analysis would tell astronomers not only what happened inside the white dwarf star during the explosion but also shed light on the prior evolution of the white dwarf. This prediction has been verified by a number of recent studies.

Production of radioactive isotopes

Other calculations predict that two important nuclear ISOTOPES were produced during the explosion on V1974 Cyg. The first is an isotope of sodium, ^{22}Na, and the second is an isotope of aluminum, ^{26}Al. Each of these is radioactive with a distinct γ-ray signature and a relatively short half-life. The importance of ^{26}Al is twofold. First, its decay product, ^{26}Mg, is found in some classes of meteorites and suggests that material has been found that has existed virtually unchanged since before the formation of the solar system. It is also thought possible that the heat produced by the decay of the aluminum isotope could be responsible for heating the asteroids and other small bodies early in the evolution of the solar system. Second, the γ-rays produced by the decay of ^{26}Al have been seen throughout the Galaxy by both the SOLAR MAXIMUM MISSION and by the COMPTON GAMMA RAY OBSERVATORY. The source of the interstellar ^{26}Al is not known, but novae are one candidate. The existence of novae that eject large amounts of aluminum has now been verified by observational studies of V1974 Cygni. Unfortunately, one can only determine the total amount of aluminum, not the isotopic abundance in the ejected

material. ^{22}Na, the other radioactive isotope produced in the explosion, should have been detected by the Compton Gamma Ray Observatory. It pointed at it in September 1993, however, but no γ-rays were detected. Since other studies have shown that the nova is at a distance of 2000–4000 ps, it may have been too far to be detected in γ-rays since theoretical studies imply that a reasonable limit to detection is about 1000 ps.

Finally, this nova has provided the most important and complete datasets ever obtained for a nova in outburst and it is still sufficiently bright that it is continuing to be observed by astronomers using both observatories in space and on the Earth.

Novae

A nova, short for *nova stella* (new star), is a star that brightens suddenly several hundred- to a million-fold, remains bright for a few days to several months and then returns to its former, low luminosity. The spectrum, too, changes considerably along with the changing luminosity. The eruption is recurrent, although for most novae the time elapsed between outbursts is thousands to tens of thousands of years, and hence only one outburst is recorded. These are often referred to as classical novae, to be distinguished from recurrent novae that erupt at intervals of tens of years, so that a number of such outbursts have been recorded for each. Nova outbursts are accompanied by mass ejection and the formation of nova shells, which slowly disperse into the interstellar medium. Although the term 'nova' refers to the VARIABLE STAR that undergoes temporary explosive eruptions, it is sometimes used to designate the outburst itself (as in the case of SUPERNOVAE). Thus terms such as prenova, post-nova, or nova progenitor are quite common.

Historical record

In ancient times, novae were classed with the guest stars, which also included supernovae, as well as COMETS, all transient objects. Early observations of such objects were made mostly in the Far East—China, Japan and Korea—where professional astronomers (astrologers, in fact) were employed by rulers to constantly watch the sky for signs of impending dangers. Meanwhile, ancient and even medieval Europe showed little interest in these temporary stars, which were in marked conflict with the dominant Aristotelian doctrine of a perfect, immutable celestial sphere. Detailed records from China go back to about 200 BC; in Korea and Japan, regular observations began around AD 800. While comets were quite early suspected and then recognized as being a separate class of objects, the distinction of novae from supernovae was made only in the 1930s, when it was realized that the two differed in maximal brightness by about 6 orders of magnitude. As novae spend most of their time in the quiescent, low-luminosity state, old novae are difficult to detect; the oldest nova that has been recovered was discovered in 1670 in the constellation Vulpecula.

By the early 1960s ample observational evidence had accumulated, mainly through the work of Robert Kraft, indicating that novae were invariably members of close binary systems (see CATACLYSMIC BINARIES: CLASSICAL AND RECURRENT NOVAE). The nova companion was found to be a low-mass main sequence star. Observations of novae after eruption, and in a few cases prior to eruption, showed them to be hot compact stars. Mass estimates, albeit scarce and uncertain, suggested that the erupting stars were WHITE DWARFS. This led to the hypothesis that the RED DWARF companion is extended enough (i.e. fills its ROCHE LOBE) to allow mass transfer to the hotter star (through the inner Lagrangian point of the binary system's gravitational field). Indeed, in some cases, a rapidly rotating region,

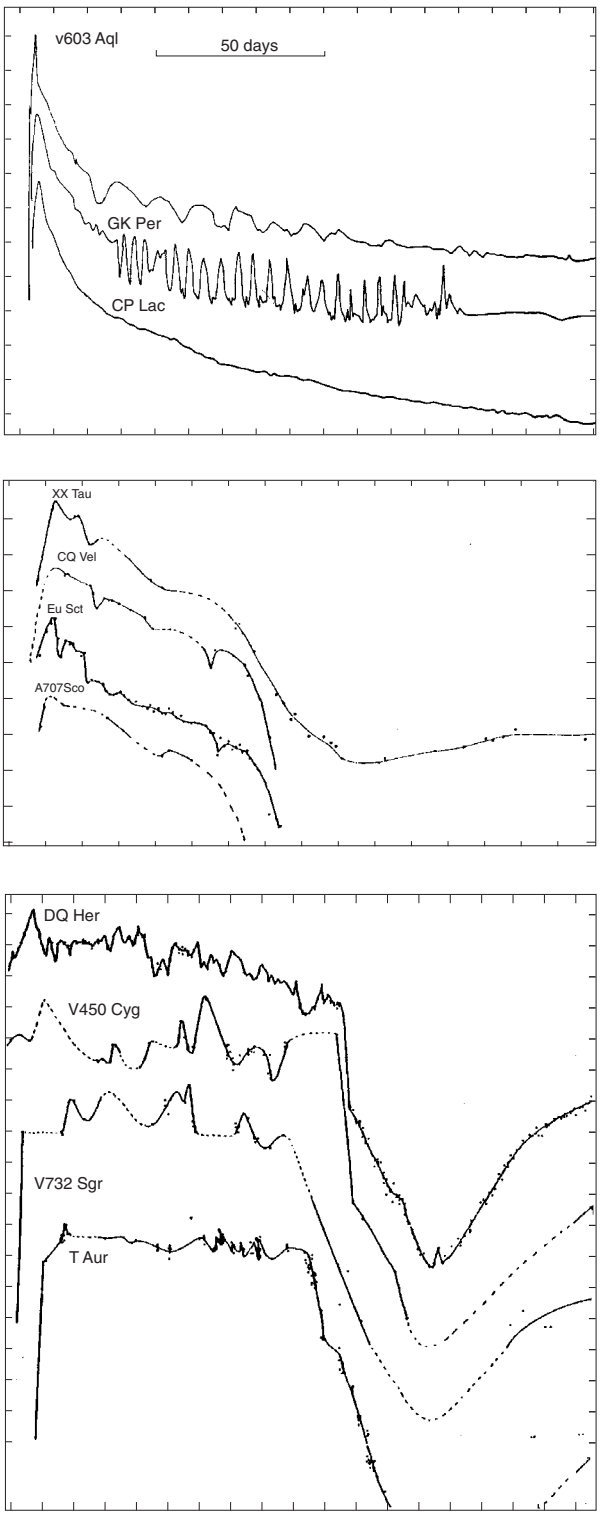

Figure 1. Light curves of (top) very fast, (middle) moderate and (bottom) slow novae. Abscissae are marked at intervals of 10 days and ordinates at intervals of 1 magnitude. (Adapted from Payne-Gaposhkin (1957).)

identified as an ACCRETION DISK, was detected around the hot star.

Thus, novae appear to be hot white dwarf members of close binary systems, which accrete matter from a cool red dwarf companion. This sets the scene for the theory that explains the outburst mechanism, its many distinctive features and its consequences.

Observations

Rate and distribution

Around the turn of the 20th century, the number of nova discoveries rose considerably, but since then it has remained fairly constant, at an average of ∼4 Galactic novae yr^{-1}. There appear to be two populations of novae: disk novae, observed in the solar neighborhood, which are brighter and evenly distributed, and bulge novae, concentrated towards the Galactic center with a larger scale height, which are fainter and have a generally slower outburst development. One should note that the bulge novae are subject to severe observational selection (interstellar extinction, etc). The true Galactic nova rate is estimated at $\sim 40 \pm 20$ yr^{-1}. For comparison, the nova population of the Large Magellanic Cloud (LMC) consists almost exclusively of disk novae, while in spiral galaxy M31 (Andromeda), mainly the novae in the pronounced bulge are observed. The established nova rate in M31 is about 30 yr^{-1}. Much lower rates are derived for M33, about 5 yr^{-1}, and for the LMC, about 2 yr^{-1}. Considering the galactic rate of nova outbursts on the one hand and the restrictive requirements for a system to undergo a nova outburst on the other, one arrives at the inevitable conclusion that nova outbursts must recur in the same system a great many times, as was realized already in the late 1930s. Most of the time, however, is spent in quiescence, while the white dwarf accretes mass from its companion.

Light curves and spectra

Early studies of novae already revealed that they varied considerably in the rate of evolution after maximum. Following Dean McLaughlin, novae are classified according to the time of decline from maximum light, usually by 3 magnitudes, denoted by t_3. Thus three—and sometimes five—speed classes are identified: very fast novae, with $t_3 \lesssim 10$ days, slow novae with $t_3 \gtrsim 100$ days and one to three intermediate classes in between. However, these are not physically distinct classes of objects, but rather convenient groupings; the variation of t_3 is continuous.

Light curves of novae belonging to different classes are shown in figure 1 and a characteristic spectral evolution is illustrated in figure 2. Several stages, distinguished by optical brightness variations and typical spectra, may be identified in the evolution of a nova outburst. Their characterization, dating back to the work of McLaughlin in the early 1940s, has remained practically unchanged to this day.

(a) The prenova stage is characterized by weak brightness variations and the spectrum of a hot star. There appears to be a small increase in (visual) luminosity 1–15 yr prior to eruption.

(b) The premaximum stage consists of a steep rise to maximum visual brightness and has a characteristic premaximum spectrum: a strong blue continuum, blueshifted absorption lines and weak or absent emission lines. The line shifts indicate lower velocities than those observed after maximum. The evolution of the blueshifted absorption line spectrum indicates an expanding and cooling photosphere. During final expansion towards maximum, the photospheric temperature declines rapidly, reaching values down to 9000–4000 K for different novae. Spectral types are B to A and sometimes F. Three successive phases are generally distinguished: the initial rise that usually lasts for a day or two, the brief premaximum halt, which in a few cases may extend to months, and the quick final rise.

(c) The maximum stage includes the early decline with the appearance of the principal spectrum, soon followed by the diffuse enhanced spectrum. The optical maximum is defined by the peak in the optical light curve. Near maximum and during early decline, nova colors are similar to those of bright supergiants. The luminosity in most novae remains constant for some time after maximum light. This is confirmed by observations in the UV, where the radiation maximum of the hot photosphere is located, and, in the presence of dust, by IR measurements of re-radiated light from dust grains that form at the outer edge of the expanding nova shell. The principal spectrum is characterized by strong P Cygni lines superimposed on a relatively cool and very strong continuum, which soon starts fading, shifting into the blue. Emission lines of hydrogen and metals in low ionization stages are strong. Their complex profiles suggest that material has been ejected in blobs, cloudlets or rings. Particle velocities deduced from the blueshifts lie in the range of a few to several hundred km s^{-1} for slow novae and around a thousand km s^{-1} for fast novae. The diffuse enhanced spectrum appears 1 or 2 days after maximum in fast novae and 1 or 2 weeks after maximum in slow ones. It is characterized by diffuse emission and absorption lines of abundant elements, such as C, N, O, Si, S and Ne. The line strengths of some elements suggest high abundances. The derived velocities are high and the large line widths indicate large velocity dispersions.

(d) The transition stage, during which the decline continues, is characterized by the Orion spectrum, line flaring and coronal lines. Magnitude measurements during this period reveal a smooth decline, or oscillations with typical timescales of the order of days or a deep decline with a possible recovery after a few weeks. The decline is attributed to the formation of dust and the light loss is due to absorption. The color

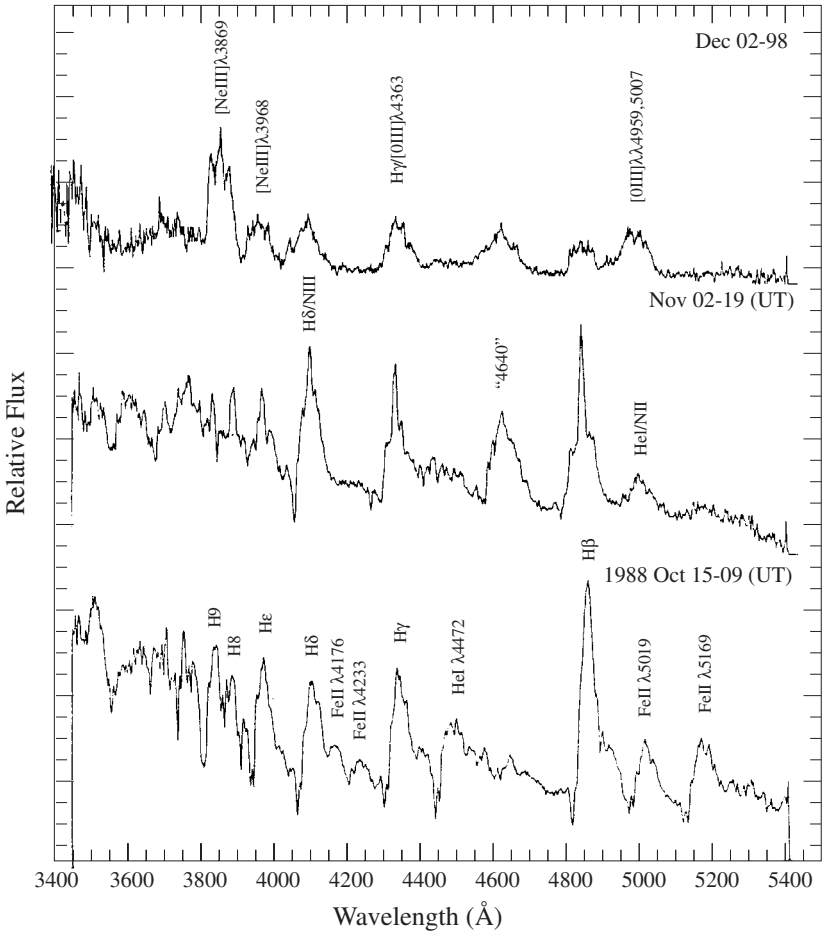

Figure 2. Illustration of the evolution of a nova spectrum (Nova LMC 1988 No 2, a very fast nova with $t_2 \approx 5$ days): (bottom) 1.34 days after maximum, showing the principal and diffuse-enhanced spectrum; (middle) 19.44 days after maximum—a typical Orion spectrum; (top) 50.23 days after maximum, showing an early nebular spectrum. The ordinate is an arbitrarily normalized flux. (From Sekiguchi K, Kilkenny D, Winkler H and Doyle J G 1989 *Mon. Not. R. Astron. Soc.* **241** 827.)

effects of dust absorption are complex and require different particle sizes at different times. As the expanding shell grows optically thin, the photosphere recedes towards deeper and hotter regions. Velocities derived from the broad spectral lines are even higher than before. An even stronger sign for a thinning atmosphere is the advent of forbidden lines. Infrared spectra of some novae at this stage are dominated by strong coronal lines.

(e) The nebular stage that follows is characterized by forbidden lines. The nova has now become fainter by several magnitudes. The photosphere is small and radiates mainly in the UV and x spectral ranges. The nebula that has formed around the nova is clumpy; its mass is estimated to be of order $(10^{-5}$–$10^{-4})M_{\odot}$.

(f) The post-nova or quiescence stage is reached when the nova returns to its pre-outburst appearance. Photometric and spectroscopic observations indicate that the accretion disk has been regenerated. The ejecta now appear as a resolved shell made of numerous blobs, as shown in figure 3 for two novae. It also appears that different parts of the ejecta have noticeable abundance differences. Observations in the UV range by the IUE satellite and, for a few novae, in the x-ray range, first by the EXOSAT satellite and later by ROSAT, indicate that the hot star remains luminous for several years after outburst. Furthermore, a correlation emerges between the decline time of the UV luminosity and the time span of the much earlier decline of the visual luminosity (t_3). On observational grounds, little can be said concerning timescales of more than a hundred years, with the possible exceptions of two old novae that have been recovered, CK Vul of 1670 and WY Sge of 1783, both very faint.

Despite the similarity in spectral and brightness evolution, novae exhibit an overwhelming variety of properties, which may differ by orders of magnitude

between one nova class and another, and even between individual novae within the same class. These must be accounted for by the nova theory.

Theory

The outburst mechanism

Theoretical studies of the nova outburst started with the work of Evry Schatzman in the late 1940s and 1950s, in which explosive hydrogen burning was first proposed as the triggering mechanism. Hydrogen accretion onto a white dwarf and the ensuing unstable burning under conditions of electron degeneracy were first studied by Leon Mestel in 1952. It is noteworthy that all this preceded the discovery that novae were members of binary systems. More than 20 yr later, it became commonly accepted that classical nova outbursts result from explosive hydrogen burning—thermonuclear runaways—on the surfaces of white dwarfs that are accreting hydrogen-rich material from red dwarf (late-type) companions in close binary systems. The process is cyclic, with the greatest part of the cycle spent in quiescence. A quite detailed picture of the evolution of such cyclic outbursts emerges from the numerous theoretical studies—numerical hydrodynamical evolutionary calculations—that have been carried out since the late 1960s.

The material gradually accumulating on the white dwarf's surface becomes compressed and the electrons at the bottom of the accreted envelope become partially degenerate. At the same time the temperature at the bottom of the hydrogen-rich envelope rises. When it reaches 2×10^7 K, hydrogen is ignited in a thin shell by the CNO nuclear reaction cycle. The energy released raises the temperature further, but since the degeneracy pressure is insensitive to temperature, no expansion and cooling results and the temperature keeps rising exponentially, boosting the nuclear reaction rates in a runaway process. However, above about 10^8 K, the CNO cycle rate is limited by the decay rates of β^+-unstable nuclei, which are temperature independent. In addition, the temperature becomes sufficiently high for the degeneracy to be lifted, turning the gas into an ideal one. The runaway is thus quenched: the shell expands, while the burning

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

temperature starts dropping after having reached a few 10^8 K. Following ignition, a convective region forms just above the thin shell source and extends towards the surface. Convection mixes the β^+-unstable nuclei throughout the envelope and brings fresh CNO nuclei into the burning shell, until the unstable isotopes prevail over the extent of the envelope. Energy generation continues, supplied by the decay of the β^+-unstable nuclei. Heat absorption now results in rapid expansion and cooling of the accreted envelope.

During the runaway, the white dwarf's luminosity rises until it attains—or even surpasses briefly—the Eddington critical luminosity, $L_{\rm Edd} = 4\pi cGM_{\rm wd}/\kappa$, where $M_{\rm wd}$ is the star's mass and κ is the photospheric opacity. When the star reaches bolometric maximum, its radius is still relatively small and its surface still hot; hence it radiates mostly in the UV or even EUV. A relatively long phase of constant bolometric luminosity, a luminosity plateau, ensues. The rapid expansion of the envelope proceeds now at constant, close to critical, luminosity. Hydrostatic equilibrium cannot be achieved; instead, mass is driven out by radiation pressure in an optically thick wind. The importance of radiation pressure for the ejection of matter by novae was first recognized by William McCrea, as early as 1937. The idea was later pursued in a vast number of analytical and numerical studies of optically thick steady winds. These calculations yield velocities of the expanding material, mass loss rates and the total ejected mass. Expansion velocities vary between a few hundred km s^{-1} for slow novae to a few thousand km s^{-1}, for very fast ones.

The optical maximum is obtained when the maximal photospheric radius is reached, of order $100R_\odot$, corresponding to effective temperatures of several thousand kelvins. Thereafter, when the envelope becomes highly diluted, and the opacity drops, the photosphere recedes through the expanding mass; its radius decreases, while the effective temperature rises. Thus the evolution traces a double horizontal path in the H–R diagram, from high to low effective temperatures and back, as shown in figure 4.

When most of the envelope has been ejected, mass loss comes to an end. The small remnant shell on the white dwarf's surface contracts and then starts cooling slowly. Hydrogen burning continues, in thermal equilibrium, with the nuclear and bolometric luminosities both slowly declining, now at constant radius. When almost all of the hydrogen in the remnant shell has turned into helium, nuclear burning ceases and the white dwarf returns to its pre-outburst state. The decline takes roughly one to several years and the white dwarf remains almost unaffected by the outburst that has taken place. Accretion resumes towards the next outburst and a new nova cycle begins.

The quiescent state

The mass transferred from the red dwarf carries substantial ANGULAR MOMENTUM. Therefore, it does not settle immediately on the surface of the white dwarf, but forms a ring around it, which is spread by viscosity into a disk. Accreting material spirals in through the disk, releasing gravitational energy, which is processed and radiated by the disk. The disk luminosity—essentially, accretion luminosity of order $GM_{\rm wd}\dot{M}/R_{\rm wd}$, where $R_{\rm wd}$ is the radius of the accreting white dwarf and $\dot{M}$ is the accretion rate—dominates the luminosities of both binary components between outbursts. Thus the visible spectrum is the featureless blue continuum of the accretion disk, typical of cataclysmic variables in general.

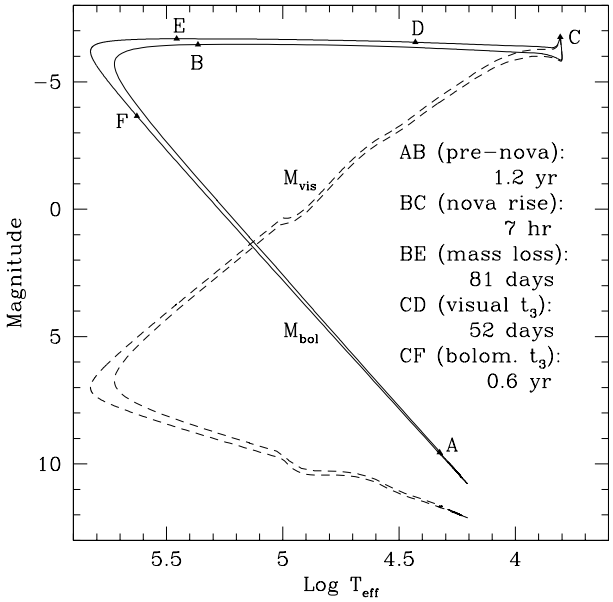

Figure 4. Illustration of the nova evolution pattern in the H–R diagram, as obtained from model calculations. Bolometric and visual magnitudes are indicated. Significant evolutionary landmarks are labeled. (Adapted from Kovetz (1998).)

From the space density of cataclysmic variables obtained in galactic surveys, of order 10^{-6} pc^{-3}, combined with the galactic rate of nova outbursts, an upper limit of about 10^3 yr is derived for the recurrence time. This demands, in turn, high mass transfer rates, which are incompatible with those inferred from nova theory. A solution to this apparent conflict is a variable mass transfer rate between outbursts: a high rate for tens to hundreds of years after outburst, which declines thereafter to lower values maintained for most of the quiescent state, and increases again centuries to decades prior to a new outburst. During the low state novae would escape luminosity-limited surveys. Thus nova systems are more numerous than they appear to be, but they erupt at much longer intervals. The very low luminosity of the oldest known novae, the relatively high luminosity of post- and prenovae, and the declining luminosity of decades-old novae support this theory.

The mass transfer rate is determined by the extent of Roche lobe overflow by the mass-donating star and may change when either the Roche lobe radius or the star's

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

radius change. Such changes are believed to be caused by several factors. Because of the mass lost by the binary system, the binary components are driven apart slightly during an outburst. The increased Roche lobe radius should result in a diminished mass transfer rate, but this effect is delayed so long as the companion star, irradiated by the hot nova, swells to some extent in order to get rid of the surplus luminosity. Eventually, as the nova fades away and the companion star contracts back to its equilibrium radius, the mass transfer rate does decline and remains low for a long time, between a few 10^3 yr and $\sim 10^5$ yr. During this long 'hibernation' phase the binary components are driven closer again owing to angular momentum losses caused by gravitational radiation or magnetic braking by a stellar wind. Thus the mass transfer rate increases again, leading to a new eruption.

General estimates

The large variation in observed nova features is attributed by the theory to differences in the values of three basic parameters that characterize the binary system: the mass of the accreting white dwarf, its internal temperature, which is a measure of the system's age, and the mass transfer rate, which is determined by the mass of the companion star and by the binary separation (orbital period). Remarkably, varying these parameters within acceptable limits reproduces roughly the entire range of observed properties. Furthermore, correlations are obtained between t_3 and the peak luminosity, the expansion velocity and the decline time of the bolometric luminosity, compatible with those derived from observations. Nevertheless, the stage where all the properties of a particular observed nova can be reproduced by one model has not yet been reached.

Despite the complexity of nova outbursts, some simple relations between the basic nova parameters and quantities that characterize the development of such outbursts may be obtained from analytical considerations. It has been shown, for example, that a thermonuclear runaway occurs when the pressure at the base of the accreted envelope—essentially, the degeneracy pressure of electrons—exceeds a critical value $P_{\rm crit}$ of order a few times 10^{18} N m^{-2}. Since the envelope, of mass $m_{\rm env}$, has negligible thickness,

$$P_{\rm crit} \approx \frac{G M_{\rm wd} m_{\rm env}}{4\pi R_{\rm wd}^4}. \tag{1}$$

For a white dwarf, the radius and mass are correlated; a simple relation, $R_{\rm wd} \propto M_{\rm wd}^{-1/3}$, holds for $M_{\rm wd} \lesssim 0.5 M_\odot$, leading, with equation (1), to

$$m_{\rm env} \propto M_{\rm wd}^{-7/3}. \tag{2}$$

For larger white dwarf masses, $R_{\rm wd}$ decreases much more strongly with increasing $M_{\rm wd}$. Thus massive white dwarfs require considerably smaller accreted envelopes in order to erupt. This conclusion has further consequences. The outburst recurrence time is given by $\mathcal{P} = m_{\rm env}/\dot{M}$ and, as the mass accretion rate $\dot{M}$ is independent of $M_{\rm wd}$, outbursts are more frequent on massive white dwarfs than on low-mass ones. In addition, since the companion's mass is another independent parameter, massive white dwarfs undergo, on average, a larger number of outbursts than low-mass ones. This results in a strong observational selection effect: the probability of discovering massive novae is higher, although they are not necessarily more numerous.

The luminosity at outburst is close to $L_{\rm Edd}$, which is proportional to $M_{\rm wd}$. Since the $M_{\rm wd}$ range is rather restricted, and since outbursts on massive white dwarfs are statistically favored, one should expect a narrow range of variation for the luminosities of novae in eruption. This should turn novae into reliable distance indicators (see below). During quiescence, the luminosity is that of accretion. Hence the outburst's bolometric amplitude A (in magnitudes) may be estimated by

$$A \approx 2.5 \log \left(\frac{\kappa \dot{M}}{4\pi c R_{\rm wd}(M_{\rm wd})} \right) \tag{3}$$

which yields, roughly, the observed range of ~ 7 to ~ 16.

The ejected mass $m_{\rm ej}$ may be estimated by assuming that it is supported against gravity at the star's surface—at the extended radius R—by the radiation pressure $P_{\rm rad} = \frac{1}{3} a T^4$, where a is the radiation constant. Thus, $m_{\rm ej} g = 4\pi R^2 P_{\rm rad}$, where g is the gravitational acceleration at the surface. Substituting the effective temperature for T and the Eddington luminosity for L,

$$4\pi R^2 \sigma T_{\rm eff}^4 = L = \frac{4\pi c G M_{\rm wd}}{\kappa} \tag{4}$$

leads to

$$m_{\rm ej} \approx \frac{16\pi R^2}{3\kappa}. \tag{5}$$

The range obtained—between $\sim 10^{-5} M_\odot$ and a few $10^{-4} M_\odot$—overlaps with that resulting from the independent estimate (1) and agrees with masses determined both observationally and by evolutionary calculations.

The energy required to power a nova outburst may be estimated as follows: the radiated energy is roughly the Eddington luminosity multiplied by the duration of an outburst, typically several weeks, which yields $\sim 5 \times 10^{37}$ J, and the kinetic energy of the expanding shell is $\sim 2.5 \times 10^{37}$ J, assuming a shell mass of $10^{-4} M_\odot$ and an average velocity of 500 km s^{-1}. However, both are negligible compared with the energy required to remove the shell from the deep gravitational potential well of the white dwarf, which is of order 10^{39} J. This energy is supplied by nuclear burning of a fraction α of the accreted hydrogen-rich envelope mass, which may be estimated by

$$\frac{G M_{\rm wd}}{R_{\rm wd}} \approx \alpha X Q \tag{6}$$

where X is the hydrogen mass fraction in the accreted matter, typically 0.7, and Q is the energy released per gram

of burnt hydrogen, 6×10^{14} J kg^{-1}. This yields $\alpha \approx 5\%$, which means that only a very small fraction of the accreted matter must be burnt in order to power the outburst.

The composition of nova ejecta—observation and theory

Characteristic abundances

The fact that nova ejecta exhibit unusual abundance features has long been recognized. Recent determinations of heavy-element abundances in the ejecta of classical novae have been based either on emission line analyses during decline or on analyses of resolved shells of older novae. The main characteristics of the nova ejecta composition derived from observations, as given in table 1, are as follows. (a) All novae show some degree of He–CNO enrichment. (b) There is simultaneous enrichment of He and CNO and/or ONeMg. (c) No apparent correlation is found between the helium mass fraction Y and the heavy-element mass fraction Z. (d) According to their neon content, novae may be roughly divided into two categories: those with a modest neon abundance, in spite of a considerable enrichment in CNO nuclei, and those which appear to have a very high abundance of neon and heavier elements. Although the theoretical prediction of significantly enriched ejecta preceded the actual observation, the enrichment mechanism has eluded astronomers for quite a long time.

Sources of enrichment

In principle, there are three possible sources for the unusual composition: (a) the accreted matter itself is rich in He, CNO and heavier isotopes; (b) heavy elements are synthesized during outburst; (c) core material is dredged up into the accreted hydrogen-rich matter. The first possibility is highly unlikely, the donor being a K or M main sequence star. In fact, no stars are known with outer layers of the nova ejecta composition. Regarding the second, the energy required to power a nova outburst in all its aspects is readily supplied, as shown above, by burning a tiny fraction of the accreted mass, and temperatures are not high enough to produce elements heavier than helium. Hence there remains the possibility of mixing of white dwarf material with the accreted mass. Two mechanisms have been suggested: (1) diffusion of hydrogen into the core, which causes ignition to take place below the core boundary and results in convective mixing of core material lying above the ignition radius into the envelope; (2) turbulent mixing due to shear-induced instabilities at the boundary between the white dwarf and the accreted material. Both may be supplemented by convective overshoot during the initial phases of the runaway.

At the onset of an outburst, the nova progenitor consists of two parts—core and envelope. The burning front separating them is located at the depth reached by the downward-diffusing hydrogen during the accretion phase in the diffusion scenario, or at the bottom of the unstable, turbulent layer, in the shear-mixing scenario. The explosive ignition of hydrogen leads to the formation of a convective zone that sweeps the entire envelope. Thus, regardless of the element distribution prior to outburst, the convective envelope's composition becomes well mixed before any matter is ejected. Hence observed abundances do not bear direct witness to the mixing mechanism, but they reflect the composition of the white dwarf. Accordingly, two types of white dwarf appear to be involved in nova outbursts: carbon–oxygen white dwarfs, in which carbon and oxygen are in roughly equal mass fractions, and oxygen–neon–magnesium white dwarfs, for which relative abundances are less certain. STELLAR EVOLUTION theory predicts that the latter must have larger masses than the former.

The source of helium excess may be either a helium-rich outer layer of the white dwarf progenitor—a relic of its early evolutionary stages—or the hydrogen-exhausted envelope remnant of a previous nova outburst. Since

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

helium and heavier-element enrichments are concomitant, the helium layer overlying the white dwarf core cannot be too thick. Thus, even if the white dwarf was originally formed with a relatively thick helium mantle, this mantle was eroded during the first nova outbursts. Hence the common helium source for the ejecta is the helium-rich remnant that forms during the decline phase of each nova outburst, to be destroyed and reformed in the next. The cyclic evolution and composition changes of a nova outburst are sketched in figure 5. The fact that helium and heavy-element enrichments have different sources explains the lack of correlation between them.

Nuclear processing

At outburst, temperatures exceed 10^8 K and densities are of order 10^7 kg m^{-3}. Under such conditions, the hydrogen burning reaction chain is

$$^{12}\mathrm{C}(\mathrm{p},\gamma)^{13}\mathrm{N}(\mathrm{p},\gamma)^{14}\mathrm{O}(\beta^+,\nu)^{14}\mathrm{N}(\mathrm{p},\gamma)^{15}\mathrm{O}(\beta^+,\nu)^{15}\mathrm{N}$$

ramifying into

$$^{15}\mathrm{N}(\mathrm{p},\alpha)^{12}\mathrm{C}$$

or

$$^{15}\mathrm{N}(\mathrm{p},\gamma)^{16}\mathrm{O}(\mathrm{p},\gamma)^{17}\mathrm{F}(\beta^+,\nu)^{17}\mathrm{O}(\mathrm{p},\alpha)^{14}\mathrm{N}.$$

Its characteristic timescale is limited by the lifetimes of ^{13}N (863 s), ^{14}O (102 s), ^{15}O (176 s) and ^{17}F (93 s), which become the most abundant heavy isotopes in the nova envelope. Their decay products, ^{13}C, ^{14}N, ^{15}N and ^{17}O, are thus greatly enhanced compared with the equilibrium CNO cycle abundances characteristic of solar composition.

The rate at which novae return mass to the interstellar medium may be estimated from the typical nova rate of about 20 yr^{-1} per galaxy multiplied by the average ejected mass per outburst, $\sim 10^{-4} M_\odot$, yielding $\sim 0.002 M_\odot$ yr^{-1}. This is about 50 times less than the rate corresponding to supernovae and over 200 times less than that corresponding to red giants and supergiants. Thus novae are significant contributors to interstellar abundances only for those isotopes which are enhanced by NUCLEAR PROCESSING more than 100 times compared with solar values. This is, indeed, the case for the rarer C, N and O isotopes. Consequently, novae have been repeatedly invoked as sources of the rarer isotopes, although their contribution to the dominant isotopes appears to be negligible (with the possible exception of ^{14}N). Isotopic ratios obtained from model calculations show that ^{13}C/^{12}C and ^{17}O/^{16}O are higher than solar by large factors for all parameter combinations, while ^{15}N/^{14}N is higher for some and lower for others. Consequently, novae are also considered potential ^{14}N sources in the interstellar medium, since this does not necessarily imply ^{15}N production in too large amounts.

Despite the high temperatures attained at outburst, the only abundant species in the ejecta of carbon–oxygen nova models are the isotopes of C, N and O. Neon production is entirely insignificant. Hence, it appears that the only way to obtain any neon in the ejecta would be to have it present in the white dwarf's composition. Indeed, carbon–oxygen white dwarfs formed in close binary systems do contain a few per cent of neon, in agreement with the amount indicated by observations.

In the case of novae occurring on oxygen–neon–magnesium white dwarfs, hydrogen burning proceeds through the NaMg reaction chain,

$$^{20}\mathrm{Ne}(\mathrm{p},\gamma)^{21}\mathrm{Na}(\mathrm{p},\gamma)^{22}\mathrm{Mg}(\beta^+,\nu)^{22}\mathrm{Na}(\mathrm{p},\gamma)^{23}\mathrm{Mg}(\beta^+,\nu)$$
$$^{23}\mathrm{Na}(\mathrm{p},\alpha)^{20}\mathrm{Ne}$$

and the MgAl reaction chain,

$$^{24}\mathrm{Mg}(\mathrm{p},\gamma)^{25}\mathrm{Al}(\beta^+,\nu)^{25}\mathrm{Mg}(\mathrm{p},\gamma)^{26}\mathrm{Al}(\mathrm{p},\gamma)^{27}\mathrm{Si}(\beta^+,\nu)$$
$$^{27}\mathrm{Al}(\mathrm{p},\alpha)^{24}\mathrm{Mg}$$

which yield substantial abundances of the radioactive species ^{22}Na and ^{26}Al. These isotopes have much longer lifetimes than the CNO radioactive isotopes, and hence they are live in the nova ejecta and in the dust grains that form in the shell. They are responsible, at least in part, for the enrichments in ^{22}Ne and ^{26}Mg—their decay products—that have been identified in meteoritic inclusions, believed to be representative of the primordial solar nebula composition. Moreover, ^{26}Al has been detected in the Galaxy through the 1.809 MeV γ-ray line and novae are considered potential sources of this isotope, competing with supernovae and red giants.

Novae as distance indicators

Novae are extremely luminous at optical wavelengths, brighter than Cepheids and surpassed only by supernovae, and they are about a hundred times more frequent than supernovae. They are therefore easy to detect in external galaxies, certainly within the Local Group, and potentially beyond. In particular, the constant luminosity maintained during part of the outburst can be used as a standard candle; if moderate to slow novae are considered, the magnitude variation among different novae does not exceed 1 magnitude.

The notorious property of nova outbursts is the apparent correlation between the maximum magnitude attained at outburst and the rate of decline, or more precisely, the time of decline by 3 magnitudes, t_3 (or, sometimes, by 2 magnitudes, t_2), a relationship that was already pointed out by Fritz Zwicky in 1936 and was first calibrated by McLaughlin in 1945. Since then, great effort has been devoted to the absolute calibration of this relation, which has became known as the maximum magnitude versus rate of decline (MMRD) relationship. The MMRD is considered a reliable distance indicator, in spite of the relatively large scatter of points, which results from observations and is expected from the theoretical point of view.

Nozomi (Planet-B)

Japanese mission to orbit Mars, launched in July 1998. Initially placed into a gravity assist orbit around the Earth and Moon. Carries instruments provided by Canada, Sweden, Germany and the United States. Intended to map the planet's surface, study the Martian atmosphere and the interaction of Mars with the solar wind. Arrival at Mars delayed until at least December 2003 after an engine malfunction necessitated an unscheduled course correction and heavy fuel consumption on leaving Earth orbit. Nozomi means 'hope'.

Nuclear Beta Decay

For over a century it has been known that atomic nuclei can undergo radioactive decay. These decays can be induced by the strong, weak or electromagnetic interaction in the case of excited nuclei. Those nuclear decays which proceed via the weak interaction are the beta decays. 'Beta' originally referred to electrons, but these decays can involve electrons or positrons, and either electron neutrinos or antineutrinos. The term beta decay covers all nuclear decays in which the charge number Z of the nucleus X for a constant mass number A changes by one unit. This includes the following decay processes:

$$\beta^-\text{decay}: \quad {}^{A}_{Z+1}\mathrm{X} \longrightarrow {}^{A}_{Z}\mathrm{Y} + \mathrm{e}^- + \overline{\nu}_\mathrm{e} \tag{1}$$

$$\beta^+\text{decay}: \quad {}^{A}_{Z-1}\mathrm{X} \longrightarrow {}^{A}_{Z}\mathrm{Y} + \mathrm{e}^+ + \nu_\mathrm{e} \tag{2}$$

$$\text{electron capture}: \quad \mathrm{e}^- + {}^{A}_{Z}\mathrm{X} \longrightarrow {}^{A}_{Z-1}\mathrm{Y} + \nu_\mathrm{e}. \tag{3}$$

The most elementary beta decay process is the free neutron decay, in which a neutron decays into a proton, an electron and an antineutrino

$$\mathrm{n} \longrightarrow \mathrm{p} + \mathrm{e} + \overline{\nu}_\mathrm{e}, \tag{4}$$

or, on the quark level, a d quark decays into a u quark, an electron and an antineutrino

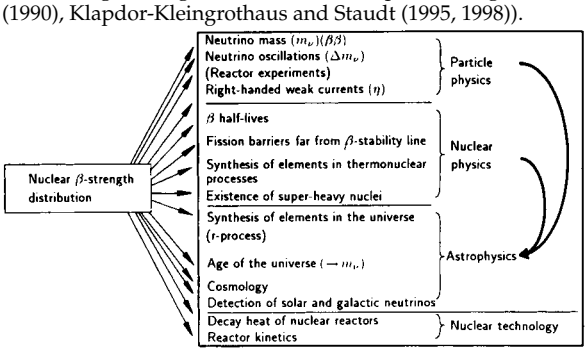
$$\mathrm{d} \longrightarrow \mathrm{u} + \mathrm{e} + \overline{\nu}_\mathrm{e}. \tag{5}$$

From a perturbation theory point of view, beta decay is a first-order effect of the classical theory. In the Glashow–Weinberg–Salam (GWS) theory, in which the pointlike current–current interaction is replaced by a boson exchange interaction, beta decay is a second-order effect.

In nuclear beta decay it is first and foremost possible to investigate the mass spectrum of the neutrino state which couples to the electron. The electron energy spectrum of an allowed transition is modified by a finite (Dirac or Majorana) neutrino mass. At present the investigations of tritium decay give the sharpest model-independent limits on the electron neutrino mass, of 2.8 eV (at 95% c.l.) (Weinheimer 2000, Lobashev 2000).

Even though the mechanism of β decay at the nucleon (respectively quark) level is in principle understood, only quite recently did it become possible to produce a quantitatively satisfactory description of the β decay processes of atomic nuclei (Klapdor 1983, 1986, Klapdor-Kleingrothaus 1991, Staudt *et al* 1990, Staudt and Klapdor-Kleingrothaus 1992, Hirsch *et al* 1992, 1993, Homma *et al* 1996). This is because the nucleus is a complex many-particle system, in which residual interactions of various types may lead to collective excitations, which can have a massive effect on the β decay properties. The distribution of the β strength in the daughter nucleus determines not only the β half-lives, and the rates for β-delayed particle emission (neutron or proton and fission) but also the shape of the emitted electron (positron) and (anti)neutrino spectra. The ability to calculate these quantities is of central importance to numerous applications in nuclear physics and neighboring disciplines such as astrophysics, particle physics and also nuclear engineering (see table 1). Some examples are (for details we refer to Klapdor (1983, 1986), Klapdor-Kleingrothaus (1991, 1998, 1999), Grotz and Klapdor-Kleingrothaus (1990), Klapdor-Kleingrothaus and Staudt (1995, 1998)):

Table 1. Nuclear beta decay and its links with some fundamental problems in nuclear, particle and astrophysics, and nuclear engineering (from Grotz and Klapdor-Kleingrothaus (1990), Klapdor-Kleingrothaus and Staudt (1995, 1998)).



Nuclear physics. Investigation of the nuclear structure of nuclei far from stability; determination of the fission barriers of nuclei from β-delayed fission; understanding the production of transuranic elements by thermonuclear devices; calculation of the electron and antineutrino spectra in nuclear reactors, originating from β decay of the around 1000 fission products (important for neutrino oscillation experiments).

Particle Physics. Calculation of $\beta\beta$-decay matrix elements as a prerequisite for determination of the neutrino mass and other particle theory parameters from measured decay rates (see below and also PARTICLE ASTROPHYSICS).

Astrophysics. Understanding the development of stars, particularly the gravitational collapse of heavy stars and the synthesis of elements in the *r* process; determining the age of the galaxy from cosmochronometers; response function of gallium detectors (and others) in solar neutrino detection. Stars shine because of the weak interaction involving either the pp reaction to form deuterium, or in the case of CNO burning, because of nuclear beta (actually positron) decays.

A precise knowledge of the beta decay of neutron-rich nuclei is crucial for the understanding of the r-process (Klapdor 1983, 1986, Klapdor-Kleingrothaus 1991). Both the element distribution on the r-path, and the resulting element distribution of stable elements—and of the cosmochronometers—are sensitive to the beta decay properties (half-lives, beta-delayed rates) of the neutron-rich nuclei involved in the process (about 6000 nuclei between the beta stability line and the neutron drip line (see figure 1)). The rates for beta-delayed fission determine where

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the r-process breaks off at high mass number A, and also influence the production rate of heavy nuclei. On the basis of microscopic calculations of the beta decay properties (since the early 1980s) of all of these nuclei for the first time reliable ages of the Galaxy and the universe were obtained with the method of cosmochronology (Klapdor 1983, 1986, Klapdor-Kleingrothaus 1991), which hinted more than ten years ago at a non-vanishing COSMOLOGICAL CONSTANT Λ (Klapdor and Grotz 1986). These hints were confirmed in 1998 by observation of high-redshift SUPERNOVAE of type Ia in the Supernova Cosmology Project.

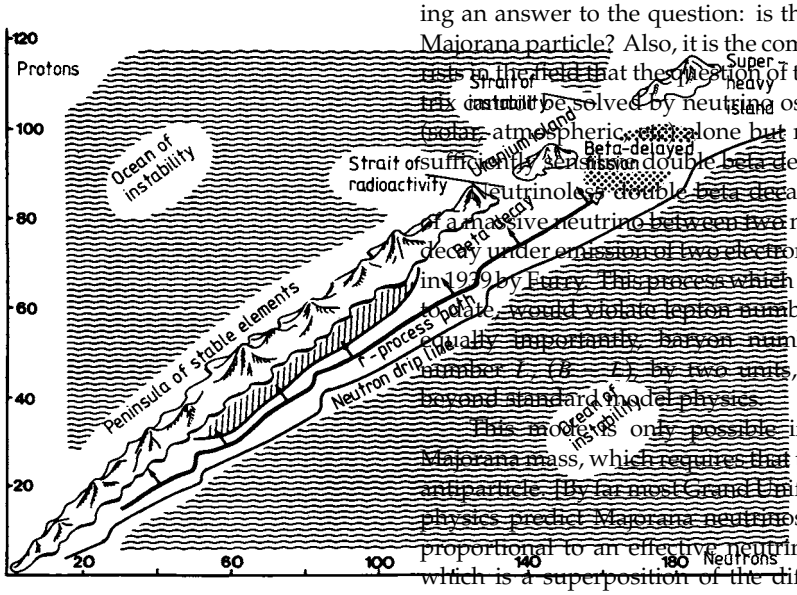

Figure 1. Schematic diagram of element synthesis by rapid neutron capture (r-process) (from Grotz and Klapdor-Kleingrothaus (1990), Klapdor-Kleingrothaus and Staudt (1995, 1998)).

Reactor physics. Calculation of the residual heat released in the β decay of fission products on switching off reactors.

It is a second order effect of the classical theory (fourth order in the GWS theory), namely double beta decay, which yields—besides proton decay—perhaps the most promising possibilities to probe physics beyond the standard model of particle physics (figure 2).

The investigation of double beta decay is indispensable to solve one of the fundamental questions of all unified theories of modern particle physics, that of neutrino mass and nature. Double beta decay is the only process allowing an answer to the question: is the neutrino a Dirac or Majorana particle? Also, it is the common opinion of theorists in the field that the question of the neutrino mass matrix can only be solved by neutrino oscillation experiments (solar, atmospheric, etc.) alone but requires in addition a sufficiently sensitive double beta decay experiment.

Neutrinoless double beta decay, in which exchange of a massive neutrino between two nucleons triggers their decay under emission of two electrons, was discussed first in 1939 by Furry. This process which has not been observed to date, would violate lepton number conservation, and, equally importantly, baryon number B minus lepton number L, $(B - L)$, by two units, which would imply beyond standard model physics.

This mode is only possible if the neutrino has a Majorana mass, which requires that the neutrino is its own antiparticle. [By far most Grand Unified Models of particle physics predict Majorana neutrinos.] The decay rate is proportional to an effective neutrino mass $\langle m \rangle$ squared, which is a superposition of the different neutrino mass eigenstates m_i

$$\langle m_\nu \rangle = \sum_i m_i U_{ei}^2. \tag{6}$$

respecting the possibility of the electron neutrino to be a mixed state (mass matrix not diagonal in the flavor space)

$$|\nu_e\rangle = \sum_i U_{ei} |\nu_i\rangle \tag{7}$$

U is the (unitary) neutrino mixing matrix.

Consequently double beta decay yields important information on the parameters of the neutrino mass and mixing matrix. The information from double beta decay is particularly important to fix the absolute neutrino mass scale, since neutrino oscillation experiments measure only differences between mass eigenstates.

There are worldwide several double beta experiments running looking for this type of decay for various nuclei (figure 3). The Heidelberg–Moscow experiment is by far the most sensitive one at present, and also for the next few years (figure 3 and see Klapdor-Kleingrothaus (1998, 1999)).

The team from the Max Planck Institute for Nuclear Physics in Heidelberg and the Kurchatov Institute in Moscow constructed a set-up of five high-purity

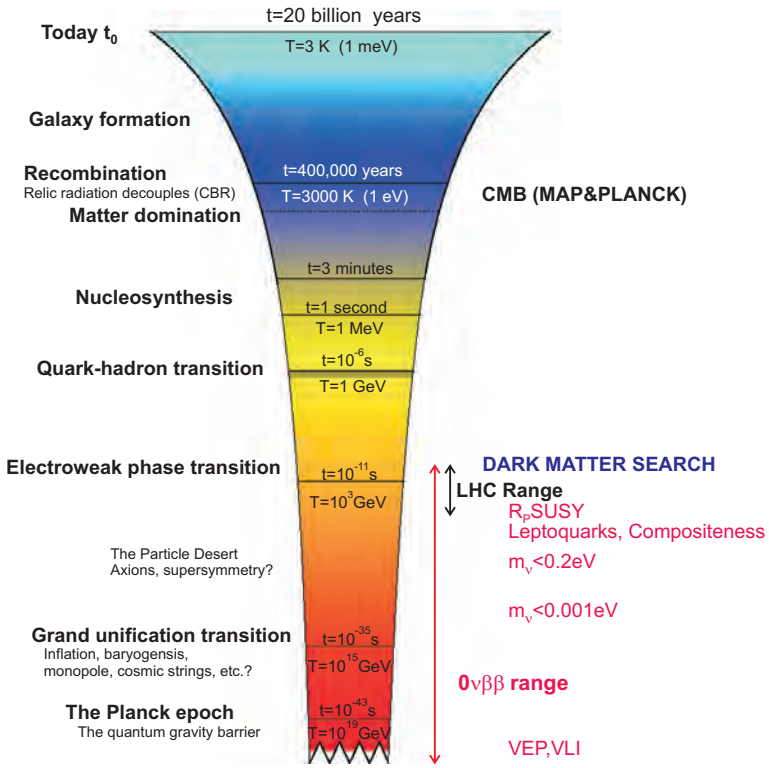

Figure 2. Energy (time) scales in the early universe where double beta decay can contribute to the related particle physics research. For the (light) neutrino masses the scale is indicated for the right-handed heavy counterparts according to the see-saw mechanism.

germanium detectors enriched in the isotope germanium-76 to 86% (natural abundance 7.8%) of total mass of 11.5 kg. This results in the largest source strength ever used in a double beta decay experiment. The set-up is operated in a heavy shielding under 1500 meters of rock (corresponding to 3500 m of water shielding) in the Gran Sasso Underground Laboratory in Italy. The background level reached by the experiment is the lowest worldwide for this kind of experiment—0.06 events per year and kilogram of detector mass in the energy range of the expected double beta decay signal, which would be a peak in the spectrum produced by the decay electrons, at 2038 keV.

In almost 10 years of measurement, the Heidelberg–Moscow team has obtained a lower limit for the half-life of neutrinoless double beta decay of germanium-76 of several 10^{25} years. This is the world record under all running investigations. With the deduced limit for the Majorana neutrino mass of 0.27 eV, the Heidelberg–Moscow experiment is not only the first one exploring the sub-eV range of the neutrino mass, but also enters in a range of values, which has stringent consequences for neutrino mass models and for cosmological models assuming neutrinos as hot DARK MATTER in the universe (see figure 4 and Klapdor-Kleingrothaus *et al* 2000a).

For example, *in degenerate neutrino mass models*, in which the neutrino mass eigenstates have very close values, the above value (and even a more conservative value of 0.35 eV) excludes models with cold and hot dark matter (CHDM models), and also those including a non-vanishing cosmological constant Λ (ΛCHDM models) for the case of the small mixing angle solution of the solar neutrino problem. (Minakata 1997, Adhikari *et al* 2000, Ellis and Lola 1999, Georgi and Glashow 2000, Yasuda 1999). This result is consistent with the recent disfavoring of the small mixing angle solution for the solar neutrino problem as reported by SUPER-KAMIOKANDE (Suzuki 2000, see also Gonzales-Garcia 2000). Assuming the best fits of the large mixing angle solution or the vacuum oscillation solutions, still CHDM models are excluded, while ΛCHDM models are still marginally possible (requiring $\langle m \rangle = 0.15$–0.30 eV). In the case of inverse hierarchical neutrino mass scenarios, with only two neutrinos contributing to hot dark matter, only ΛCDM models with a small Hubble constant $h = 0.5$ are marginally not yet excluded.

Already now, still assuming the small angle solution of the solar neutrino problem to be valid, the experiment would rule out almost the whole range of sensitivity of the future satellite experiments MAP and PLANCK for cosmological models of the above types involving neutrinos as hot dark matter (see figure 4). Figure 4 also demonstrates that, combined with the neutrino oscillation results obtained in the recent solar and

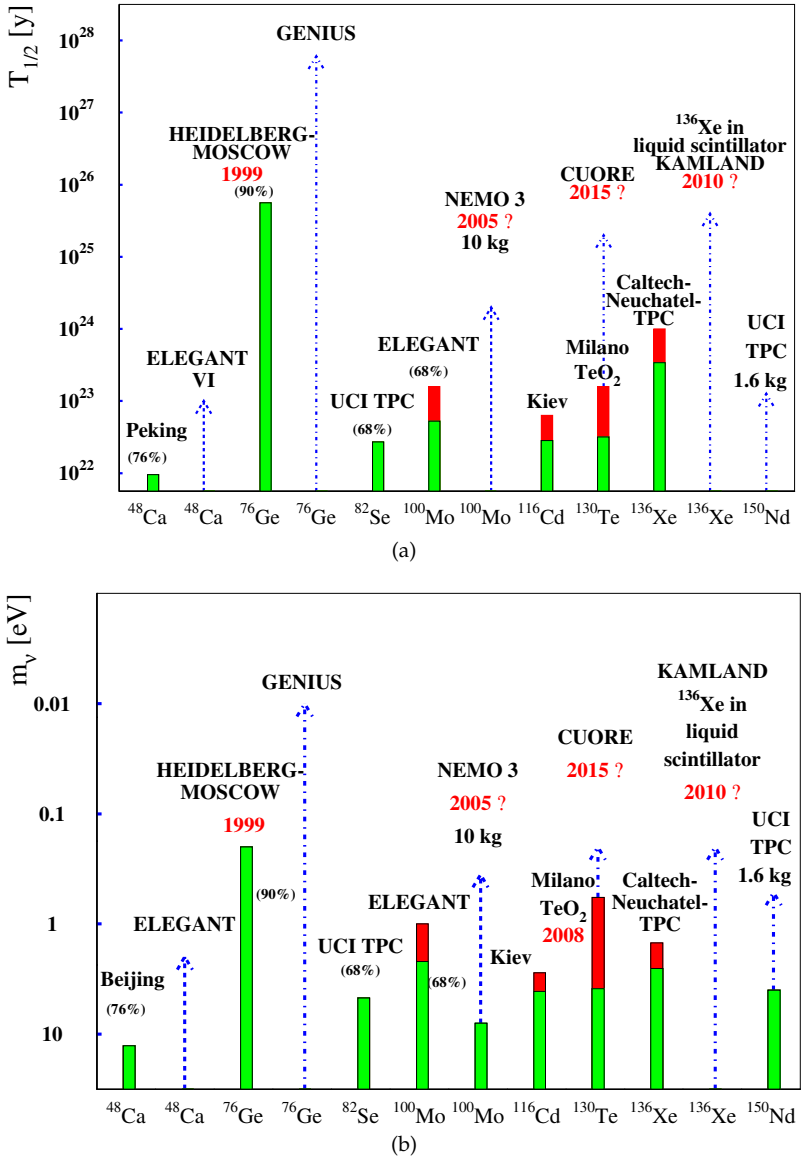

Figure 3. Present situation, 2000, and expectation for the near future and beyond, of the most promising $\beta\beta$-experiments concerning accessible half-life (a) and neutrino mass limits (b). The light-shaded parts of the bars correspond to the present status, the dark parts of the bars to expectations for running experiments, dashed lines to experiments under construction and dash-dotted lines to proposed experiments.

atmospheric neutrino oscillation experiments (see also SOLAR INTERIOR: NEUTRINOS) and with precise determinations of cosmological parameters, double beta decay is obviously the only way to obtain precise informations about the neutrino mixing and the absolute mass scale in partially degenerate and degenerate neutrino mass scenarios.

Looking into four-neutrino scenarios, including in addition to the three known neutrino flavours a fourth 'sterile' neutrino, there are as shown recently by Giunti *et al*, Bilenky *et al*, and others, only two schemes that can accommodate the results of *all* neutrino oscillation experiments (including the Los Alamos experiment LSND). The first of these two scenarios is ruled out by the Heidelberg–Moscow experiment.

An application of the extremely low background of the germanium double beta detectors is to search for cold dark matter in the form of WIMPs (weakly interacting massive particles; see WIMPS AND MACHOS) which are expected to populate the halo of our Galaxy. They could be looked for by elastic scattering off the Ge nuclei and the following ionization by the recoiling nucleus in the double beta decay detectors. The deposited energy for neutralinos with masses between 10 GeV and 1 TeV

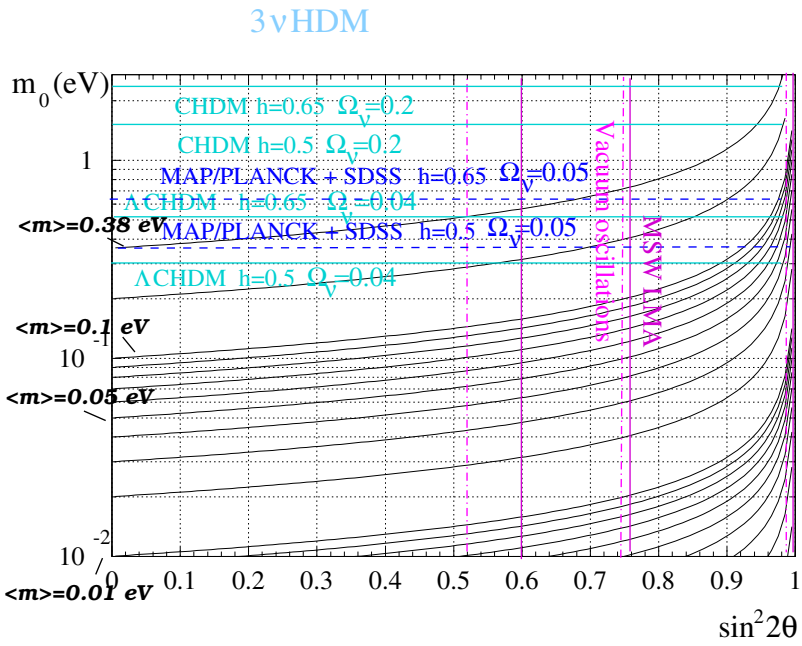

Figure 4. Isomass lines for the effective neutrino mass $\langle m \rangle$ measured in double beta decay in the m_0–$\sin^2(2\theta)$ plane *for the case of a degenerate three-neutrino scenario* with mass m_0. Also shown are the best fits for CHDM and ΛCHDM for different values of the Hubble constant, the sensitivity of MAP/PLANCK combined with SDSS, and the regions of the MSW LMA and of the vacuum oscillation solutions of the solar neutrino problem. The Heidelberg–Moscow experiment excludes already most of the cosmological models and also, assuming the MSW SMA solution, almost the whole range of sensitivity of the future satellite experiments MAP and PLANCK for cosmological models involving neutrinos as hot dark matter (from Klapdor-Kleingrothaus *et al* 2000a).

is below 100 keV. The best current limits on WIMP nucleon cross sections come from the DAMA experiment, from the CDMS experiment and from the Heidelberg–Moscow experiment, the latter experiment yielding the most stringent limits for using raw data without pulse shape analysis. All of these experiments at present just marginally touch only the upper part of the parameter space predicted for neutralinos as cold dark matter. A huge increase in sensitivity could be expected from the future double beta (and dark matter) detector GENIUS (see Klapdor-Kleingrothaus (1997, 1998, 1999), Klapdor-Kleingrothaus and Hirsch 1997, Klapdor-Kleingrothaus *et al* (1999a, 2000a)).

In addition to the information on the neutrino mass, double beta decay experiments, and in particular the Heidelberg–Moscow experiment yield already now information on beyond standard model physics on the TeV scale, where new physics could be expected. This is possible since the $\Delta L = 2$ process of neutrinoless double beta decay could occur in *any* lepton-number violating theory, so, e.g. by exchange of supersymmetric particles like neutralinos, gluinos, sleptons, etc, and thus the process would yield information on the underlying theories and on properties of the involved particles. This has been realized in the last 10–15 years only (see Klapdor-Kleingrothaus (1998, 1999), Klapdor-Kleingrothaus and Päs (1998) and Klapdor-Kleingrothaus and Krivosheina (2000)). It is important to note, and has been proved theoretically already in the early 1980s by Schechter and Valle, that independent of the mechanism underlying the double beta decay, its occurrence *always* would imply a nonvanishing Majorana neutrino mass.

The half-life limit measured in the Heidelberg–Moscow experiment yields a *lower* limit on the mass of a superheavy left-handed neutrino of $M > 8 \times 10^5$ GeV, a limit which could be reached only by a far-future 2 TeV linear electron–electron collider. It yields further an upper limit on the Yukawa coupling Λ'_{111} in the R-parity breaking part of the superpotential of the minimal supersymmetric standard model (MSSM), which is more stringent than present limits from the TEVATRON and HERA colliders, and which immediately excluded the possibility of squarks of first generation being produced in the recently discussed high-Q squared events at HERA.

The Heidelberg–Moscow result also restricts stringently products of higher generation Yukawa couplings, it yields the sharpest limits for a Majorana-type mass of the sneutrino, the supersymmetric partner of the neutrino, sets limits to compositeness (assuming a substructure of quarks and leptons), which are, as shown recently by Panella *et al* (2000), more stringent than those from the LEP II accelerator, yields bounds on violation of Lorentz invariance (VLI) and equivalence principle (VEP) in the neutrino sector, in the range of small mixing, which cannot be constrained by other experiments. This implies that double beta decay probes even physics at the Planck scale,

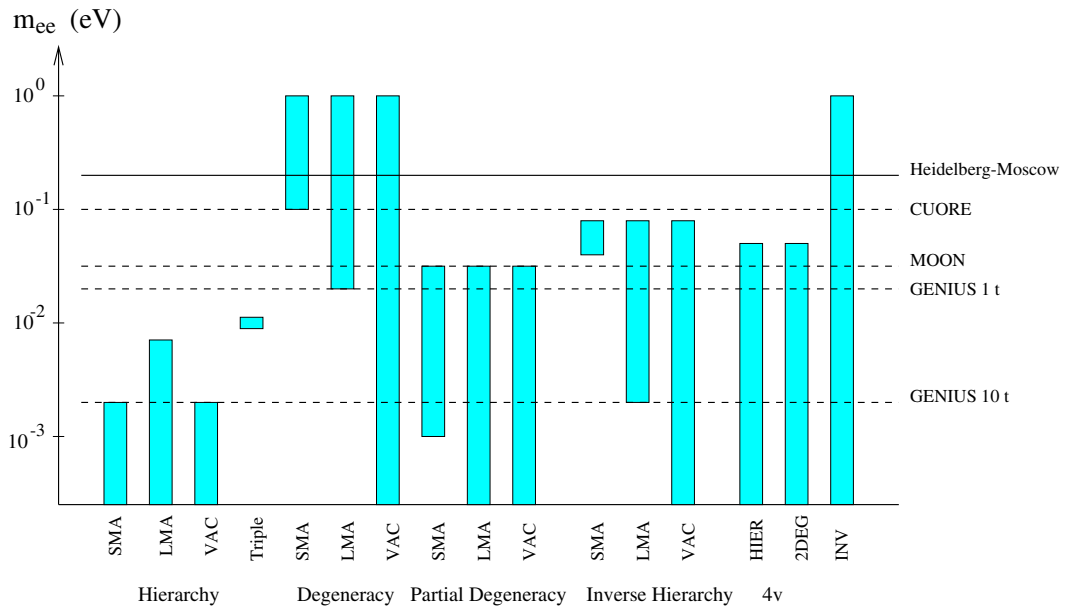

Figure 5. Summary of expected values for the *effective neutrino mass* $m_{ee} \equiv \langle m_\nu \rangle$ in different neutrino mass schemes and the potential of future double beta experiments to probe them (from Klapdor-Kleingrothaus *et al* 2000a).

since violation of Lorentz invariance and of equivalence principle (as well as CPT violation) could occur in superstring theories (see STRING THEORY/SUPERSTRING THEORY). Violation of the latter could result from contributions of dilatons (excitations in compactified spacetime dimensions) to gravitation by flavour-characteristic couplings. This could lead to neutrino oscillations. Violation of Lorentz invariance can originate from the fact that in QUANTUM GRAVITY theories the vacuum has a non-trivial SPACETIME structure, and thus particles propagating through the quantum foam show energy-dependent recoil and vacuum polarization effects (for details see Klapdor-Kleingrothaus (1998, 1999), Klapdor-Kleingrothaus *et al* (1999b, 2000a, b, c)).

In summary the most sensitive present double beta experiments yield important complementary information to accelerator experiments, which partly can be covered only by future colliders.

The method of double beta decay could be pushed in another type of set-up to a limit of 0.1 eV or ultimately 0.001 eV, which probably would be the ultimate value obtainable in double beta decay experiments. For this purpose the Heidelberg group has proposed the new project GENIUS (Klapdor-Kleingrothaus 1997, Klapdor-Kleingrothaus and Hirsch 1997, Klapdor-Kleingrothaus *et al* 1999a, Klapdor-Kleingrothaus and Zuber 1997). Its research potential for neutrino physics is demonstrated in figure 5. It is complementary to that of solar neutrino experiments (see, e.g., Bahcall *et al* 2000). More generally, this would have implications for a broad area of physics encompassing particle physics in the multi TeV range, and astrophysics, and which would serve as an important bridge between the physics that will be gleaned from high energy accelerators such as LHC and NLC on the one hand and satellite experiments such as MAP and PLANCK on the other.

Nuclear Combustion

Nuclear combustion is the rapid consumption of stellar material by a thermonuclear fusion front, propagating subsonically (deflagration) or supersonically (detonation), releasing large amounts of energy that are observable as astrophysical flashes.

Overview

In some astrophysical events, stellar material becomes sufficiently strongly compressed and heated that nuclear fusion reactions occur much more rapidly than during the slow, gradual nuclear burning that takes place for most of every star's lifetime. If this happens, a thin sheet of reacting material, a so-called nuclear combustion front, forms and travels from the point of its ignition outward. The huge amount of energy released by the combustion front within a very short time is believed to be the source for the bursts of light that are observed as astrophysical flashes. There are mainly three types of astrophysical explosions whose theoretical explanations invoke fast nuclear combustion: classical NOVAE, X-RAY BURSTERS and—most violently—type Ia SUPERNOVAE. In the former two, the hydrogen gas accreted onto a WHITE DWARF or NEUTRON STAR in a BINARY SYSTEM becomes more and more compressed by the strong gravitational field of the accreting star and eventually explodes, leaving the underlying star intact. In the case of a type Ia supernova, the accreting white dwarf ignites nuclear combustion deep in its interior, leading to the explosion of the entire star.

In order to understand these astrophysical phenomena, one must construct mathematical models that describe the structure of nuclear combustion fronts and their modes of propagation. If one neglects the influence of turbulent fluid motions, all combustion fronts can be classified as either deflagrations or detonations. Deflagrations (or 'flames') are thin layers of hot nuclear burning material that diffuse heat into the cold, unburned material ahead of the front, igniting it and thus moving the front forward. They propagate subsonically and resemble, for instance, flames in car engines. Detonations, on the other hand, are driven supersonically by a shock wave that is formed by the energy released in the reacting layer.

In astrophysical explosions, however, the burning material is often not at rest but undergoes strong, turbulent motions—often stirred by the combustion front itself—making the modeling of the event much more difficult. Turbulent deflagrations can propagate much faster than laminar ones, and may sometimes even turn into detonations. Computers are needed to solve the mathematical models in all but the simplest cases, but even they can only provide us with a rough glimpse of the complexity of turbulent nuclear combustion fronts.

Basic physics of nuclear combustion fronts

Just like the hydrostatic nuclear burning that takes place in the core of our Sun, astrophysical thermonuclear flashes obtain their energy from nuclear FUSION reactions that combine light atomic nuclei to heavier ones. They differ mainly in the speed at which these reactions take place, described by the energy generation rate $\dot{w}$. Since the reaction rate depends on the probability of two nuclei colliding and therefore on their speeds and mean separation, $\dot{w}$ is a very steeply rising function of the density ρ and, even more crucially, the temperature T. How do thermonuclear flashes reach sufficiently high temperatures to burn their nuclear fuel explosively?

Stars control their central temperature, and thus their energy generation rate, by expansion or contraction that causes cooling or heating respectively. This feedback control becomes impossible if the pressure is almost independent of the temperature, as in the case of electron degeneracy. All three cases of known astrophysical thermonuclear flashes involve degenerate nuclear fuel (we shall use the terms 'fuel' and 'ashes' in a general sense for the nuclear reactants and reaction products respectively): in novae and x-ray bursts, the hydrogen layer on top of a white dwarf or a neutron star is compressed by the strong gravitational field and becomes degenerate, whereas in type Ia supernovae the nuclear fuel is the degenerate carbon and oxygen core of a Chandrasekhar mass white dwarf itself. In all three cases, accretion from a binary companion heats the material and triggers nuclear reactions. In the absence of an efficient cooling mechanism, T, and therefore $\dot{w}$, rises at an accelerating pace that is only stopped when all of the material is burned to nuclear ashes. A thermonuclear runaway begins. It is localized in a small region where the initial temperature fluctuation was highest, the so-called ignition region.

When a critical temperature T_c is exceeded, all of the fuel inside the ignition region is consumed almost instantaneously, and a thin reaction zone forms at the interface of burned and unburned material. It propagates into the surrounding fuel by one of two mechanisms: if the overpressure created by the heat of the burning products is sufficiently high, a hydrodynamical shock wave forms that ignites the fuel by compressional heating. A self-sustaining combustion front that propagates by shock-heating is called a detonation (cf figure 1). Detonations generally move supersonically, and therefore do not allow the unburned medium to expand before it is burned (this is important in the context of type Ia supernovae). Their speed depends only on the total amount of energy released per unit mass, ϵ. On the other hand, if the initial overpressure is too weak, the temperature gradient at the fuel–ashes interface steepens until an equilibrium between heat diffusion (carried out predominantly by electron–ion collisions) and energy generation is reached. The resulting combustion front consists of a diffusion zone that heats the fuel up to T_c, followed by a thin reaction layer where the fuel is consumed and energy is generated. It is called a deflagration or simply a flame and moves subsonically with respect to the unburned material (cf figure 2). Flames, unlike detonations, may therefore be strongly affected by turbulent velocity fluctuations of the fuel. Only if the unburned material is at rest, can a unique

laminar flame speed S_l be found which depends on the detailed interaction of burning and diffusion within the flame region. It can be estimated by assuming that in order for burning and diffusion to be in equilibrium, the respective time scales, $\tau_b \sim \epsilon/\dot{w}$ and $\tau_d \sim \delta^2/\kappa$, where δ is the flame thickness and κ is the thermal diffusivity, must be similar: $\tau_b \sim \tau_d$. Defining $S_l = \delta/\tau_b$, one finds $S_l \sim (\kappa\dot{w}/\epsilon)^{1/2}$, where $\dot{w}$ should be evaluated at $T \approx T_c$. This is only a crude estimate due to the strong T dependence of $\dot{w}$. Numerical solutions of the full equations of hydrodynamics including nuclear energy generation and heat diffusion are needed to obtain more accurate values for S_l as a function of ρ and fuel composition.

Flame instabilities and turbulent nuclear combustion

Even if the laminar, one-dimensional structure of flames and detonations is understood, one has to ask whether small perturbations of this structure grow in three-dimensional reality, i.e. whether the solution is hydrodynamically unstable (there are also non-hydrodynamical, one-dimensional flame instabilities which will not be discussed here). If it is, the perturbations may either grow to a finite size and stabilize, or grow until the fluid becomes fully turbulent. In either case, the exact mathematical description of the combustion front becomes very complicated or even impossible. Instead, phenomenological or statistical methods must be employed to model important global quantities such as the total extent, propagation speed and energy generation rate of the front. The following discussion will be limited to flames; although detonations are known to develop cellular instabilities, their relevance in astrophysical explosions has not been as clearly established as flame instabilities.

Let us first consider very thin flames, such that their internal structure can be neglected when observed on scales of the perturbation wavelength. These flames are unstable to the Landau–Darrieus (LD) instability which arises as a consequence of the density jump produced by thermal expansion within the flame, and is present whenever a density discontinuity moves subsonically in the direction of the higher density. The instability grows until a web of cellular structures forms and stabilizes the front against further growth of the perturbations. The LD instability therefore does not, in general, lead to the production of turbulence.

If the flame moves upward in a gravitational field, it is also subject to the Rayleigh–Taylor (RT) instability resulting from the buoyancy of the hot, burned fluid with respect to the dense, unburned material. Here, small perturbations grow until they form bubbles that begin to float upward. After a short time, bubbles of fuel and ashes with various sizes create a foamy RT mixing layer that continually grows in size. Secondary instabilities related to the velocity shear along the bubble surfaces may then lead to the production of turbulence.

The problem of turbulent combustion has been researched extensively in the engineering sciences in the context of car engines, turbines and chemical explosions. Owing to the nonlinearity of the underlying equations, the Navier–Stokes equations of FLUID DYNAMICS including reactions and diffusion, exact solutions are rarely obtainable. Even numerical simulations on supercomputers can only yield limited insight into the complexity of turbulent combustion. The main problem is the tremendous range of length scales that need to be observed (or solved for), ranging from the size of the largest turbulent eddy L (reaching some fraction of the stellar radius in the astrophysical case) down to the smallest one, which can be smaller than a millimeter. Since no computer is capable of resolving this range of scales, one has to resort to statistical or scaling approximations of those length scales that are not properly resolved. The most prominent scaling relation in the science of turbulence is Kolmogorov's law for the cascade of velocity fluctuations: it states that under the assumption of isotropy and statistical stationarity, the mean velocity v of turbulent eddies with size l scales as $v \sim l^{1/3}$. Given the velocity of large eddies, e.g. from computer simulations, one can use this relation to extrapolate the eddy velocity distribution down to smaller scales under the assumption of isotropic, fully developed turbulence.

Knowledge of the eddy velocity as a function of length scale is important to classify the burning regime of the turbulent combustion front. The ratio of the laminar flame speed and the turbulent velocity on the scale of the flame thickness, $K = S_l/v(\delta)$, plays an important role: if $K \gg 1$, the laminar flame structure is nearly unaffected by turbulent fluctuations. Turbulence does, however, wrinkle and deform the flame on scales l where $S_l \ll v(l)$, i.e. above the Gibson scale l_g defined by $S_l = v(l_g)$. These wrinkles increase the flame surface area and therefore the total energy generation rate of the turbulent front. One can define the turbulent flame speed, S_t, as the mean overall propagation velocity of the turbulent flame front (obviously, $S_t > S_l$). If the turbulence is sufficiently strong ($v(L) \gg S_l$) the turbulent flame speed becomes independent of the laminar speed (and therefore of the microphysics of burning and diffusion) and scales only with the velocity of the largest eddy: $S_t \sim v(L)$. Because of the unperturbed laminar flame properties on very small scales, and the wrinkling of the flame on large scales, the burning regime where $K \gg 1$ is called the 'corrugated flamelet regime'.

The opposite limit, $K \ll 1$, is the 'well-stirred reactor' burning regime. In this regime, a laminar flame structure ceases to exist because the fluid is stirred by turbulence on scales of δ and below. Nuclear reactions are no longer confined to thin layers but occur everywhere at once at varying intensities, depending on the local temperature and fuel concentration. The flame instabilities mentioned above are replaced by reactive convection as a source for the turbulence. Unlike the flamelet regime, the well-stirred reactor regime does not give rise to a simple estimate for S_t, as the details of burning and diffusion continue to matter. It is, however, accessible to simplified

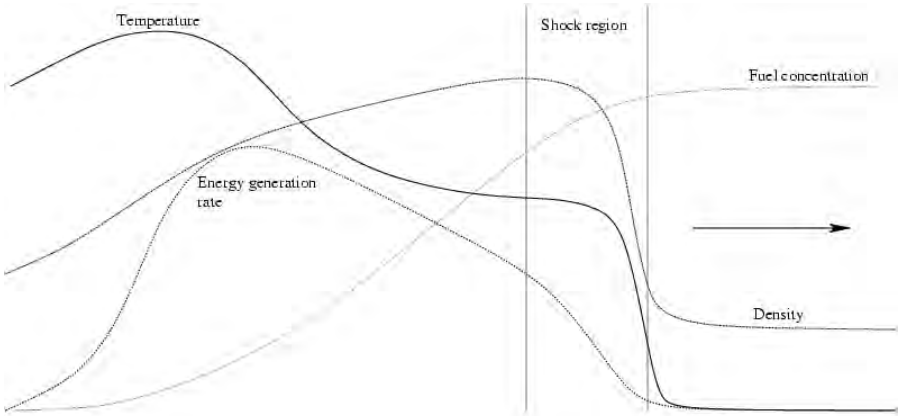

Figure 1. Sketch of the variation of flow properties across a detonation front.

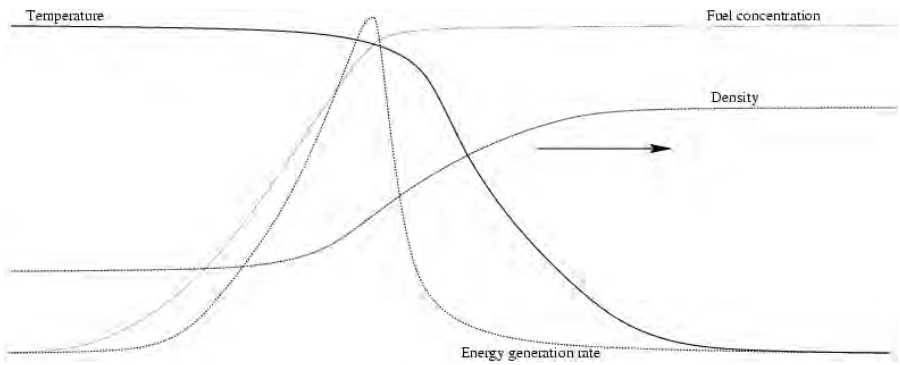

Figure 2. Sketch of the variation of flow properties across a deflagration front.

treatments by approximating the effect of turbulent mixing with the help of statistical methods.

The intermediate case of $K \approx 1$ is called the 'distributed burning regime' and is the least understood of all three. It recently received some attention in the framework of type Ia supernova models suggesting that the turbulent deflagration front, after beginning its life in the flamelet regime, may turn into a detonation (deflagration–detonation–transition, DDT) when it passes through the distributed burning regime. It is very difficult to study theories that involve distributed burning, since neither nuclear burning and diffusion nor turbulent mixing can be properly described by simplified models in this regime. Phenomenologically, the laminar flame structure is believed to be disrupted by turbulence and to form a distribution of reaction zones with various lengths and thicknesses.

Burning regimes in astrophysical flashes

This section gives a brief summary of the burning regimes of nuclear combustion fronts that are currently believed to occur in the three most studied astrophysical flashes: novae, x-ray bursts and type Ia supernovae.

In novae, hydrogen accreted onto a white dwarf star burns explosively. Even at the high temperatures $T \approx 3 \times 10^8$ K that may be reached in nova outbursts, τ_b for hydrogen burning in the CNO cycle is larger than the turnover time scale of turbulent eddies driven by the convective instability of the hot burning region at the base of the cold hydrogen envelope. Consequently, $K \ll 1$, and the burning proceeds in the well-stirred reactor regime. Additional carbon enrichment, for instance caused by convective dredge-up of white dwarf material, may locally enhance the burning rate significantly by acting as a catalyst for the nuclear reactions.

X-ray burst models invoke the nuclear runaway of accreted hydrogen, helium or a mixture of both on the surface of a neutron star. Very little is known about the propagation mode and burning regime of the combustion front. In the case of pure helium flashes, the front will most likely propagate as a convectively driven turbulent deflagration or even a detonation. An additional complication is the possible presence of dynamically important strong magnetic fields.

The currently most successful model for type Ia supernovae involves the thermonuclear explosion of a Chandrasekhar mass carbon–oxygen white dwarf. Here, it is known from spectroscopical observations of the explosion products that the star needs to expand before being consumed by the combustion front, ruling out the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

possibility of a single, centrally ignited detonation. If the explosion begins as a deflagration, the flame front immediately becomes turbulent due to the RT instability. Until the density has declined by roughly a factor of 100, the front is in the flamelet regime and therefore depends only weakly on the microphysics of burning and diffusion. The final fate of the turbulent flame front is still the subject of active research: it may (a) release a sufficient amount of energy to power the explosion exclusively by turbulent combustion, (b) transition into a detonation (delayed detonation) upon entering the distributed burning regime, or (c) fail to release enough energy to unbind the star, whereupon it re-collapses and possibly ignites a detonation (pulsational detonation).

Nuclear Processing

Solar abundances, s-, r- and p-nuclei, reaction networks, thermonuclear reactions

Nuclear processing is the of the heavy elements (better, ISOTOPES) with mass numbers $A > 60$ in stars by thermonuclear non-explosive as well as explosive breeding processes. The fuel and seed material are gravitationally contained in the hot interior of the star. Efficient breeding of heavy nuclei is possible with a fuel of neutral nuclear particles, i.e. neutrons and photons. The heavy isotopic abundances are generated by processing iron seed with neutrons (bulk of material) and by reprocessing so-formed heavy abundances under shock heating. The isotopic abundances created in the stellar cauldrons are ejected into the interstellar medium.

The solar system is the object of the universe which provides the most complete set of high-quality cosmic abundance data. It is understood that solar system material is made of the ashes of many nucleosynthetic events that have been mixed in the interstellar medium before the formation of the solar system. The SOLAR ABUNDANCES are chiefly extracted from the spectrum of the Sun and from primitive METEORITES of unfractionized material (Anders and Grevesse 1989; Palme and Beer 1993).

The origin of the heavy isotopes can be understood with only three different nuclear formation processes, the s-, r- and p-processes (figure 1)(see, e.g., the reviews of Burbidge *et al* 1957; Meyer 1994). In the solar abundance distribution the nuclei of the s-process population show up in sharp maxima at mass numbers 88, 138 and 208 which correspond to isotopes of the magic neutron numbers 50, 82 and 126. The s-process nuclei are made by a neutron capture process (successive neutron captures) on a slow time scale. The synthesis path of the isotopes ${}^{A}Z$ with A the mass and Z the element numbers lies in the valley of β stability of the $Z,A–Z$ plane (figure 2). The nuclei of the r-process population show up in broader maxima near the mass numbers 80, 130 and 195. The r-process nuclei including ^{232}Th and ^{235,238}U are formed by a neutron capture process on a rapid time scale. The synthesis path is located far off the β stability valley at the neutron-rich side of the $Z,A–Z$ plane (figure 2). The peak structures are associated with the magic neutron shells at 50, 82 and 126 as well. The shift to smaller mass numbers compared with the s-process peaks and the broader structure of the peaks indicate that the abundances are the decay products of the originally synthesized unstable neutron-rich nuclei. Additionally there is an ensemble of neutron-deficient isotopes with considerably smaller abundances than r- and s-isotopes. These rare isotopes form a distribution with peaks at $A = 92$ and 144 which are also associated with the magic neutron shells 50 and 82. The p-abundances are suggested to be made from s- and r-process seeds shifted by photodisintegration reactions to unstable neutron-deficient isotopes. Post-p-process β decay then leads eventually to the abundances of the p-nuclei (figure 2).

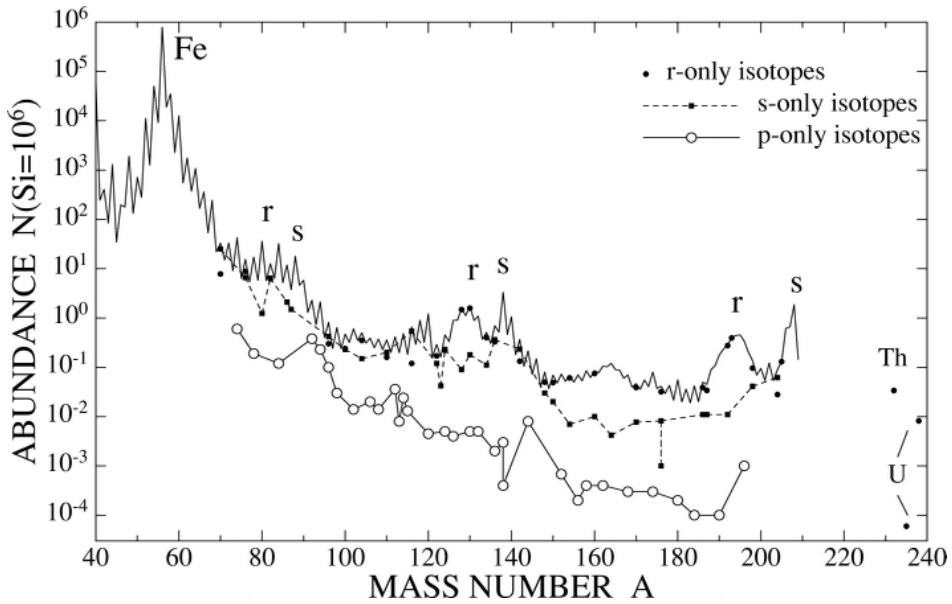

Figure 1. Solar system abundances by mass number of the heavy isotopes. The double peaks at A =80,88, 130,138 and 195,208 are from r- and s-process nucleosynthesis. The abundances of isobars which are added in the global curve are also shown separately as full circles (r-only isotopes) and full squares (s-only isotopes connected by a dashed line). The p-process abundance population (open circles) is significantly lower than the s- and r-process. (From Palme and Beer 1993.)

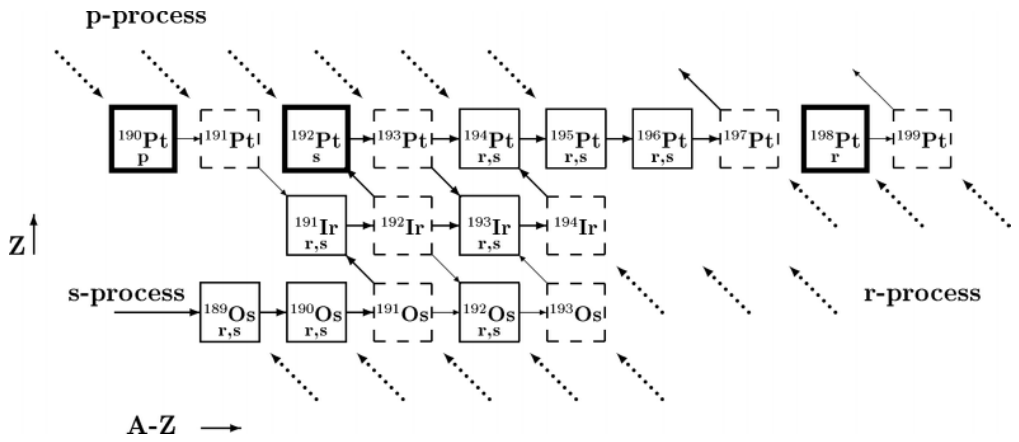

Figure 2. A section of the chart of nuclides in the stability valley and the s-process path through the stable and radioactive isotopes in this mass region (solid and dashed boxes). The p-only ^{190}Pt and r-only ^{198}Pt nuclei not on the path are destroyed in the s-process. At ^{191}Os, ^{192}Ir and ¹⁹³Pt the s-process flow is branched because of competition between β decay and neutron capture. The p- and r-process occurs off the stability valley. Abundance contributions to the stable isotopes are obtained via isobaric β decay chains. This flow of post r- and p-process is indicated by the inclined dotted arrows. The s-only ^{192}Pt isotope is shielded from r-abundance contributions.

The network equations can be written in the form

$$\frac{dN}{dt} = -\ (\text{sum of destruction terms}) + (\text{sum of creation terms}). \quad (1)$$

In s- and r-process nucleosynthesis these terms are essentially proportional to neutron capture reaction rates, λ^{n}, and beta decay rates λ^{β} of the types β^-, β^+ and electron capture decay; in the p-process to photodisintegration rates of neutrons, protons and α particles, $\lambda^{\gamma n}$, $\lambda^{\gamma p}$ and $\lambda^{\gamma\alpha}$, respectively. The neutron capture rate is given by $\lambda^{n} = n_n\langle\sigma_{n\gamma}v\rangle$ with the in-general time-dependent neutron density n_n and the radiative capture cross section $\sigma_{n\gamma}$ folded with the Maxwell–Boltzmann velocity distribution of the particles at the specified thermal energy kT, k being the Boltzmann constant and T the temperature. The radiative proton and alpha capture rates are defined equivalently. As for the majority of heavy isotopes $\sigma_{n\gamma}$ follows a v^{-1} energy dependence λ^{n} is approximately independent of temperature. It is also practice to form a Maxwellian average capture (MAC) cross section $\sigma = \langle\sigma_{n\gamma}v\rangle/v_T$ by dividing $\langle\sigma_{n\gamma}v\rangle$ by the thermal velocity $v_T = (2kT/\mu)^{1/2}$ with the reduced mass $\mu = M_A M_n/(M_A + M_n)$. M_n and M_A are the neutron mass and mass of the isotope, respectively (Beer *et al* 1992). Then λ^{n} can be expressed as $\lambda^{n} = n_n v_T \sigma$.

The photodisintegration rates $\lambda^{\gamma n}$, $\lambda^{\gamma p}$ and λ^{α} are related to the inverse radiative capture reactions by the requirements of statistical physics and thermodynamics. For example the (γ, n) rate is related to the (n, γ) reaction by

$$\lambda^{\gamma n}_{A,Z} = \frac{n_n N_{A-1,Z}}{N_{A,Z}}\langle\sigma_{n\gamma}v\rangle_{A-1,Z}. \quad (2)$$

The equilibrium concentrations of the neutrons n_n and the particles $N_{A,Z}$, $N_{A-1,Z}$ which form a non-relativistic, non-degenerate Boltzmann gas at temperature T are described by a nuclear Saha equation

$$\frac{n_n N_{A-1,Z}}{N_{A,Z}} = \frac{(2\pi\mu kT)^{3/2}}{h^3}\frac{g_n g_{A-1,Z}}{g_{A,Z}} \times \exp(-B_{n,A,Z}/kT) \quad (3)$$

with the binding energy $B_{n,A,Z}$ of the neutron in the nucleus ^{A}Z, h Planck's constant, μ the reduced mass of neutron and isotope ^{A-1}Z, $g_n = 2$ the statistical spin factor of the neutron, and with $g_{A,Z}$ the partition function for isotope ^{A}Z

$$g_{A,Z} = \sum_i (2j_{i,A,Z} + 1)\exp(-E_{i,A,Z}/kT).$$

The summation is over all excited states with spin $j_{i,A,Z}$ and energy $E_{i,A,Z}$.

s-Processing

The canonical s-process

According to the concept of equation (1) the buildup of nuclei in the s-process is formulated by

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$\frac{dN_{s,A,Z}}{dt} = \lambda^{n}_{A-1,Z} N_{s,A-1,Z} - \lambda^{n}_{A,Z} N_{s,A,Z} + \lambda^{\beta}_{A-1,Z} N_{s,A-1,Z} - \lambda^{\beta}_{A,Z} N_{s,A,Z} + \text{termination terms due to alpha decay at } A > 209 \tag{4}$$

where λ^{β} is zero if ${}^{A-1}Z$ and/or ${}^{A}Z$ is stable. In the case of an unstable isotope ${}^{A}Z$ and an s-process neutron density n_n between 10^7 and 10^9 cm^{-3} corresponding to capture lifetimes between 35 yr and 128 days for an MAC cross section of 300 mbarn the condition $\lambda^{n}_{A,Z} < \lambda^{\beta}_{A,Z}$ holds in general; then the term with $\lambda^{n}_{A,Z}$ is neglected and the term $\lambda^{\beta}_{A,Z} N_{s,A,Z}$ quickly transforms into $\lambda^{n}_{A,Z+1} N_{s,A,Z+1}$, the s-process synthesis path has reached a higher Z and remains in the valley of β stability of the Z,A–Z plane. However, as β decay rates near the stability valley can vary over many orders of magnitude (see NUCLEAR BETA DECAY), there are a number of cases where λ^{β} is comparable with λ^{n} and then the synthesis path is branched (figure 2).

Starting in equation (4) from ^{56}Fe as the major seed each isotope is formed and destroyed by neutron capture and β decay. In terms of a convenient notation $\psi_A = \sigma_A N_{s,A}/N_{\text{tot},0}$ with σ_A the MAC cross section for neutron capture of isotope A, N_A the abundance of isotope A on the synthesis path from ^{56}Fe to ^{209}Bi and N<inf>tot,0</inf> the total seed abundance, we formulate a set of differential equations dependent on the exposure $\tau = \int_0^t n_n v_T \, dt$:

$$\begin{aligned}
&\frac{1}{\sigma_{56}}\frac{d\Psi_{56}}{d\tau} = -\Psi_{56} \\
&\vdots \\
&\frac{1}{\sigma_A}\frac{d\Psi_A}{d\tau} = \Psi_{A-1} - \Psi_A \\
&\vdots \\
&\frac{1}{\sigma_{A'}}\frac{d\Psi_{A'}}{d\tau} = \Psi_{A'-1} - \left[1 + \frac{\lambda^{\beta}_{A'}}{\lambda^{n}_{A'}}\right]\Psi_{A'} \\
&\frac{1}{\sigma_{A''}}\frac{d\Psi_{A''}}{d\tau} = \frac{\lambda^{\beta}_{A'}}{\lambda^{n}_{A'}}\Psi_{A'} - \Psi_{A''} \\
&\vdots \\
&\frac{1}{\sigma_{A'''}}\frac{d\Psi_{A'''}}{d\tau} = -\Psi_{A'''} \\
&\vdots
\end{aligned} \tag{5}$$

The isotope A is a typical stable nucleus on the unique synthesis path, whereas A' represents a radionuclide with a β decay rate $\lambda^{\beta}_{A'}$ in competition with the neutron capture rate $\lambda^{n}_{A'} = \sigma_{A'} n_n v_T$. Note that the occurrence of radionuclide A' with coefficients containing explicitly the neutron density n_n requires a constant neutron density. Otherwise, the time dependence of n_n must also be considered.

The stable isotope A'' is, therefore, formed by the s-process in proportion to this competition. The quantities ψ_{56} and $\psi_{A''}$ refer to the seed-only isotopes ^{56}Fe and A''', respectively. The isotopes which feel the neutron density explicitly are the few located within a branch (see figure 2). Equations (5) can be written in matrix form $d\psi/d\tau = \mathbf{M}\psi$ with $\mathbf{M}$ the coefficient matrix. Equations (5) can be solved by special numerical techniques or analytically. The matrix $\mathbf{M}$ is diagonalized: $\mathbf{M} = \mathbf{ABA}^{-1}$. With $\mathbf{B}$ the diagonal matrix the equation is solved with $\exp(\mathbf{M}\tau) = \mathbf{A}\exp(\mathbf{B}\tau)\mathbf{A}^{-1}$. The matrix $\mathbf{A}$ is the matrix of eigenvectors with respect to the eigenvalues contained in $\mathbf{B}$. The solution is given by

$$\mathbf{N}(\tau) = (\boldsymbol{\sigma})^{-1}\mathbf{A}\exp(\mathbf{B}\tau)\mathbf{A}^{-1}\boldsymbol{\sigma}\mathbf{N}_0 \tag{6}$$

with $\boldsymbol{\sigma}$ the diagonal matrix of the MAC cross sections and $\mathbf{N}_0$ the vector of seed abundances. Special solutions to be derived from this ansatz are the Bateman solution which does, however, not include branchings. The solution $\mathbf{N}(\tau)$ for single exposures is relevant to special s-process scenarios, s-processing of nuclei in the mass range 56–90 (weak s-process, figure 3) and from sulfur to calcium.

The s-process formation of the bulk of heavy isotopes ($85 < A < 209$) (main s-process, figure 3) is not the result of one exposure τ but a superposition of exposures $\rho(\tau)$. The differential equations describing the synthesis have to be integrated over that distribution. For a stable isotope A on the unique synthesis path we obtain

$$\begin{aligned}
&\frac{1}{\sigma_A}\int_0^\infty \rho(\tau)\frac{d\Psi_A(\tau)}{d\tau}\,d\tau \\
&\quad = \int_0^\infty \rho(\tau)\Psi_{A-1}(\tau)\,d\tau - \int_0^\infty \rho(\tau)\Psi_A(\tau)\,d\tau.
\end{aligned} \tag{7}$$

Partial integration of the left-hand side of equation (7) yields

$$\begin{aligned}
&-\frac{1}{\sigma_A}\Psi_A(0)\rho(0) - \frac{1}{\sigma_A}\int_0^\infty \Psi_A(\tau)\frac{d\rho(\tau)}{d\tau}\,d\tau \\
&\quad = \sigma_{A-1}N_{s,A-1} - \sigma_A N_{s,A}.
\end{aligned} \tag{8}$$

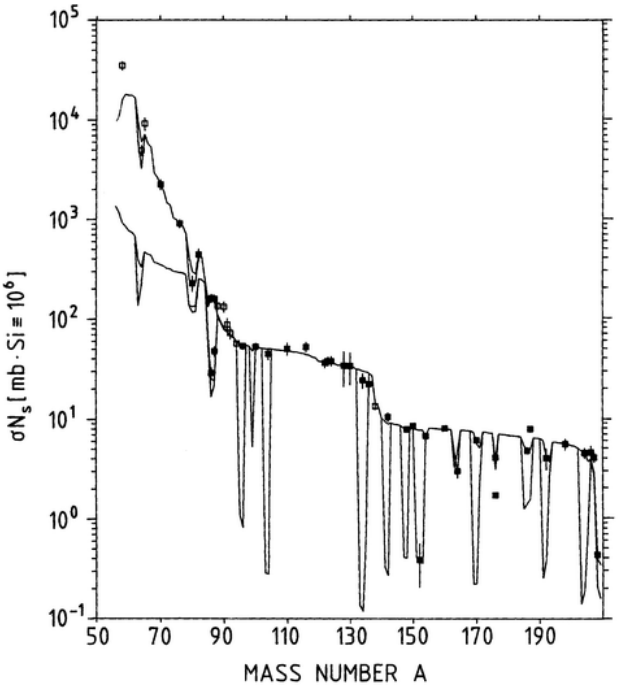

Figure 3. σ*N* curve versus mass number, characterized by a ledge precipice structure at nuclei with magic neutron shells (*A* = 88, 138 and 208) and flat portions between with approximately equilibrium abundance flow. The negative spikes indicate branchings. A weak s-process component is superimposed responsible for the steep increase for $A < 90$. Not all empirical data points shown are used to adjust the curves. Full symbols are s-only nuclei. Open symbols are data at the magic neutron numbers 50 and 82 (^{88}Sr, the Zr isotopes and ^{138}Ba) with dominant s-process abundance as well as the data points ^{58}Fe, ^{64}Ni and ^{65}Cu. Other empirical data too low (^{176}Lu) or too high (^{187}Os, ^{206,207,208}Pb) are affected by long-lived radioactive decay and in the case of ^{206,207,208}Pb contain extra r-process contributions from transbismuth nuclei and from an additional strong s-process exposure. (From Beer 1991.)

As the empirical σN_s values of s-only isotopes are decreasing with increasing mass number a monotonically decreasing function $\rho(\tau)$ is required. The form $d\rho(\tau)/d\tau = -\tau_0^{-1}\rho(\tau)$ with the mean exposure τ_0 yields analytical solutions. From equation (8) we obtain the recursion formula

$$\left(1+\frac{1}{\tau_0\sigma_A}\right)\sigma_A N_{s,A} = \sigma_{A-1}N_{s,A-1} + \tau_0^{-1}N_{A,0} \tag{9}$$

and in the same way from the two differential equations describing a branching at the nucleus *A*' (see equation (5)) the recursion formulae

$$\left(1+\frac{\lambda^{\beta}_{A'}}{\lambda^{n}_{A'}}+\frac{1}{\tau_0\sigma_{A'}}\right)\sigma_{A'}N_{s,A'} = \sigma_{A'-1}N_{s,A'-1}$$

$$\left(1+\frac{1}{\tau_0\sigma_{A''}}\right)\sigma_{A''}N_{s,A''} = \frac{\lambda^{\beta}_{A'}}{\lambda^{n}_{A'}}\sigma_{A'}N_{s,A'} + \tau_0^{-1}N_{A'',0}. \tag{10}$$

Finally for an isotope *A*''' not lying on the synthesis path we obtain

$$\left(1+\frac{1}{\tau_0\sigma_{A'''}}\right)\sigma_{A'''}N_{s,A'''} = \tau_0^{-1}N_{A''',0}. \tag{11}$$

The quantity $N_{A,0}$ represents the seed abundance of the nuclide *A*. The exposure distribution $\rho(\tau)$ is given by $\rho(\tau) = G\exp(-\tau/\tau_0)$ with $G = N_{\mathrm{tot},0}/\tau_0$, $N_{\mathrm{tot},0}$ the total seed abundance. This form was suggested to arise from the effect of galactic reprocessing, i.e. the total exposure experienced by some fraction of material would relate to the number of times that material had been processed through stars (Seeger *et al* 1965).

We write the final result for all isotopes involved in the s-process in the convenient matrix form (Ward *et al* 1976; Beer *et al* 1997)

$$(\mathbf{M}-\mathbf{U}\tau_0^{-1})\sigma\mathbf{N} = (-\tau_0)^{-1}\sigma\mathbf{N}_0 \tag{12}$$

where **U** is the unity matrix. The vector $\mathbf{N}(\tau_0)$ represents the wanted abundances. Normally a solar seed abundance distribution $\mathbf{N}_\odot$ is used and a seed fraction F_{seed} defined by $\mathbf{N}_0 = F_{\mathrm{seed}}\mathbf{N}_\odot$. If only the dominant ^{56}Fe is taken as seed material, the vector of solar seeds $\mathbf{N}_0$ reduces to a scalar as only the first element is non-zero $N_0(1) = F_{\mathrm{seed}}N_\odot$ (^{56}Fe) (Ward *et al* 1976). Without branchings and ^{56}Fe as the only seed material, $\sigma_A N_{s,A} = \xi_A\xi_{A-1}\ldots\xi_{56}\tau_0 - {}^1\mathrm{N}_0(1)$ is simply the product of propagators $\xi;_A = (1 + (\sigma_A\tau_0)^{-1})^{-1}$. An s-process analysis using the analytical solutions of Ward *et al* (1976) is shown in figure 3 (Beer 1991). To treat reprocessing the s-process solutions of equations (6) and (12) can be used as seed distribution input for s-processing by a second exposure (Beer *et al* 1997).

In the solutions equations (9), (10) and (11) of the main component s-process the efficiency of the s-process exposure of the isotopes on and beyond the synthesis path depends on the size of their cross sections (Beer *et al* 1997). For $\sigma_A \gg \tau_0^{-1}$ stable isotopes on the path are characterized by the well-known correlation, $N_A \sim \sigma^{-1}{}_A$

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(equation (9)), and stable isotopes beyond the path are destroyed, $N_{A''} \approx 0$ (equation (11)). For $\sigma_A \approx \tau_0^{-1}$ stable isotopes on and beyond the path are sensitive to the average exposure τ_0 (bottle-neck or waiting-point isotopes) and may contain information on the burning temperature of the neutron source. The synthesis is controlled by these isotopes. For $\sigma_A \ll \tau_0^{-1}$ the abundances of stable isotopes on the path become independent of the MAC cross section and are determined by τ_0 which is a function of temperature. The seed abundances of isotopes beside the path are practically unaffected. The MAC cross sections of the isotopes on the synthesis path have been compiled and tabulated as a function of temperature (Bao *et al* 2000). For unstable isotopes with $\lambda_{A'}^{\beta} \approx \lambda_{A'}^{n} = \sigma_{A'} n_n v_T$ a branching in the synthesis path occurs which constrains n_n. In addition the β decay rate can be a strong function of temperature and even electron density which in turn depends on the mass density of the stellar environment; then also temperature T and mass density are constrained (figure 2). Calculated values of the β decay rate $\lambda_{A'}^{\beta}$ as a function of the temperature and electron density for the significant branch point isotopes have been published (Takahashi and Yokoi 1987).

Experimental and observational constraints, stellar models

The s-processing of the heavy nuclei with the canonical s-process using a best set of chiefly experimentally determined input parameters (figure 3) requires two components, the weak and main components. Each component is globally characterized by the fraction of seed material and the neutron exposure. The bottle-neck isotopes Sr, Y, Zr, Ba, La, Ce and ^{208}Pb with magic neutron shells at 50, 82 and 126 control the main s-process synthesis. The processing can go up to Pb and Bi if ^{138}Ba is bypassed; ^{138}Ba is, next to ^{208}Pb, the isotope with the smallest MAC cross section on the unique synthesis path ($\sigma(^{138}\text{Ba}) = 4.0\pm0.2$ mbarn, $\sigma(^{208}\text{Pb}) = 0.36\pm0.03$ mbarn at $kT = 30$ keV). The required mean exposure must therefore be comparable with $\tau_0(kT = 30 \text{ keV}) \approx \sigma(^{138}\text{Ba})^{-1} = 0.25$ mbarn^{-1} (value found in the calculations $\tau_0(kT = 30 \text{ keV}) \approx 0.30$ mbarn^{-1}) (Beer *et al* 1997). Only the MAC cross section of ^{208}Pb is still smaller and requires, therefore, an extra-strong exposure. At the nuclei with a magic neutron shell, abundance is accumulating because of the small destruction rate. For the majority of nuclei lying in flat portions of the σN curve with practically steady flow conditions the $N_A \approx \sigma_A^{-1}$ correlation is approximately fulfilled. From the local abundance structures of branchings, neutron and mass density and temperature are deduced ($n_n = (2\text{–}4) \times 10^8$ cm^{-3}, $\rho = (2.6\text{–}13) \times 10^3$ g cm^{-3} $kT = 25\text{–}30$ keV).

The basic questions of s-processing to be clarified are the possible stellar site or sites and the neutron source or sources which produced the solar s-abundances. Weak s-processing can be located in the STELLAR EVOLUTION of massive stars ($M \geq 15M_\odot$) from the core He burning to the subsequent shell C and Ne burning phases. Neutrons are provided by the ^{22}Ne reaction. The ^{22}Ne being produced from the ashes of the pre-existing nuclei of the CNO cycle via the reaction sequence $^{14}\text{N}(\alpha,\gamma)^{18}\text{F}(\beta^+)^{18}\text{O}(\alpha,\gamma)^{22}\text{Ne}$ makes the s-process yields increase with metallicity. In the stellar model calculations the accuracy of the ^{22}Ne(α, n) and competing ^{22}Ne(α,γ) rates is crucial for the final results.

For the main s-process component the temperature estimated with the canonical s-process would suggest also the ^{22}Ne(α, n) neutron source and shell He burning in the stellar interior of thermally pulsing intermediate-mass stars (IMSs; with $4 < M/M_\odot < 8$) as the s-process site. The exponential exposure distribution was shown to derive from the neutron release during the convective instabilities in the He shell (Ulrich 1973). It is obtained if the total exposure of the seed material occurs in a series of individual neutron exposures, where a decreasing fraction of seed material $r, r^2, r^3, \ldots, r^l$ ($r < 1$) obtains an increasing number of exposures $\Delta\tau$, 2 $\Delta\tau$, 3 $\Delta\tau$,…,$l\Delta\tau$. The exponential exposure distribution $\rho(\tau = l\Delta\tau)$ is given as follows: $\rho(\tau = l\Delta\tau) = Gr^l = G[\exp(-\Delta\tau/\tau_0)]^l = G\exp(-l\Delta\tau/\tau_0) = G\exp(-\tau/\tau_0)$ (Ulrich 1973). This would relate the mean exposure τ_0 to r and $\Delta\tau$ (note the equivalent arguments in the case of reprocessing in stars during the galactic s-process enrichment). However, IMSs which could provide this scenario are too rare and the predicted temperature and neutron densities were far too high to reproduce the abundance patterns of the s-process branchings. In addition the increase of the s-process yields with metallicity associated with the ^{22}Ne(α, n) neutron source and an enhancement of ^{25}Mg in these stars are not observed.

Since the discovery of s-process Tc in the stellar atmospheres of RED GIANTS (the short 2.1×10^5 yr half-life of ^{99}Tc suggests Tc nucleosynthesis in the star itself) elemental s-process abundances from Rb to Nd were found and studied in many low-mass asymptotic giant branch (AGB) stars. The s-process enrichment in these cool MS and S type stars (surface temperatures between 2800 and 3800 K) is considered intrinsic in contrast to s-enhancements in the hotter Ba stars interpreted to originate from mass overflow in a binary system. The observation of Rb and ^{96}Zr in the MS and S stars gives constraints for a low neutron density in accordance with the ignition of the ^{13}C(α, n) neutron source at a temperature of only $T_8 = 1$. Additional evidence for a dominantly primary ^{13}C s-process neutron source comes from studies of the observed galactic enrichment of s-process yields which are independent of metallicity. From very low metallicity stars very strong neutron exposures can then be expected which are necessary to build up the abundance of ^{208}Pb.

The idea that the solar s-process abundances are a mixture of s-process yields from different stellar sources

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

is also supported by cosmochemistry. The primitive unfractionized meteorites which represent well in their total composition the solar abundance mixture also carry presolar SiC grains containing elements with preserved isotopic abundance patterns of the s-process. These grains are supposed to be formed in the cicumstellar environments of low-mass AGB stars. Evidence for this s-process origin is the correlation between the isotopic ratios and the inverse of the corresponding MAC cross sections (e.g. s-Xe, s-Nd). The isotopic ratios of s-Kr, s-Sr and s-Ba which are sensitive to details of the s-process neutron exposure show additional variations for different grains. The scatter of the data with regard to the isotopes ^{86}Kr, ^{88}Sr and ^{138}Ba is interpreted to indicate an origin from a variety of stars with different masses and neutron exposures and suggests that the solar system s-process abundances are indeed an average over many sources.

Low-mass thermally pulsing AGB stars ($1 < M/M_{\odot} < 3$), where the ^{13}C(α,n) reaction is most likely the dominant neutron source, are therefore the most favored site for the main s-process component. The ^{13}C is supposed to be produced in a thin layer of the He shell by the reaction chain ^{12}C(p,γ)^{13}N(β^{+})^{13}C from primary ^{12}C with protons which have penetrated the envelope by diffusion or semiconvection. The formation and size of the ^{13}C pocket which are crucial for the quantitative description are still treated in a parametrized way (Gallino *et al* 1998). It should be noted that in these stellar model calculations the solar s-process abundances are reproduced for the supposed model star with an exposure distribution that is much more complex than the exponential distribution of neutron exposure. In order to meet the constraints on s-process temperature imposed by the branching analysis of the canonical s-process the ^{22}Ne neutron source must also be invoked marginally towards the end of the thermal pulse, providing a small additional exposure to reset the abundances of the branch point thermometer isotopes to the higher temperature of the ^{22}Ne(α, n) ignition. As the average MAC cross section in the mass region of the s-process thermometers is of the order of 300 mbarn this reprocessing is possible for a mean exposure of $\tau_0(kT = 30\ \text{keV}) \approx 1/300 = 0.0033$ mbarn^{-1} without affecting the global structure of the s-process determined by the very small cross sections of the bottle-neck isotopes (see also figure 4). Evidence for the ^{13}C(α, n) source is also obtained from a significant temperature dependence of the neutron capture rate λ^{n} of some bottle-neck isotopes (e.g. ^{142}Nd, ^{208}Pb; see also the general temperature dependence of λ^{n}). The stellar model is put to the test by laboratory neutron capture measurements (see, e.g., Guber *et al* 1997, Koehler *et al* 1998, Arlandini *et al* 1999).

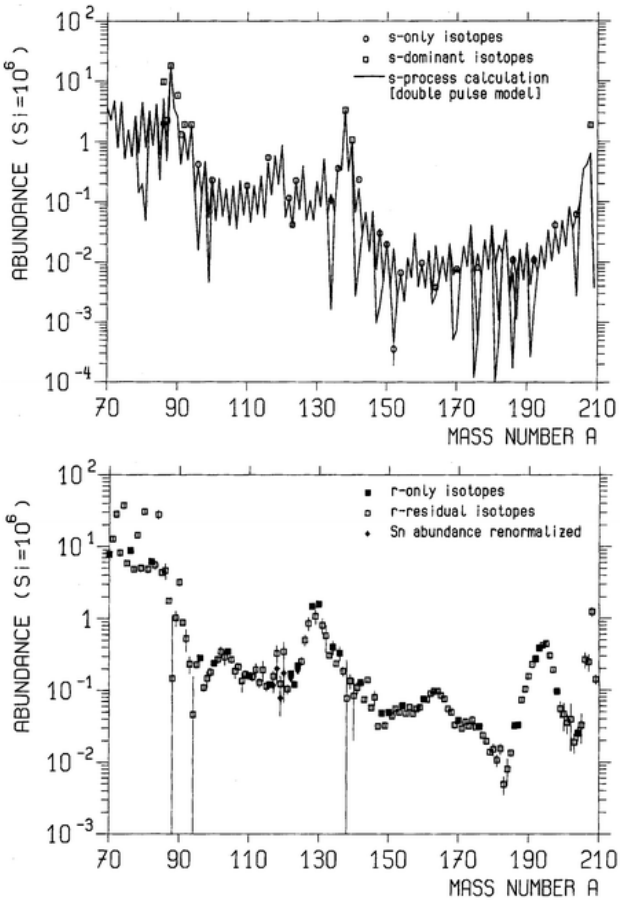

Figure 4. Decomposition of the solar abundances. (Top) Parametrized s-process abundance calculation with combined neutron exposure at $kT = 8$ and 28 keV associated with the ^{13}C(α, n) and ^{22}Ne(α, n) neutron sources, respectively. The calculation is a fit to the empirical s-only isotopes shown as full symbols. The typical signature of the s-process, an odd–even abundance staggering, is visible. (Bottom) The empirical r-process distribution $N_r = N_{\odot} - N_s$ exhibits a smooth behavior. The r-only isotopes are shown as full symbols. Note that for the similarities of s- and r-isotopes produced in about equal amounts no obvious genetic relation is known. (From Beer *et al* 1997.)

r-Processing

Empirical r-process distribution

The empirical r-process distribution is obtained by subtraction of the calculated s-contributions from the solar abundances. Possible p-process contributions are small and were, therefore, neglected:

$$N_{r,A,Z} = N_{\odot,A,Z} - N_{s,A,Z}. \tag{13}$$

The so-constructed r-process distribution (figure 4) with abundance maxima at A = 80, 130 and 195 (the waiting

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

points) related to the magic neutron shells at 50, 82 and 126 is fundamental. It forms the basis for comparisons with r-process model calculations. Tables of the calculated empirical r-process distribution have been reported elsewhere (Käppeler *et al* 1989; Palme and Beer 1993; Beer *et al* 1997; Arlandini *et al* 1999).

The canonical r-process

The general equation for the r-process is

$$\begin{aligned}\frac{\mathrm{d}N_{\mathrm{r},A,Z}}{\mathrm{d}t} &= \lambda^{\mathrm{n}}_{A-1,Z}N_{\mathrm{r},A-1,Z} - \lambda^{\mathrm{n}}_{A,Z}N_{\mathrm{r},A,Z} \\ &+ \lambda^{\beta}_{A-1,Z}N_{\mathrm{r},A-1,Z} - \lambda^{\beta}_{A,Z}N_{\mathrm{r},A,Z} \\ &+ \lambda^{\gamma\mathrm{n}}_{A-1,Z}N_{\mathrm{r},A-1,Z} - \lambda^{\gamma\mathrm{n}}_{A,Z}N_{\mathrm{r},A,Z} \\ &+ \text{termination terms due to fission for } A > 260.\end{aligned} \tag{14}$$

Successive neutron captures in a thermonuclear environment ($n_{\mathrm{n}} > 10^{20}$ cm^{-3}, $T > 10^{9}$ K) will continuously build up for each isotopic chain more and more neutron-rich isotopes on a rapid time scale (10^{-4} s) compared with the much longer β decay half-lives (10^{-1}–10^{-3} s) (λ^{n}>λ^{β}). This goes on until an equilibrium is reached via the reactions

$$^{A-1}Z + \mathrm{n} \rightleftharpoons {}^{A}Z + \gamma. \tag{15}$$

This is because continuous neutron capture leads to nuclei with decreasing neutron binding energy. This process will go on until a neutron binding energy of B_{n} = 2–4 MeV is reached because of the incidence of (γ, n) reactions at the temperature of the thermonuclear environment. If this point is reached with $\lambda^{\mathrm{n}}_{A,Z} \approx \lambda^{\gamma\mathrm{n}}_{A-1,Z}$ and

$$\frac{\mathrm{d}N_{\mathrm{r},A,Z}}{\mathrm{d}t} = \lambda^{\beta}_{A,Z-1}N_{\mathrm{r},A,Z-1} - \lambda^{\beta}_{A,Z}N_{\mathrm{r},A,Z} \tag{16}$$

then the isotopes have to wait for β decay to isotopes with $Z + 1$ where quickly a new different (n, γ) ⇌ (γ, n) equilibrium is established. At the magic neutron shells 50, 82 and 126 β decays are long and therefore large abundances are accumulated. In (n, γ) ⇌ (γ, n) equilibrium the relative abundances for isotopes of a given element are determined by the properties of a Boltzmann gas at temperature T. The nuclear abundances and the neutron density are related by a nuclear Saha equation (3). Via equation (3) the distribution of nuclei of an isotopic chain Z is determined. We can describe the abundance flow from one isotopic chain to the next as (Seeger *et al* 1965)

$$\begin{aligned}\frac{\mathrm{d}N_{\mathrm{r},Z}}{\mathrm{d}t} &= \sum_{A}\lambda^{\beta}_{A,Z-1}N_{\mathrm{r},A,Z-1} - \sum_{A}\lambda^{\beta}_{A,Z}N_{\mathrm{r},A,Z} \\ &= \lambda^{\beta}_{Z-1}N_{\mathrm{r},Z-1} - \lambda^{\beta}_{Z}N_{\mathrm{r},Z}\end{aligned} \tag{17}$$

where we have defined

$$N_{\mathrm{r},Z} = \sum_{A}N_{\mathrm{r},A,Z} \qquad \text{and} \qquad \lambda^{\beta}_{Z} = \frac{1}{N_{\mathrm{r},Z}}\sum_{A}\lambda^{\beta}_{A,Z}N_{\mathrm{r},A,Z}.$$

Starting from ^{56}Fe as seed material the canonical r-process characterized by an ^{A-1}Z + n ⇌ ^{A}Z + γ equilibrium proceeds for constant neutron density and temperature along a contour line of constant neutron binding energy B_{n} towards the heavy nuclei according to the nuclear Saha equation. This binding energy B_{n} is estimated in the abundance peak maxima where the nuclear flow of a chain is concentrated mainly at one isotope pair with $N_{A-1,Z}/N_{A,Z} \approx 1$. Via the equations (17) for all element numbers Z on the r-process path a set of differential equations has to be solved by special numerical techniques as a function of duration time t_{dur}. With the solutions $N_Z(t_{\mathrm{dur}})$ and the relative isotopic abundances from the Saha equation (3) isotopic abundances are determined. The final r-process abundances of the stable isotopes are obtained in the post-r-process phase after radioactive decay. Therefore, besides the nuclear properties, i.e. binding energies and essentially β decay rates, the astrophysical quantities n_{n}, T and t_{dur} are sufficient to predict the whole set of r-abundances.

Experimental and observational constraints, stellar models

The unstable isotopes of the r-process path, 15–35 mass units off the valley of β stability in the Z,A–Z plane, are in their majority not studied directly in laboratory experiment. Theoretical nuclear physics has to provide a reliable data basis: mass formulas to determine r-process paths (equation (3)), β decay rates to solve equation (17) eventually with effective β decay rates, excited states properties of nuclei on the path for the partition functions (equation (4)), fission barriers and yields to assess the termination of the r-process, β delayed neutron emission and fission and α decay half-lives for the post r-process phase to obtain the r-process yield at the stable isotopes. To improve the applied nuclear mass formulas quenching of shell effects was suggested. This led to considerably better reproductions of the r-abundances around A = 120 and 140. An important clue to an understanding of the r-

process was given by the measurement of the half-lives of waiting point nuclei at the magic neutron shells 50 and 82. These data give evidence that the r-process achieves really ${}^{A-1}Z + n \rightleftharpoons {}^{A}Z + \gamma$ equilibrium and steady flow locally in the abundance peaks (Kratz *et al* 1993). Eventually the r-process calculations show that after each r-process abundance maximum the ${}^{A-1}Z + n \rightleftharpoons {}^{A}Z + \gamma$ equilibrium breaks down so that the reproduction of the empirical r-process distribution requires for the specified temperature ($T_9 = 1.35$) at least three different canonical r-process paths superimposed with three sets of neutron densities (10^{20}–10^{24} cm^{-3}). The duration time of the synthesis lies between 1.2 and 2.3 s (figure 5) (Kratz *et al* 1993). An important question about the canonical r-process is a check of the validity of the waiting point approximation by a boundary condition which marks the transition from equilibrium to conditions that require accounting for the competition of neutron capture and β decay. To what extent this limit, which is dependent on the local nuclear parameters, affects the r-abundances at freeze-out is a matter of debate. Detailed investigations stress the importance of the transition phase at r-process freeze-out for the final abundances. The suggested mechanisms of freeze-out can prevent abundance troughs in the r-process calculations ascribed to deficiencies of the nuclear input physics and explain the observed smoothness of the empirical r-process abundance distribution (figure 4).

The yield of r-process elements in the galactic chemical evolution appears to require a neutron source which is not dependent on initial stellar metallicity. This is one of the arguments against a secondary r-process in an explosive environment fuelled by neutrons from the ^{22}Ne(α, n) source interacting with preexisting heavy element seeds (e.g. nova outbursts, shock-induced explosive He or C burning).

The heavy element abundance pattern of old very low metallicity stars matches rather well the corresponding solar system r-process (derived from the empirical r-process, figure 4, by summation over isotopic abundances). This would suggest that the r-process is primary and contributed to the galactic element enrichment before the s-process. A secondary r-process would have to rely on an already abundant s-process enrichment. From the resemblance of the elemental stellar r-process and solar r-process distributions for elements heavier than Ba it is concluded that a unique r-process mechanism exists that always produces the abundances in similar proportions. Also, in these low-metallicity old stars, indications of the existence of a second r-process source for elements in the nuclear mass range A ≈ 80–120 were detected (Sneden *et al* 2000). The definitive identification of these heavy elements in the low-metallicity stars as r-process products would, however, require the isotopic abundance determination.

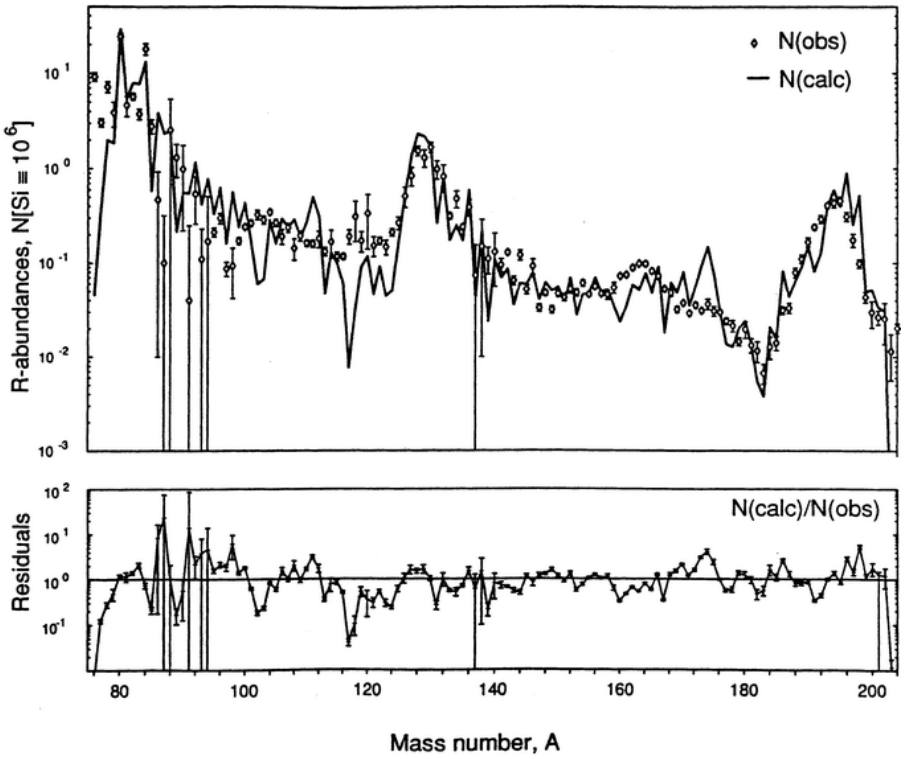

Figure 5. Global r-process abundance curve obtained from a superposition of three time-dependent calculations with the best fit n_n–T_9 values for the $A = 80$ peak and the $90 \leq A \leq 130$ and $135 \leq A \leq 195$ mass ranges. The weights of the individual components are 10:2.6:1. In the lower part the ratio of calculated and observed r-process abundances is shown. (From Kratz *et al* 1993.)

The question of the site of the r-process is not settled. Several scenarios, ranging from the neutrino-driven winds in type II SUPERNOVA explosions (Woosley *et al* 1994) to merging neutron stars, have been suggested. Supernova explosions of type II, understood to be initiated by the iron core collapse of a massive star with the formation of a NEUTRON STAR, are assumed to be a prominent site for an r-process at the mass cut of matter exploded and locked up in the neutron star. However, it was also argued that the total mass fraction of r-process material of $\sim 10^{-7}$ (figure 4) which amounts to only $\sim 10^{-7} \times 10^{11} M_\odot \approx \sim 10^4 M_\odot$, where $\sim 10^{11} M_\odot$ is the total mass of the Galaxy, would require a contribution per supernova explosion over the history of the Galaxy (estimated age of the Galaxy at the birth of the solar system $\sim 10^{10}$ yr) of only $\sim 10^4 M_\odot / (10^{-2} \times 10^{10}) \approx \sim 10^{-4} M_\odot$. This estimate, where a supernova rate of $\sim 10^{-2}$ yr^{-1} is assumed, would suggest that either the r-process occurs for only a small subset of supernova explosions or the efficiency of r-production is as small as $\sim 10^{-4} M_\odot$. The latter possibility has been studied with some success in the framework of a primary r-process model site located at the formation of a hot neutron star predominantly cooling via neutrino emission (Woosley *et al* 1994). The compelling new scenario, a neutrino-driven explosion, appears to meet the time scales, temperature and neutron density conditions for a canonical r-process with β-flow equilibrium in the r-abundance peaks beyond nuclear masses A=110. In addition, as most neutron stars possibly pass through a similar early cooling development, the expectation that the same r-process relics will always be observed in old low-metallicity stars seems to be fulfilled.

p-Processing

Photodisintegration p-process

In the p-process it is assumed that preexisting r- and s-process seed nuclei are exposed to a high temperature ($2.1 \leq T_9 \leq 3.2$) for a short time (≈1 s). The first reactions to occur are the (γ, n) reactions which produce quite proton-rich nuclei. With each neutron ejected the neutron binding energy B_n becomes on the average larger and the photoneutron reaction rate $\lambda^{\gamma n}$ slower (see equations (2) and (3)). At the same time the binding energy for a proton and α particle is decreasing and the rate for photodisintegration accompanied by charged-particle emission $\lambda^{\gamma p}$, $\lambda^{\gamma \alpha}$, is increasing. Once the nuclei become sufficiently proton rich about 5 mass units away from the stability valley, they begin a (γ, p) and (γ,α) cascade. The reaction network consists, therefore, of equations of the form

$$\frac{dN_{p,A,Z}}{dt} = -(\lambda^{\gamma n}_{A,Z} + \lambda^{\gamma p}_{A,Z} + \lambda^{\gamma \alpha}_{A,Z}) N_{p,A,Z} + \lambda^{\gamma n}_{A+1,Z} N_{p,A+1,Z} + \lambda^{\gamma p}_{A+1,Z+1} N_{p,A+1,Z+1} + \lambda^{\gamma \alpha}_{A+4,Z+2} N_{p,A+4,Z+2} \quad (18)$$

ordered in terms of decreasing element and mass numbers. In this way nuclei are shifted towards iron. In the already large network of equations (18) to be solved the possible reactions of the n, p and α background particles as well as the weak interactions ((e^-,ν), (e^+,ν)) are neglected owing to assumed particle reaction and weak decay time scales much longer than the p-process duration. This makes the results independent of the composition and density of the p-process site. The results are only dependent on the abundance distribution of the input seed nuclei and the photon temperature. During the synthesis abundance is accumulating especially at the nuclei, where the photodisintegration flow is deflected to lower-Z elements by the (γ, p) or (γ,α) reactions because of a long disintegration time (waiting points). When the disintegration flow crosses the closed neutron shells at 50 and 82, the disintegration time scales become especially large because of the particularly strong binding energies. The abundances are then built up directly at the closed shell nuclei ^{92}Mo and ^{144}Sm. The abundances of the primary unstable p-nuclei eventually β decay after freeze-out to stable p-nuclei. The concept of the photodisintegration p-process was elaborated by Woosley and Howard (1978).

No single temperature exposure can produce all p-nuclei. However, with a distribution of exposures an approximate representation of the solar abundances is obtained. This is true also for the extended network including the n, p and α background reactions (figure 6) (Rayet *et al* 1990). Only the (n, γ) reactions have some influence on the yield of individual p-nuclei. In particular, it appears to be impossible to reproduce the solar abundances of the isotopes ^{92,94}Mo and ^{96,98}Ru by the photodisintegration p-process because they are too abundant and there is insufficient s- and r-process seed at $A > 96$. In the search for possible solutions of this problem, a significantly higher s-process seed abundance is suggested (Costa *et al* 2000), which would result from a higher rate of the ^{22}Ne(α,n)^{25}Mg neutron-producing reaction varied within the quoted uncertainty. In another suggestion, a different synthesis process, the rp-process on accreting neutron stars, is considered (Schatz *et al* 2001).

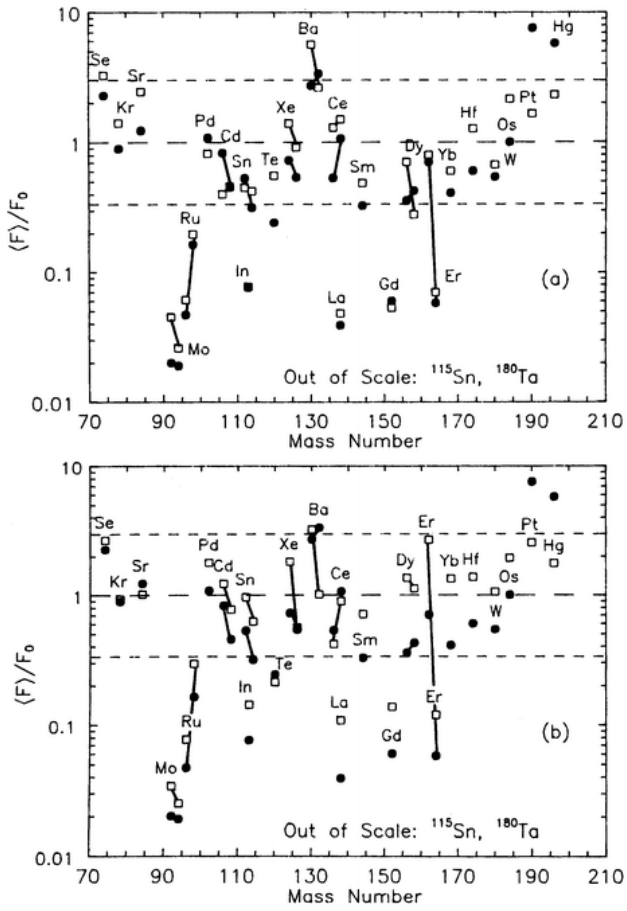

Figure 6. Relative overproduction factors for p-process nuclei. Lines connect isotopes of the same element. (*a*) Predictions for a uniform weighting of the initial temperatures: filled and open symbols correspond to different time scales and mean overproduction factors (t_{HYD}(s), F_0) = (0.446,200) and (1, 145), respectively. (*b*) Comparison of predictions for t_{HYD} = 0.446 s for uniform weighting of the initial temperatures (filled symbols) and for a best fit mix of temperatures (open symbols and F_0 = 114). (From Rayet *et al* 1990.)

Experimental and observational constraints, stellar models

The correlation found between neutron binding energy (hence photoneutron disintegration rate) and solar abundance of the p-process nuclei represents the first experimental evidence pointing to nuclear p-processing in terms of a photodisintegration process (Macklin 1970). This correlation is verified more properly between the total photodisintegration rate ($\lambda^{\gamma n} + \lambda^{\gamma p} + \lambda^{\gamma \alpha}$) of the synthesized p-nuclei and solar p-abundances at that mass number.
